The widespread adoption of AI technologies is increasingly accompanied by calls for mitigating the risks that AI technologies pose. As a response, a variety of societal actors such as governments, policymakers and international organizations, businesses, professional associations, advocacy groups, and multi-stakeholder initiatives have produced ethical guidelines with the goal of defining and creating AI in accordance with ethical values and principles. Despite the multitude of guidelines coming from different institutional backgrounds, some overlap among the principles can be observed. According to Jobin et al. [43], eleven overarching ethical values and principles are found when comparing eighty-four AI ethical guidelines. These are, by frequency of the number of sources in which they were featured: transparency, justice and fairness, non-maleficence, responsibility, privacy, beneficence, freedom and autonomy, trust, dignity, sustainability, and solidarity. Another paper [31] states that eight main principles were found after analyzing thirty-six ethical guidelines: privacy, accountability, safety and security, transparency and explainability, fairness and non-discrimination, human control of technology, professional responsibility, and promotion of human values. When comparing these two papers and their results, partial overlap can be observed in the content of these ethical guidelines, e.g., transparency, privacy, fairness.

However, as Jobin et al. [43] note, relying on a numerical assessment of mentioned ethical values and principles, i.e., assessing which values and principles are mentioned how often, obfuscates divergences regarding "(1) how ethical principles are interpreted; (2) why they are deemed important; (3) what issue, domain or actors they pertain to; and (4) how they should be implemented". Thus, the landscape of AI ethics guidelines still is marked by extensive heterogeneity and is far away from "a unified framework that can guide the governance of AI" [60:11]. This raises questions about the applicability of AI ethics guidelines more generally, as it is difficult for AI practitioners to determine which ethical issues they may run into [61] and how they should interpret, account for, and operationalize proposed ethical values and principles [31, 43]. This challenge has also been investigated empirically. A behavioral ethics study on the effects of the ACM ethical guidelines [50] shows that the availability of the guidelines alone has no statistically relevant influence on ethical decision making and concludes that future research needs to find different ways that can influence ethical decision making. Vakkuri et al. [73] conclude in their study that the academic discussion around ethical values has been too conceptual and as a result, does not seem to have influenced the industry at large yet.

In short, there are still things left unclear within the AI ethics community. The rather broad character of AI ethics typically does not account for social complexities and the situated realities of ethical breaches. In the analysis, this is taken into account, as real world incidents are examined in relation to such ethical values and principles. In doing so, this study aims to understand how applicable general AI ethics principles are in different sectors.

2.2 Sectoral context and ethical AI

To account for the ways the social environment shapes both the development as well as the post-deployment phase of AI, researchers have called for broadening the analytical lens [3, 23, 24]. As discussed in the introduction, this could be achieved by introducing a sector-based approach, allowing to account for sector-specific characteristics. The field of AI ethics does have numerous case studies that ontologically assume the relevance of understanding sectoral context in relation to AI ethics. For instance, in her analysis on novel elder care technologies, Burema [15] argues that such technologies embed a neoliberal understanding of the welfare state. In other words, the (un)ethical nature of such technologies was assessed in the context of the sector: aging, and the welfare system.

Thereby, the author does not isolate the technology from its sectoral environment.

One of the few publications that does *explicitly* refer to sectors in understanding AI ethics is the European Commission's High-Level Expert Group on Artificial Intelligence [25]. The authors argue that the AI ethics recommendations the EU has made thus far are too general in their nature, and in-depth knowledge is needed for specific sectors. In their paper, they choose three sectors to make specific recommendations for the creation and deployment of AI in relation to three sectors: health care, the public sector (e-governance and justice/law enforcement), manufacturing, and (industrial) Internet of Things (IoT) sector. Though these authors thereby explicitly acknowledge the relevance of being sensitive to sector-specific contexts of AI ethics, the work reads as three different case studies on three different sectors in which the content of these recommendations was made based on workshops with experts from the respective fields, i.e. without data about deployment.

In contrast, this study does two things differently: 1) instead of solely describing ethical issues for each individual sector, this paper compares the ethical issues of sectors to see how sector-specific mechanisms are (not) relevant when discussing AI ethics, 2) instead of relying on expert interviews, this paper analyzes incidents in particular sectors after deployment, which provides the opportunity for analyzing AI systems and their use "in the wild". Furthermore, by looking at incidents post-deployment, this study takes a broad definition when defining a sector compared with the approach of the European Commission [25]: it does not only concern industry actors situated in a sector, but also users. A sector, therefore in this paper, functions as a broader frame of reference where the incidents took place.

3 METHOD

This study sampled incidents based on media reports shown in the AIAAIC database developed by Pownall [1]. At the time of writing this paper, this database covers more than 950 entries of incidents and includes several variables, such as sector, country, year, and URL links of media reports. For this study, two variables are of interest: sector and URL links that relate the incident to the media report. The content of these media reports is analyzed qualitatively with a thematic analysis according to sector as is explained later. First, the selection procedure for the sectors is explained, as there were many to choose from in the database.

This paper does not follow a predefined operationalization of sectors, where certain sectors are chosen over others before sampling. Rather, sectors are selected based on feasibility and sample size (i.e. the number of incidents per sector in the database): it needs to be feasible to code the data in a limited amount of time while keeping a sufficient number of cases. For that reason, the biggest sector, "technology", is omitted for this study because the database shows more than 220 incidents and is therefore not feasible to code qualitatively in a restricted amount of time, as well as the smaller sectors such as "religion" which shows one incident with a robot priest and is therefore too small in sample size to draw any conclusions. This sampling procedure resulted in the selection of five sectors: police, education and academia, politics, automotive, and healthcare. Initially, taking all the sectors together, a total of 180 cases were identified. After the data was cleaned by two analysts, the sample size was reduced to n=125 cases: police (n=39), education/academia (n=34), politics (n=16), automotive (n=21) and healthcare (n=15). The exclusion criteria applied are: duplicates, not accessible media reports (e.g., paywall), cases that do not relate to AI technologies per se, technologies that are not deployed yet, or media reports that do not discuss an incident (e.g., commentary texts that expressed an author's opinion about an incident or an entire field). Furthermore, cases that were labeled incorrectly according to sector, were moved to the respective sector. In total, 55 cases were excluded due to these reasons, resulting in a sample size of n=125. It should be noted that the database was retrieved in February 2021. Since then, more cases were added to the database and it has been reorganized.

The content of the media reports is analyzed qualitatively with a thematic analysis. In essence, this is a tool for data reduction by first exploring the data, then establishing initial codes, and finally establishing themes by comparing and contrasting codes. The unit of analysis is the incident itself, not the media report. In other words, the analysis is not conducted on a semantic level (e.g., framing analysis or discourse analysis) but rather on a descriptive level (i.e., understanding the critical elements of the AI incidents by directly assigning a descriptive code). To elaborate on this process, first the media reports are read in order to understand the nature of the incidents. Then, the media report is coded in terms of the ethical issue that is described in the report (i.e. breach of ethical principle). Since these reports typically deal with a case that has multiple issues, one media report is able to include more than one ethical code. Additionally, special attention is paid to sector-specific activities: where exactly did the incident in the sector take place?

Thus, two pieces of information are analyzed and coded from the media reports: the **ethical issues** (i.e. what ethical principle has been breached?) and sector-specific **activities** (i.e. where is this incident situated within the sector?). Concerning the former, it should be noted that the database already coded each incident according to the respective ethical issue (e.g., accuracy/reliability, transparency, etc.). However, all incidents are re-coded with the purpose of this study in mind, albeit sometimes with the same terminology. The reason for reassessing each incident in terms of their ethical issue is because certain incidents were initially coded in ways that were not aligning with this research's aim. For instance, codes such as "marketing" and "ethics" were found to describe certain incidents. Still, bad marketing is not inherently an AI-related ethical incident, and using "ethics" as a label to describe unethical AI deployment is too generic.

After getting to know the data and developing initial codes, the rest of the coding process involves steps in data reduction: how are these initial codes related to one another (i.e., is there overlap found?), and are there themes able to be established? This is an iterative process, especially for the data and codes that describe sectoral activity. This coding procedure resulted in a couple of themes that describe the ethical issue (i.e. what ethical principle has been breached?) as well as themes that describe their sectoral context in terms of activities (i.e. where is this incident situated within the sector?), as is discussed in the results. The final step is to compare the results across sectors: are certain themes only occurring in particular sectors, or is there overlap found? Can we

speak about general ethics or should AI ethics be tailored towards sectoral contexts?

4 RESULTS

The results are presented in two parts: first a description of the incidents per sector are described in detail. Here, the core ethical principles that are breached (e.g. transparency) are described as well as the sectoral activities (e.g. tracking, monitoring and identifying people in the police sector). Then, two tables are presented in which the sectors and ethical issues are compared.

Before discussing the results in-depth, it should be noted that the data used for this study are media reports. Therefore, the list of incidents are not exhaustive due to media bias, as some topics might be picked up more than others in favor of media logic. Thereby, not all incidents that occurred after deployment and their ethical issues in their respective sector are reflected in the results. Also, it means that the incidents were not observed first-hand, but are filtered through observations of the reporter and its editorial process. This issue of relying on media reports for the analysis is further discussed in the limitations section of this paper.

4.1 Description per sector

4.1.1 Police. When AI is deployed in the police sector, it concerns issues related to tracking, monitoring, or identifying people. Often but not always, this is done with the help of personal data. AI technologies can be used in both ongoing police investigations and predictive policing. What all cases (n=39) in the database have in common is the use of AI for either visual detection of objects or people, or administrative purposes. When AI gets used in this sector, ethical themes relate to accuracy/reliability, bias and discrimination, transparency, surveillance and privacy, as is explained next.

Accuracy/reliability relates to cases that misidentify people, sometimes leading to wrongful arrests [44]. This ties in with another theme: bias and discrimination, as certain racial minorities are often misidentified as also the case of [44] shows. The issue of transparency relates to not knowing when personal data is being used, and for what purpose. For instance, Biddle [11] discusses how the Los Angeles police department requested home security videos of Amazon Ring users to identify protesters in the Black Lives Matter protests. Though the author hints to the possibility of using video footage for facial recognition, and calls surveillance through Ring a "ubiquitous camera network" there is much unclarity about the use of data: "Policies guiding how long cops can retain privately obtained data like Ring videos—and what they can do once it lands on their hard drives—are rare and typically weak". This latter example also ties in with privacy/surveillance issues: as new technologies were primarily used by the police to track, monitor, or identify people, it by default taps into issues of privacy and surveillance. The use of personal data to observe citizens is for instance found in China, where illegal street crossings are being detected with facial recognition software at intersections. After being detected, pictures of supposed offenders are publicly displayed at those intersections on LED screens, and a fine is announced via text message to the offenders [70]. In other words, law enforcement is able to observe its citizens closely with AI, in this case leading to public shaming and fining.

4.1.2 Education and academia. **Education -** The incidents related to this sector (n=25) concern teaching and administrative activities that can be divided into three types: 1) evaluation and grading 2) monitoring and tracking behavior of students; 3) physical and digital access. These three types of activities show a mix of different ethical issues, as is explained next.

Issues with grading show problems with accuracy/reliability and bias/discrimination. Meaning, the systems were not doing the tasks that they were supposed to do but also affect certain sociodemographic groups differently than others. To elaborate, the algorithms used are not accurate or reliable, for instance, when grading tests [19] or predicting students' grades that otherwise could not be performed due to Covid 19 [26]. Bias and discrimination were found when the technologies disadvantage certain groups over others, typically (and at the intersection of) gender and race, such as AI that predicts student success [28], or assesses PhD applications [58].

Tracking and monitoring the behavior of students predominantly breaches principles of privacy and surveillance, but also bias/discrimination and security. Concerning the latter, cybersecurity breaches were found in, for instance, online learning environments and proctoring software [46] though this does not inherently have to do with AI per se but rather could be seen as a side-effect when AI gets implemented. Examples of privacy and surveillance breaches are proctoring software used to administer tests [29], or facial recognition used in Australian schools to check attendance [7]. Bias and discrimination occurs when for instance proctoring software does not identify students with dark skin tones [20].

Access refers to physical access to school and its environment or access to digital learning environments of schools on the basis of biometric data. The incidents related to restricting access due to misidentification. In doing so, the systems are biased/discriminatory or inaccurate. For instance, in the Lockport city school district in the US, media reports mention how the system disproportionally misidentifies black students [27]. Furthermore, there are privacy issues as biometric data are stored, processed, and shared to regulate access [49].

Academia - In academic publications (n=9), the ethical issues concern ethically disputable premises of hypotheses and underlying arguments used to test and create AI. In other words, when publishing, scholars have to specify what ideas they are testing or developing and why, in this case all publications develop an AI or a component thereof. The ethical issues of these incidents do not refer to the output (i.e. how well the AI is performing), rather, the very starting point of the academic publication: the initial ideas that lead to the development of a newly developed AI system. Examples are a publication that developed AI to detect people's sexual orientation with facial recognition [47], or similarly a publication that uses facial recognition to predict political orientation [79].

4.1.3 Politics. The sector "politics" in the dataset refers to the communication of political viewpoints in which deepfakes and twitterbots are created by citizens and political organizations alike to credit and discredit political figures and/or their agendas (n=16). The incidents that occurred in this sector concern ethical issues with misinformation and transparency by communicating messages without disclosing that AI was involved in the construction of the

messages. To clarify, 15 incidents (out of 16 cases) concerned the communication of a message by a deepfake of a politician. Without a disclaimer that such technologies were involved when creating the message, this can be misleading about the authenticity of the message. The content of these deep faked messages ranges from creating fake political statements from politicians [71], to videos used in political election campaigns [53] and advertisements by lobby groups [80]. Only one case was found that did not directly involve audiovisual deepfakes: Twitter bots that disseminated misinformation about climate change [9]. Nonetheless, what all cases have in common, regardless of the exact technology used, is that the incidents concern the communication of political ideas with AI to the general public.

4.1.4 Healthcare. In healthcare (n=15), the activities where AI-related incidents were found concern care provision and medical analyses (i.e. prevention/prognosis/diagnosis), data management (i.e. storing/sharing/tracking medical data), and allocation of care.

Care provision and medical analyses refer to the actual "doing" of care: Prevention, prognosis, and diagnosis. Flawed COVID-19 prediction models [72], and digital symptom checkers [33] show issues with AI's accuracy/reliability. There were issues found in AI with bias/discrimination towards certain populations (most typically gendered and ethnic/racial) e.g., estimating kidney function [65] and in chest x-ray classifiers [76]. Finally, scientists criticized Google's lack of transparency in their breast cancer predicting AI [77].

Data management refers to the administration and logistics of handling personal and medical information: storing, sharing, and tracking of medical data. This concerns issues with surveillance/privacy such as the case of Amazon's Halo Band [32], a fitness tracker that constantly tracks medical data of the person wearing it, and an incident of asking for private medical data on the platform Facebook by a chatbot linked to the account of Israeli politician Netanyahu [69]. Also, transparency is an issue with storing, sharing, and tracking medical data, as for instance the transfer of medical data from a healthcare provider to Google was criticized for not informing the patients [22].

Concerning the allocation of care, two incidents were found: one involving the allocation of care work (i.e. how many hours a caregiver ought to spend with their patient) [45], and a case that concerns the allocation of Covid-19 vaccines [78]. Both of these incidents showed issues with accuracy/reliability, as the people in need of care were not able to access it due to inaccurate algorithms. At the same time, there were issues with transparency, as it was unclear in the case of Covid vaccination allocation how the algorithm makes its decision [78].

4.1.5 Automotive. All identified incidents in the automotive sector (n=21) involve self-driving cars in traffic. Three main causes were identified: external, human, and other (i.e. difficult to determine who/what caused the incident).

External incidents refer to incidents with self-driving cars in traffic due to external manipulation by researchers for the sake of calling for more security in self-driving cars [13, 68]. Self-driving cars were manipulated with, for instance, shiny stickers, drones with projectors, or through taking remote control to move seats, trigger indicators, wing mirrors, and windscreen wipers.

Human incidents concern incidents with self-driving cars in traffic due to human error. In these cases, drivers watched movies [34] or slept while using the autopilot [16], leading to slow responses of the driver when approaching subjects such as pedestrians or other cars or due to exceeding speed limits. Sometimes, human error does not necessarily refer to the human driver of an autonomous vehicle. Rather, two incidents in the database show how human error occurs when also other participants in traffic make estimation errors allegedly [10, 55].

In other types of incidents, it is difficult to determine the cause of the incident due to either the nature of the incident or lack of details reported about the incident. For instance, cases where the car could not detect a white vehicle due to bright weather while human drivers allegedly were not attentive enough [36, 37], or car crashes where details of the incident are missing [21, 38]. However, even though it is difficult to pinpoint responsibility and cause, it does not mean that there is no indication of possible technical issues: e.g. when the autopilot emergency braking systems were not used when an object or traffic situation was not (timely) detected [37] or all the lack of defensive driving when approaching a pedestrian, e.g. allegedly stopping too close to the subject [74].

Interestingly, there is a case involving two autonomous vehicles, i.e., a traffic situation where the key players are technologies, not humans. Two self-driving cars nearly collided when one car tried to switch lanes while being cut off by the other car. The crash was prevented as the first car detected the other one on time and waited until the lane was clear again [42].

All these incidents relate to safety, accuracy/reliability, and security issues with autonomous driving vehicles. Safety refers to (the lack of) physical harm when, for instance, a self-driving car crashes or is involved in any type of physical accident [e.g., 38]. Accuracy/reliability shows the lack of accuracy and reliability in the use of sensors e.g. for recognizing objects in traffic [e.g., 37]. Security deals with safety from external manipulation [13, 68].

4.2 Comparing sectors

While the analysis above provides a rich description of each specific ethical issue and how it relates to its respective sector, boiling down the results to key insights, one can identify the following overlap between sectors (table 1).

This indicates that there is merit in the approach of general AI ethics guidelines and principles because several issues are not sector specific but cut across different sectoral contexts: accuracy/reliability, bias/discrimination, transparency, surveillance/privacy, security. Yet, even though the findings show that ethical values span across sectors, there are sector-specific characteristics found in the data when looking at specific sectoral activities as is explained next.

In addition to understanding ethical issues within their sectoral context, specific sectoral activities are also studied. Focusing on these activities reveals further contextual characteristics of the sector: the actions that are inherent to the sector that AI systems got involved in. This gives additional information on the nature of the incidents.

When reading this table, three things are observable, 1) certain ethical issues are found in only one sector, 2) the same ethical issue

Table 1: Ethical issues listed by sector

Sector	Ethical issue
Police	Accuracy/reliability, bias/discrimination, transparency, surveillance/privacy
Education	Accuracy/reliability, bias/discrimination, transparency, surveillance/privacy, securitys
Academia	Premise/intent
Politics	Misinformation, transparency
Healthcare	Accuracy/reliability, bias/discrimination, privacy/surveillance, transparency
Automotive	Safety, security, accuracy/reliability

Table 2: Ethical issues and sectoral activities listed by sector

Sector	Ethical issue	Sectoral activity
Police	Accuracy/reliability, bias/discrimination, transparency, Surveillance/Privacy	Predictive or investigative tracking/identification/monitoring
Education	Accuracy/reliability, bias/discrimination, transparency, surveillance/privacy, security	Administrative work and teaching (Regulating access, tracking student behavior, evaluating work)
Academia	Premise/intent	Academic publishing
Politics	Misinformation, transparency	Political communication and persuasion
Healthcare	Accuracy/reliability, bias/discrimination, privacy/surveillance, transparency	Care provision and medical analyses, data management, allocation of care
Automotive	Safety, security, accuracy/reliability	Self-driving cars

that is being breached across sectors leads to different consequences and refers to different meanings 3) pre-existing sector-specific structures are reproduced, as is explained next.

First, there are some ethical issues that are inherently sector-specific. In academia, the only ethical concern found is the issue of having questionable premises or intentions when developing the technologies (table 1). In other words, the AI systems were not at fault when the incident occurred, rather the worldviews/theories that humans hold when developing the technologies. While this in itself could happen in other sectors, i.e. having bad intentions or unethical ideas about the sociotechnical, when looking at the sectoral activity, it shows that this relates specifically to scientific publishing (table 2). To elaborate, the realm in which this incident occurred is where academia produces its knowledge, i.e. the creation of scientific output. Framed differently, the premise/intent principle that is being violated relates to scientific ideas that are being published: ethically questionable hypotheses and theoretical premises prior to developing the AI, that guides the narrative in the publication. To give an example, an AI "gaydar" was developed in academia and got published [47]. Regardless of how the technology itself is working, the main theoretical starting point was ethically questionable, i.e. the "need" that one can or should scan faces to detect one's sexual orientation. In other words, the main concern for academia in relation to AI deployment is the social and moral theories that scholars that develop AI hold. Again, this is not something only academia struggles with, as developers in all sectors could have questionable premises/intent when developing their technologies. However, the data shows that it is inherent to academia to focus on scientific publishing, which by default links the questionable premises/intent with unethical hypothesizing. In other words, this intersection is a quirk specific to the sector of academia (i.e. coming up with unethical hypotheses and theoretical premises which then get tested and published).

Similarly, the ethical issue of "misinformation" was only found in the sector of politics, albeit together with the breached ethical principle of "transparency". When looking at the sectoral activity, one can see that it relates to political persuasion (table 2). All incidents in the political sector thereby relate to creating a political message with AI, but this message is 1) not disclosing that AI was made in the making of the message, thereby not being transparent and 2) having elements of deceit/not being factual, thereby being able to misinform the audience. To elaborate, the incidents all relate to deepfakes and twitter bots that spread political messages but are not informing the audience about the nature of such messages. While such technologies could also be used in other sectors for other purposes than politics, for instance, in popular culture for satire purposes, the sector "politics" specifically struggles with this phenomenon, as the data for instance do not show other AI-related incidents in other realms of the political sector (e.g. using AI for administrative work in the political sector) or other ethical values being breached that were repeatedly found across other sectors (e.g. accuracy/reliability). This does not mean that there are no other activities in the sector of "politics" where AI could get deployed in, but rather that the most pressing issue (according to media logic and the public sphere) where AI gets deployed are activities related to public persuasion. Political communication and persuasion are activities specific to the sector, to, for instance, assert dominance

of certain political ideas over others. By doing so, the sector "politics" is prone to misinformation and transparency when AI gets embedded into this context. The results show that the combination of ethical principles being breached, i.e. misinformation and transparency play into those pre-existing sector-specific characteristics: the struggle of competing belief systems.

Second, one can see that if the same ethical principles are breached, it leads to radically different consequences in different sectors, as the principle intersects with the sectoral activity. The same principle can manifest differently in different sectors due to the sectoral activity being involved. To give an example, when the principle "security" is being breached, which in all cases means the event where an external person hacks into a system, the consequences for the sectors "education" and "automotive" are very different. In "education", as seen in table 2, a security breach happens in administrative and teaching activities, i.e. everything that relates to grading or administering data and information about students. The worst outcome that could happen in a security breach, is that an external person would be able to access, retrieve, and modify personal data. However, for the automotive industry, a security breach could potentially have physical consequences as all AI-related incidents refer to self-driving vehicles (table 2). If external actors are able to hack the autopilot of cars, the possible effects are bodily. This does not mean that one ethical problem is lesser than the other. Rather, it means that in order for people to truly understand the nature of the breach of an ethical principle and its potential consequences, it has merit trying to understand the sectoral activity it is embedded in.

Related to this argument, not only are the consequences of ethical breaches different for different sectors, regarding transparency, the meaning of the ethical value in itself can be different for different sectors. Transparency in the political domain focuses primarily on the transparency *that* AI systems were used to, for instance, manipulate images or videos ("deepfakes") whereas the question of *how* the manipulation was conducted technically is less relevant from an ethical perspective. After all, the ethical breach lies in political persuasion (table 2) where the goal of the AI is to convince people of certain beliefs without revealing the lack of authenticity involved in creating the message, thereby it is irrelevant to know from an ethical perspective e.g. which data is used to create such AI systems or showcase technical documentation. In healthcare, however, transparency refers to technical elements of AI such as data and methods that are used to construct the AI that could influence for instance care provision and medical analyses (table 2). Whereas the former breaches of transparency concern the lack of revealing *that* an AI was used, the latter refers to the lack of transparency involved where AI classifies things or comes to a certain decision.

Third, when intersecting the ethical value with the sectoral activity, it raises the question whether the phenomena are really new or whether it is rooted in a sectoral structure. As an example, the sector police is discussed in detail. Surveillance and privacy are ethical issues that could be seen as inherent to police work, since police work is a form of state governance that, with or without AI and machine learning, involves monitoring and identifying suspects [48]. This would require some form of gathering personal information from people. Also, when tracking, identifying or monitoring people, bias and discrimination is not a new phenomenon following the introduction of new technologies, but police work has previously been associated with racial bias [8]. Of course, the source of human bias and machine bias might be different. But the phenomenon itself in the police force is not new. In terms of transparency, it should equally be questioned whether law enforcement has thus far, i.e. without AI, been transparent in terms of how they collect their data and how much this differs when AI is being used. Finally, accuracy/reliability is an ethical theme that refers to the technicalities of the AI: if it works as it is intended. Thereby this theme by default does not discuss e.g. how accurately human police officers identify their suspects, but rather how well a machine performs this task. Nonetheless, one could still make the claim that also without AI police work has issues with accuracy/reliability, since making mistakes such as misidentification and making false estimations is by definition a human quality.

Of course, it is one-sided to claim that all of these ethical issues are inherent to the sector without intervention of AI systems, as if technologies do not introduce societal change and new ethical issues. To take the principle of surveillance/privacy as an example: one could for instance argue that the scalability of surveillance and privacy breaches in relation to tracking, identifying and monitoring people have the potential to increase or change form. To elaborate, Andrejevic and Gates argue that whereas prior, surveillance was targeted, data-driven surveillance techniques allow for a "collect-everything approach" [4]. However, this current paper does not deny that AI systems could trigger social change in form or intensity. Rather, the main argument is that the *very premise* of these ethical issues is sometimes inherent to the sector. For example, one of the core activities in the police sector is surveilling. It is thereby no surprise that ethical breaches occurred related to privacy, transparency and surveillance, when AI got deployed in this sector. In other words, the ethical problems with AI are arguably rooted in something rather stable and structural: specific sectoral routines and structures.

5 DISCUSSION

The results show that most ethical themes are recurring across sectors: accuracy/reliability, bias/discrimination, transparency, surveillance/privacy, security. This means that it makes sense to discuss ethical issues on a more general level as there is empirical evidence that some principles are repeatedly breached in across contexts. General ethical values and principles can and should be addressed when, for instance, discussing and conceptualizing ethics in policies, academic texts, or public communication. Furthermore, what this present paper also shows, is that additionally, knowing sectoral context can be helpful when understanding AI ethics in-depth as is explained next.

Taking sectoral context into consideration, one becomes aware they have their own dynamics and routines: the police surveils, teachers administer tests, physicians diagnose. Understanding these activities helps with understanding AI ethics better, as it is no surprise when AI gets deployed, e.g. issues of safety occur in the automotive industry, misinformation and transparency in politics, or

questionable theoretical premises are put forward in academic publishing because such principles and values are related to their respective sector and their specific activities. In other words, the results show that there is merit in understanding how ethical principles intersect with sectoral activities, as these reveal specific meaning of AI deployment in specific sectoral contexts. Therefore scholars, developers and operators, and other actors of AI systems ought to take sectoral context that an AI system is deployed in into account because each sector has its own quirks. Moving forward, applying a sector-based approach to AI ethics means studying the activities of that respective sector. Taking it one step further, one could even argue that domain specific knowledge is needed to assess sectors before AI deployment with e.g. a historical analysis. By doing so, one can understand *why* some ethical issues are more prevalent in a sector than others, even before AI systems are deployed.

Knowing that sectors have specific cultures and quirks, has several implications for the field of AI ethics. First, a sector-based approach argues for sector-specific sensitivity when discussing guidelines. A sector-based approach to AI ethics can address varying demands on and trade-offs to ethical values and principles. For instance, in policing, there is a legitimate interest for some level of secrecy to not hamper police investigations. Other sectors make different demands on trade-offs to ethical values and principles. Therefore to evaluate privacy or transparency-related incidents, requires to make sector-specific considerations. To give another example of such trade-offs, while some of the accuracy- and reliability-related issues of autonomous vehicles presumably can be best solved by advancing capabilities on the basis of providing more training data, such calls for ever more data are problematic in other sectors where data is often more personal and sensitive. For instance, the increased use of personal data in education is considered to be highly problematic due to privacy issues and problems regarding consent [41, 67]. In policing, the surveillance necessary to acquire data is a vividly discussed ethical issue itself [4]. The solutions that AI ethics guidelines suggest using to address specific ethical issues need to take these context-specific requirements for solutions to ethical issues into account. In contrast to non-contextualized general AI ethics guidelines, sector-specific guidelines with their much smaller scope can name and discuss sector-specific risks, and, in doing so, provide much more awareness for specific ethical issues. For instance, the historical issues in the political sector concerning attempts to persuade masses with certain beliefs and thereby not always being truthful or honest about their reporting (regardless of the use of AI or not), shows that the ethical value of accuracy/reliability of the system (as shown in the results, an often-found problem across the sectors) is less relevant to focus on compared with misinformation and transparency. In other words, a sector-based approach shows how certain issues are particularly relevant for some sectors, while less so for others. A sector-based approach to AI ethics can take these differences into account.

So far, contextuality is highlighted as one of the key aspects of a sector-based approach: try to understand each sector's activities, because ultimately, the technology gets embedded in this context and might reproduce and reinforce ethical issues that are already present. However, what this perspective does not offer, is an outlook on how AI technologies are able to *change* the dynamics of the sector. For instance, while the analysis shows that the automotive industry has safety in their breaches of ethical values, it does not show how autonomous vehicles could change the notion and perception of safety if a car is driven by non-human drivers compared with human drivers or the scalability of faked/inauthentic political messages in the field of political persuasion with deepfakes and twitter bots.

A second limitation concerns the data used in this study. This study shows representations of incidents, as they are represented in media reports – i.e., secondary data. This means, that 1) the narrative is framed by media outlets with their own media logic (i.e. the inner workings of the media sector), although it should be noted that the performed method of analysis is not on a semantic level, and 2) it might be that other kinds of incidents occurred post-deployment, but were not picked up by the sampled media reports. For instance, in politics, all cases except one relate to deepfakes that communicate political messages or ridicule political personas. However, the political sector concerns more than mediated messages. It is also an administrative institution in which AI technologies could be used. Similarly, in the automotive sector, media reports focused primarily on incidents with self-driving cars. Yet, AI systems might also be used for administrative purposes in the automotive sector and different ethical issues might arise there. Such potential blindspots could be related to having media reports as the unit of analysis. Future research on incidents could consider different types of data to understand human-computer interaction or human-robot interaction "in the wild", with e.g. an ethnography.

Third, the sampling strategy of this paper ended in 2021. Arguably, many other AI technologies have been introduced and deployed since then. The deployment of AI and its consequences are a moving target to study, and therefore it is important to study how the landscape of AI ethics has changed over time. Follow-up studies could thereby replicate this research to understand if the sheer increase in incidents also somehow diversifies the nature of the incidents in their breaches of ethical principles in particular sectoral contexts.

6 CONCLUSION

This article makes the case for a sector-based approach to AI ethics, in which sectoral context is regarded as relevant information to understand the ethics of AI deployment. To do so, it analyzes n=125 incidents from the AIAAIC repository [1] from the sectors police, education/academia, politics, healthcare, and automotive. The analysis shows that while certain ethical issues are recurring and their relevance spans across sectors, 1) other ethical issues are inherently related to specific sectors, 2) ethical issues appear to have different meanings and manifest differently in different social contexts 3) the problems with AI-deployment are related to pre-existing issues in the sector (i.e. prior to AI deployment). Instead of asking how AI ethics ought to look like, a sector-based approach argues to look at the activities and pre-existing social realities of such sectors, in order to understand the situated context of AI deployment. It serves as an addition to general AI ethics guidelines that have been described by the AI ethics community in terms of their vagueness, high level of abstraction, and ambiguity, as well as them being generic, difficult to apply, and vague [31, 43, 60]. While these

principles could be viewed as rather generic etc., they are empirically found breached across contexts. A sector-based approach serves as an additional view to AI ethics that enables scholars and practitioners to understand the relevance of sectoral cultures in AI deployment.

ABSTRACT

Numerous parties are calling for "the democratisation of AI", but the phrase is used to refer to a variety of goals, the pursuit of which sometimes conflict. This paper identifies four kinds of "AI democratisation" that are commonly discussed: (1) the democratisation of AI use, (2) the democratisation of AI development, (3) the democratisation of AI profits, and (4) the democratisation of AI governance. Numerous goals and methods of achieving each form of democratisation are discussed. The main takeaway from this paper is that AI democratisation is a multifarious and sometimes conflicting concept that should not be conflated with improving AI accessibility. If we want to move beyond ambiguous commitments to "democratising AI", to productive discussions of concrete policies and trade-offs, then we need to recognise the principal role of the democratisation of AI governance in navigating tradeoffs and risks across decisions around use, development, and profits.

1 INTRODUCTION

Over the last couple years, discussion of "AI democratisation" has surged. AI companies around the world—such as Stability AI [1][1], Meta [2], Microsoft [3], and Hugging Face [4]—are talking about their commitment to democratising AI, but it's not always clear what they mean. The term "AI democratisation" seems to be employed in a variety of ways, causing commentators to speak past one another when discussing the goals, methodologies, risks, and benefits of AI democratisation efforts. This paper aims to provide a foundation for more productive conversations about democratising AI that move beyond ambiguous commitments.

Sections 2 through 5 describe four different notions of AI democratisation commonly used by AI labs—democratisation of AI use, democratisation of AI development, democratisation of AI profits, and democratisation of AI governance. We focus primarily on how the term "AI democratisation" is used by AI labs because of the impact they have on the rate of AI advances, and the influence they currently wield over the use, development, profit, and governance of AI. If labs are claiming commitments to AI democratisation, then it's important to clarify what those commitments mean and how they might be fulfilled.

Each section is divided into two subsections. The first subsection (x.1) discusses various goals the particular form of democratisation is proposed to achieve and notes conflicts with the goals of other forms of democratisation where they arise. The second subsection (x.2) describes various proposed methods for facilitating the form of democratisation.

Although the four concepts of democratisation we discuss often complement each other, it is important to note that they sometimes conflict. For instance, if the public prefers for access to certain kinds of AI systems to be restricted, then the "democratisation of AI governance" may require access restrictions to be put in place—but enacting these restrictions may hinder the "democratisation of AI development" for which some degree of AI model accessibility is key.

Section 6 then concludes, driving home the main observation of the paper; though the term "democratisation" can seem to imply otherwise, AI democratisation is not inherently good. The first three forms of democratisation (democratisation of use, development, and profits) are about improving accessibility to AI or AI derived profits which can yield both beneficial and harmful consequences. The desirability of AI democratisation therefore cannot be assumed, but rather is derived from alignment with the interests and values of those who will be impacted.

2 DEMOCRATISATION OF AI USE

When people speak about democratising some technology, they often refer to democratising its use—that is, making it easier for a wide range of people to use the technology. For example, in the early 2010's the "democratisation of 3D printers" referred to how

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604693

3D printers were becoming much more easily acquired, built, and operated by the general public [5].

The same meaning has been applied to the democratisation of AI. Stability AI, for instance, has been a vocal champion of AI democratisation. The company proudly describes its main product, the image generation model Stable Diffusion, as "a text-to-image model that will empower billions of people to create stunning art within seconds" [6]. Microsoft similarly claims to be undertaking an ambitious effort "to democratize Artificial Intelligence (AI), to take it from the ivory towers and make it accessible to all." A salient part of its plan is "to infuse every application that we interact with, on any device, at any point in time, with intelligence" [3].

2.1 Goals

2.1.1 Distributing Benefits of Use. It is important to recognize, however, that for some AI applications the benefits of making the technology available for anyone to use can be relatively minor while the risks are significant. For example, the circle of individuals who would greatly benefit from access to an AI drug discovery tool is relatively small (mainly pharmaceutical researchers), however these tools can be easily repurposed to discover new toxins that might be used as chemical weapons [7]. This is an instance in which unfettered democratisation of AI use—making an AI tool accessible to all—may not always be desirable.

That said, an AI tool need not be widely accessible to all for the benefits to be widely distributed. A designated user could employ a high-risk AI system for the benefit of the community. In this way a drug discovery system could be used in a controlled, limited-access setting, while resulting pharmaceuticals are "democratised" in the sense that they are made accessible to anyone in need.

2.1.2 Receiving Feedback for Better and Safer AI. Another reason given for disseminating AI tools widely is so that developers can gather information about how their products are being used (or misused) in a wider variety of contexts than they would have been able to test, let alone imagine, internally [8]. In turn, that feedback informs improvements that enhance model performance and help guard against any new misuse applications that have emerged.

Importantly, where there are concerns about potential misuse, there is an option to cautiously democratise AI use via a staged release of the product [9]. Incrementally larger and more powerful versions of the model are released allowing time between each stage to evaluate how the AI application is being used and to conduct risk benefit analyses of releasing yet a more powerful version of the model. Feedback and staged release may also help provide time and notice for societies to adapt to the new capabilities and harden vulnerable systems, processes, and institutions. Unfortunately, where the risk and consequences of misuse are expected to be severe, responsible AI deployment may require that access restrictions be placed on certain AI capabilities.

Such restrictions limit the democratisation of AI use, but they are not necessarily a blow to AI democratisation more generally. As will be discussed in Section 5, AI democratisation can also refer to the democratisation of AI governance, which is about introducing democratic processes into decision-making about how AI is used, developed, shared and otherwise regulated. Indeed, one might say that the democratisation of AI use—making AI accessible to be used by everyone—is but one possible outcome of democratising AI governance. It is the outcome if the demos choose that distributing use is desirable. Another possible outcome may be to designate (perhaps through licensing) specific actors to use or study high-risk AI systems for the public's benefit.

2.2 Methods

Overall, efforts to democratise AI use—to make AI capabilities more widely accessible—may involve reducing the costs of acquiring and running AI tools (again, this may be done via staged release if there are concerns about misuse), providing accessible services to help users integrate AI models into their work streams (e.g. consulting services), and developing intuitive interfaces to facilitate human-AI interaction without the need for extensive training or technical knowhow. In some regions, democratising AI use may also require improvement to more fundamental infrastructure like internet access [10].

3 DEMOCRATISATION OF AI DEVELOPMENT

When the AI community talks about democratising AI, they rarely limit their focus to the democratisation of AI use. Much of the excitement is about democratising AI development—that is, helping a wider range of people contribute to AI design and development processes.

3.1 Goals

3.1.1 Accelerate AI innovation and Progress. It should not be assumed, however, that accelerating AI progress is always desirable. As AI research progresses and AI capabilities improve, we should expect the potential consequence of harms, misuse, or misalignment to also become more severe [12], [13]. The implementation of necessary policy and interventions to ensure safe and responsible AI development going forward may struggle to keep up with unbridled progress, and so there may be a case for exercising some restraint [14].

3.1.2 Cater to Diverse Interests and Needs. Calls for the democratisation of AI development also respond to concern that a small number of leading AI labs monopolise control over AI development and that those labs employ a narrow demographic of developers. The worry is that the AI products, which are deployed globally, consequently perform disparately for users of different ethnic, geographic, cultural, professional, and financial backgrounds [15–18].

Enabling more people to participate in AI design and development processes may help facilitate the development of AI applications that cater to more diverse interests and needs [19]. This is one reason Stability AI offers for its decision to open-source Stable Diffusion—meaning that the company allows anyone to download, modify, or build on the Stable Diffusion model on their own computer so long as they agree to the terms of use. CEO Emad Mostaque advocates that "everyone needs to build [AI] technology for themselves. . .. It's something that we want to enable because nobody knows what's best [for example] for people in Vietnam besides the Vietnamese" [1]. The company motto reads "AI by the people, for the people" [20].

But again, it should not be assumed that the diffusion of AI development is universally desirable. Open-source sharing in particular may enable more numerous and diverse contributions, but it also opens a door for malicious use and model modification, and controls are difficult to enforce [21].

3.1.3 External Evaluation. Third, many argue that involving more people (e.g. academics, individual developers, smaller labs) in AI development processes provides a critical external evaluation and auditing mechanism. By making models accessible for more people to study, AI labs might distribute auditing duties to a larger and more diverse group of developers than a lab would be able to employ internally. This assumes that more eyes on a model will reveal more flaws leading to safer and more well-aligned technology [8].

3.2 Methods

A variety of activities can help enable productive participation in AI design and development processes. Some strategies provide access to AI models and resources to facilitate AI community engagement—e.g. model sharing (3.2.1), providing compute access (3.2.2), project support and coordination (3.2.3). Other strategies help to expand the community of people capable of contributing to AI development processes—e.g. via educational & upskilling opportunities (3.2.4) or through the provision of assistive tools (3.2.5).

A key takeaway from this section is that there is much more to AI democratisation—even to the democratisation of AI development specifically—than model dissemination.

3.2.1 Model Sharing. Model sharing involves providing access to AI models including code, model weights and the ability to query, modify, study, or otherwise examine the model.

While model sharing is needed to enable external study and auditing of AI models, it also increases the opportunity for model misuse by malicious actors. In some contexts, for higher risk capabilities, it may therefore be wise to limit model accessibility [22].

That said, model sharing is not an all or nothing activity [23]. Rather, model sharing options range from full open-source sharing (all aspects of the system are downloadable for the public) to fully closed (only a select group of developers may even know the model exists) [21], [22], [24]. In the middle there are options for gated access, hosted model access, cloud-based or API access, and downloadable access with some model components withheld. In some of these middle options some degree of advantage from external study and auditing may be maintained while risk of misuse might be reduced.

These options should not be interpreted naively with respect to their stated intent, but with realism about their likely impacts. Google Research published a paper on a technique for style cloning in generative art, and chose to not release any code, citing the potential "societal impact" risk that "malicious parties might try to use such images to mislead viewers" [25]. However, in a mere 11 days one person was able to reproduce the technique to run on Stable Diffusion which they then chose to open-source [26]. Similarly, Meta chose to restrict access to the weights of its large language model LLaMa to academic researchers and others on a case by case basis, "to maintain integrity and prevent misuse" [27]. However, a week later the weights (predictably) were leaked and are now available publicly on a torrent [28]. In both these cases, realism is needed in assessing the likely impact of a nominally more restrictive model sharing policy.

3.2.2 Improving Compute Access (and other technical infrastructure). Large AI models require significant compute power to run. Accordingly, democratising development may also require improvements to compute access. Developers might, for instance, offer cloud computing services or issue grants for computer cluster access to facilitate smaller and less well-resourced groups in working with more powerful models [21]. Alternatively, developers might explore options for providing smaller model versions that require less compute to run. For example, Emad Mostaque describes Stable Diffusion as "a breakthrough in speed and quality [...] that can be run on consumer GPU's" [6].

Note, however, that restrictions on compute can also be leveraged to help minimise misuse of powerful AI by limiting the ability of prospective malicious actors to build or modify large models [29], [30]. Therefore, like decisions to open-source AI models, decisions to provide significant compute resources should involve adequate risk benefit analysis.

Other tech infrastructure that limits participation in AI development in a similar way to compute access include network accessibility (i.e. access to high bandwidth, low latency internet), access to data storage facilities, access to high quality ethically sourced data, and cyber security infrastructure. These all pose significant barriers to participation in AI development in resource constrained countries, barriers which might be lessened through infrastructure investment and/or remote access [10].

3.2.3 Project Support and Coordination. Democratising AI development is not just about providing resources and assuming that people will come. Effective input elicitation often benefits from dedicated project coordination and support.

For example, the BigScience project was a collaborative effort coordinated by the AI startup Hugging Face—another organisation dedicated to "democratising AI"—and funded by the French government to develop the large language model (LLM) BLOOM [31]. BLOOM was developed over the course of a year by a global coalition of over 1000 volunteer AI developers yielding an LLM functional in 46 languages. Similar collective efforts in other domains may also benefit from funding or other resources to support coordination.

3.2.4 Educational and Upskilling Opportunities. Democratisation of AI development can also be furthered by expanding the community of people capable of making contributions to AI design and development processes.

One option toward this end is for governments and large developer labs to invest in making educational and upskilling opportunities more widely available, especially for demographics traditionally underrepresented in AI developer communities. Investment in computer science and machine learning educational resources is, for instance, seen as an essential step for establishing AI talent pipelines and narrowing the 'AI divide' between the Global North and South [10].

3.2.5 Assistive Tools. Another option for expanding the community of prospective contributors is to lower barriers to participation in AI development activities by making it easier for people with minimal programming experience and little familiarity with machine learning to partake.

This might be done through the provision of tools that enable those with less experience and expertise to create and implement their own machine learning applications. For example, Microsoft [32], Google [33], H2O [34] and Amazon [35] have developed "no-code" tools that allow people to build models that are personalised to their own needs without prior coding or machine learning experience. In a similar vein, GitHub Copilot (powered by OpenAI Codex) is a generative AI system that can be used by less experienced developers to help write code [36].

4 DEMOCRATISATION OF AI PROFITS

A third sense of "AI democratisation" refers to democratising AI profits—which is about facilitating the broad and equitable distribution of value accrued to organisations that build and control advanced AI capabilities.

The notion is nicely articulated by Microsoft's CTO Kevin Scott: "I think we should have objectives around real democratisation of the technology. If the bulk of the value that gets created from AI accrues to a handful of companies in the West Coast of the United States, that is a failure" [11]. Though DeepMind does not employ "AI democratisation" terminology, CEO Demis Hassabis expresses a similar sentiment. As reported by TIME, Hassabis believes the wealth generated by advanced AI technologies should be redistributed. "I think we need to make sure that the benefits accrue to as many people as possible—to all of humanity, ideally" [38].

4.1 Goals

The goal is rather straightforward: equitably distribute profits generated by AI to ensure wealth and advantages conferred by AI improve human well-being across the board. A few sub-aims are: to avoid widening a socioeconomic divide between AI leading and lagging nations [10]; to ease the financial burden of job loss to automation; to smooth economic transition in case of rapid growth of the AI industry; and, when AI labs are able to voluntarily participate, to provide mechanisms for labs to powerfully demonstrate their commitment to pursuing advanced AI for the common good [39], [40]. Finally, profit democratisation acknowledges through compensation the human labour and creativity that underpins AI capabilities. Generative AI, in particular, unlocks economic value in training data that has been produced through centuries of human effort.

4.2 Methods

There are a variety of mechanisms by which AI profits might be more widely distributed or "democratised". Profits might be redistributed, for instance, via philanthropic giving, though philanthropy can be an inconsistent mechanism of wealth redistribution and, if not well-managed, may worsen inequalities and injustices [41].

Another option is for taxation and profit redistribution to be managed directly by the state [42]. For example, the provision of Universal Basic Income (UBI) has been suggested as a wealth distribution mechanism to help compensate for job loss to automation associated with more advanced AI capabilities [39], [43].

There is concern, however, that taxation methods may be insufficient given the potential of monopolised windfall profits to major AI labs. Accordingly, the proposed "Windfall Clause" offers a third, middle-ground approach [40]. AI firms that voluntarily adopt the Windfall Clause would be bindingly obliged to donate a meaningful portion of their profits when the firm's profits for the year exceed "a substantial fraction of the world's total economic output" (e.g. at least 1%). Those donations would then go to a "Distributor" charged with finding and funding effective welfare-maximising projects. Distributors might offer grants to philanthropic organisations, invest directly in infrastructure building projects, or direct funds to state governments for further distribution.

Finally, there is a question of if and how individual content creators can be compensated when their creative outputs (art, music, code, etc.) are used to train generative AI models [44]. One option is through the creation of licensed data sets [45]; content creators are compensated for permitting their content to be included in a catered data set that AI developers can then use to train and fine-tune their models without risk of copyright infringement. However, there is still an open question as to if and how further compensation should be provided as generative AI continues to produce value after it is trained. Here is perhaps where the more general profit redistribution schemes described above play an important role.

5 DEMOCRATISATION OF AI GOVERNANCE

Finally, some discussions about AI democratisation refer to democratising AI governance. AI governance decisions often involve balancing AI-related risks and benefits to determine if, how, and by whom AI should be used, developed, and shared. The democratisation of AI governance is about distributing influence over these decisions to a wider community of stakeholders and impacted populations. OpenAI CEO Sam Altman has expressed such a sentiment, writing, "We want the benefits of, access to, and governance of AGI to be widely and fairly shared" [46].

5.1 Goals

The overarching goal of the democratisation of AI governance is to ensure that decisions around questions such as AI usage, development, and profits reflect the will and preferences of the people being impacted [47]. In this sense, democratisation of AI governance arguably supersedes the previously discussed notions of democratisation. Decisions to democratise use, development, and profits derive their acceptability and desirability from the acceptance and desire of those who will be impacted.

Democratic processes such as referenda, citizen assemblies, and public hearings facilitate the representation of diverse and often conflicting beliefs, opinions, and values into decisions about how people and their actions are governed. Importantly, the desired result is not necessarily agreement among constituents that the best decision was made, but legitimacy—a state of acceptance that the decision-making process was fair and well-considered.

5.1.1 Reducing Unilateral Decision-making. Motivation for democratising AI governance often stems from concern that individual tech companies hold unchecked control over the future of a transformative technology and too much freedom to decide for themselves what constitutes acceptable tradeoffs between risks and benefits of choices around AI use, development, and distribution of profits. It is a worry exacerbated by concern that fierce competition between leading AI labs incentivises reckless decision-making [48].

A single actor in control of a powerful technology or resource can cause significant harm with an ill-considered decision. Consider, for example, the avoidable 2010 Deepwater Horizon oil spill in the Gulf of Mexico. It is one of the greatest environmental disasters in history and largely attributed to a series of cost cutting decisions made by BP including failure to implement proper risk control measures [49]. It is reasonable to assume that in the face of fierce competition and massive financial incentive that AI developers are also liable to make rash decisions about model development and release, the potential negative repercussions of which will only grow as AI capabilities improve [12], [13]. Therefore, it is perhaps unwise, as Stability AI CEO Emad Mostaque puts it, to have "a centralised, unelected entity controlling the most powerful technology in the world" [50]. Introducing democratic processes to enable checks and balances or collective decision-making around AI development, use, and release can potentially guard against ill-considered and potentially detrimental moves. Though Mostaque was justifying Stability AI's decision to open-source its models as a method of disseminating control over AI, not commenting on how or by whom such a high-stakes decision should be made.

5.1.2 Justice and Fairness. Another commonly articulated goal is to ensure the benefits and burdens of AI development and deployment are distributed justly and fairly.

It is widely documented that AI systems can replicate or even amplify racial and societal injustices [51], for example, through algorithmic bias in hiring [15], facial recognition [16], loan appraisal [18], and recidivism prediction applications [17]. Some AI misuse cases, such as voice cloning-based phishing, may also have a disproportionate effect on some populations over others [52].

Overall, facilitating the participation or representation of a wide array of stakeholders is seen as a crucial step towards mitigating AI associated injustices [53], [54]. It is to work towards a future for AI in which no communities are disproportionately harmed by development and use activities, and in which no communities are unfairly overlooked as possible beneficiaries of AI capabilities.

5.1.3 Navigating Complex Normative Challenges. The implementation of AI systems in public and private applications raises a variety of normative questions. Some are readily agreed upon such as the high-level assertion that human fatality should be avoided. But there are also many "hard normative questions" to which responses will likely differ depending on culture, context and other value priorities [55]. These challenges include, for example, establishing acceptable risk thresholds, interpreting high-level terms like the above mentioned "justice" and "fairness", and determining what values should underpin value-aligned AI [47]. Democratic discourse among diverse stakeholders may help distil areas of agreement or areas in which consensus forming practices are likely to be productive [47]. Inversely, and of equal importance, they might identify cases in which finer-grained details of interpretation and implementation can be determined at a context-specific, local level [55].

5.2 Methods

Even though it is already a subcategory of AI democratisation, the democratisation of AI governance is itself a broad and multifaceted concept, some forms of which may be more relevant or useful than others depending on the context [56].

One might speak, for instance, about the introduction of democratic processes to high-level AI policy formation at the national or international governance level or about more fine-grained AI design or deployment decisions made within individual labs [57]. "Democratic processes" can also refer to a variety of methods for eliciting citizen participation, ensuring substantive representation of stakeholder viewpoints, facilitating well-informed deliberation, holding fair and open election processes, or instituting constitutional protections for individuals and minorities [58].

In what follows, we briefly describe a variety of strategies that have been proposed to underpin democratically legitimate decision making about AI.

5.2.1 Harnessing Existing Democratic Structures. Democratic societies already have many tools and infrastructures in place to facilitate democratically legitimate decision-making about a variety of topics through e.g. legislation and regulation or multilateral standards. Harnessing and modifying effective structures already in place avoids redundancy and reinventing the wheel [57]. It has been proposed, for instance, that with some modification we might make use of procedures laid out by the European Union's standard-setting organisations (SSOs) to establish context-sensitive standards for safe and responsible AI [55]. We might also structure a new AI governing body after the United States' FDA (Federal Food and Drug Administration) [59].

While such efforts require minimal new infrastructure, they can, however, get bogged down in existing political quagmires, and are only applicable for decisions that remain within the borders of democratic societies.

5.2.2 Multistakeholder Bodies. Given the global impacts of many AI advances, there has been significant interest in the use of more inclusive processes for input and decision-making around AI. One option is through the formation of multistakeholder bodies to convene diverse, international perspectives for the purpose of navigating complex AI governance challenges. For example, the Partnership on AI (PAI)—a global coalition of academic, civil society, industry, and media organisations—has orchestrated initial non-binding agreements on generative AI across some relevant organisations [60]. There have also been proposals for smaller multistakeholder bodies to form the basis of ethical review boards for high risk AI application and model release decisions [24], [61].

5.2.3 Participatory Processes. Another strategy is to employ modern participatory processes to gather input from diverse populations

to guide AI governance decisions. Orchestrating large scale public participation can be cumbersome and costly, so much promising work focuses on exploring technical solutions such as deliberative tools and digital platforms [62] and generative voting applications [63] to improve the practicability and accessibility of participatory AI governance.

A disadvantage with a participatory approach to governance, however, is that those involved are generally self-selected as stakeholders, community members, or participants, and their outputs may thus only have a weak claim to democratic legitimacy.

5.2.4 Representative Deliberation. A strategy for addressing the challenges of both transnational AI impacts and self-selection is the use of representative deliberation [64], [65], building on heavily researched approaches to deliberative democracy [66]. Representative deliberation involves putting AI governance questions to a representative microcosm of the population of an impacted region, or even the global population (selected by sortition, i.e. stratified sampling) thus granting democratic legitimacy. As is common practice with citizen assemblies, the representative groups are provided access to experts and stakeholders to help inform their deliberations on more technical topics such as AI governance.

Representative deliberation is increasingly lauded by both governments [67] and multilateral bodies [68] as a valuable modern approach to democracy generally, and which has found footholds even in authoritarian and global contexts under the less threatening frame of deliberative governance [66], [69].

Companies developing AI systems that want to 'democratise their governance' can also delegate such decisions to representative deliberations, and often will have the incentive to do so in the face of competing stakeholder pressures [62], [65]. Meta, for example, has quietly run a set of national and transnational pilots [70] to navigate their 'complex normative challenges' and have since scaled up to a near-global deliberative process [71]. Twitter had also planned to pilot such processes before its acquisition [72].

Lighter weight variants of representative deliberations that build on the aforementioned modern participatory practices but in a representative fashion (e.g. using sortition) might also be used to provide a level of democratic legitimacy for less complex AI governance questions [62], [63].

6 CONCLUSION

This paper has outlined four different notions of "AI democratisation"—the democratisation of use, the democratisation of AI development, the democratisation of AI profits, and the democratisation of AI governance—and discussed numerous goals and methods of achieving each.

For the first three forms of democratisation, "democratisation" is used almost synonymously with "increasing accessibility". The democratisation of AI use and the democratisation of AI development are about making AI systems accessible for everyone to use or to contribute to their development, and the democratisation of AI profits is about distributing access to profits accrued through AI development and control. The democratisation of AI governance, however, is about balancing these questions of accessibility with other societal needs and values.

Sometimes decisions to democratise AI use, development, and profits will align with societal preferences (ideally determined through democratic processes), and sometimes those preferences will involve restrictions on access. Such is the case, for instance, with legal restrictions on certain medications, treaty restrictions on nuclear weapons, and regulation of labs containing potential hazards. The same may be true of decisions to restrict access to AI models for development or use purposes if risks of open model access are felt to outweigh the benefits.

We should therefore be wary of using the term "democratisation" too loosely or, as is often the case, as a stand-in for "all things good". The democratisation of AI use, AI development, and even AI derived profits are not inherently good. Their value is derived from alignment with interests and values of those who will be impacted. As such, where the democratically aligned decision would be to limit accessibility, the democratisation of AI governance takes precedence over the others as the source from which the moral and political value of the "democratisation" terminology is derived.

Perhaps the proper response to this paper, then, is to conclude that "AI Democratisation" is a (mostly) unfortunate term. As it is most commonly used within the AI community it refers to facilitating widespread AI use and development. However, invoking the term "democratisation" tells another story. It holds the hidden assumption that the decision to distribute or make accessible is what a democratic governance process would select. In other words, AI democratisation ultimately refers to the democratisation of AI governance. If by "AI democratisation" all a speaker means is "make available to everyone", then we would suggest less normatively loaded language (something like "broad accessibility") be used.

ABSTRACT

Understanding the landscape of potential harms from algorithmic systems enables practitioners to better anticipate consequences of the systems they build. It also supports the prospect of incorporating controls to help minimize harms that emerge from the interplay of technologies and social and cultural dynamics. A growing body of scholarship has identified a wide range of harms across different algorithmic technologies. However, computing research and practitioners lack a high level and synthesized overview of harms from algorithmic systems. Based on a scoping review of computing research (n=172), we present an applied taxonomy of sociotechnical harms to support a more systematic surfacing of potential harms in algorithmic systems. The final taxonomy builds on and refers to existing taxonomies, classifications, and terminologies. Five major themes related to sociotechnical harms — representational, allocative, quality-of-service, interpersonal harms, and social system/societal harms — and sub-themes are presented along with a description of these categories. We conclude with a discussion of challenges and opportunities for future research.

1 INTRODUCTION

Harms from algorithmic systems — that is, the adverse lived experiences resulting from a system's deployment and operation in the world — occur through the interplay of technical system components and societal power dynamics [97]. This analysis considers how these "harms (not bounded by the parameters of the technical system)" can "travel through social systems (e.g., judicial decisions, policy recommendations, interpersonal lived experience, etc.)" [151, n.p.]. Computing research has traced how marginalized communities — referring to communities that face structural forms of social exclusion [130] — disproportionately experience sociotechnical harms from algorithmic systems [90, 96]. Such experiences include, but are not limited to, the inequitable distribution of resources [63], hierarchical representations of people and communities [156, 242], disparate performance based on identity categories [23, 143], and the entrenchment of social and economic inequalities [27, 84]. In this way, algorithmic systems' enactment of power dynamics [106, 162] can function as a minoritizing practice [64] through which unjust social hierarchies are reinforced.

Practitioners have sought to develop practices that better identify and minimize sociotechnical harms from algorithmic systems (e.g., [25, 62, 135, 144]). This includes work to taxonomize harms in HCI on digital safety [3, 193, 216], in sociolegal studies on technology-facilitated violence [109, 231], and canonical responsible ML research on representational, allocative [20], and quality-of-service harms [36] that have significantly shaped the responsible ML field

and standards development [146]. Alongside broader movements towards regulation and standardization [208], harm reduction practices often draw on fields of auditing, impact assessment, risk management, and safety engineering where a clear understanding of harm is essential [112]. Researchers have also developed "ethics methods" [150] for practitioners to identify and mitigate sociotechnical harms, including statistical assessment [135, 145], software toolkits [32], and algorithmic impact assessments and audits [178], providing notable benefit in how harms are anticipated and identified within algorithmic systems. Existing work on defining, taxonomizing, and evaluating harms from algorithmic systems, however, is vast and disparate, often focusing on particular notions of harm in narrow circumstances. As such, it presents navigational challenges for practitioners seeking to comprehensively evaluate a system for potential harms [178, 179, 182], particularly for large generative models that perform different tasks across many use cases. Moreover, the use of different terminologies for describing similar types of harm undermines effective communication across different stakeholder groups working on algorithmic systems [135, 159].

Recognizing these challenges, we conducted a scoping review [128] and reflexive thematic analysis [41] of literature on sociotechnical harms from algorithmic systems, offering a taxonomy to help practitioners and researchers consider them more systematically. A scoping review offers a generative starting place for a landscape harm taxonomy. The purpose of a scoping review is to map the state of a field [11, 128]; and here, provides a synthesis of existing articulations of harm, calls attention to forms of harm that may not be well-captured in regulatory frameworks, and reveals gaps and opportunities for future research. As scholarly articulations of harm emerge from different epistemic standpoints, values, and methodologies, this paper pursues the broader question of: How do computing researchers conceptualize harms in algorithmic systems? Three research questions guide this work:

(1) What harms are described in previous research on algorithmic systems? How are these harms framed in terms of their impacts across micro, meso, and macro levels of society? What social dynamics and hierarchies do researchers of algorithmic systems implicate in their descriptions of harms?
(2) Where is there conceptual alignment on types of harm from algorithmic systems? What type of organizational structure of harms is suggested by conceptual alignment?
(3) How do gaps or absences in research on sociotechnical harms suggest opportunities for future research?

This research contributes to computing scholarship and responsible AI communities, offering:

- A scoping review of harms, creating an organized snapshot of articulations of computational and contextual harms from algorithmic systems;
- A reflexive thematic analysis of harms definitions, their impacts to individuals, communities, and social systems, providing a framework for identifying harms when conducting impact and risk assessments on an algorithmic system;
- Support for interdisciplinary communication by providing terms, definitions, examples of harms, and directions for future work.

In what follows, we discuss the sociotechnical character of harms from algorithmic systems and existing harm taxonomies, followed by a description of our methodology (Section 3). We then detail the harm taxonomy (Section 4), and propose next steps for related work (Section 5). This analysis offers a starting place for practitioners and researchers to reflect on the myriad possible sociotechnical harms from algorithmic systems, to support proactive surfacing and harm reduction.

2 BACKGROUND

2.1 Sociotechnical Harms

Scholars in HCI, machine learning, Science and Technology Studies (STS), and related disciplines have identified various harms from digital technologies (e.g., [9, 121, 192, 193, 207]). This literature underscores harm as a relational outcome of entangled dynamics between design decisions, norms, and power [8, 27, 70, 148, 238], particularly along intersecting axes of gender [34, 197], race [106, 156], and disability [28, 29], among others. Harms from algorithmic systems emerge through the interplay of technical systems and social factors [35, 90] and can encode systemic inequalities [36, 141, 143, 213]. This duplicity of technology, as Ruha Benjamin [27] explains, is a challenge: algorithms may have beneficial uses, but they often adopt the default norms, and power structures of society.

Recognizing the sociotechnical character of harms from algorithmic systems draws attention to how the development and experience of digital technologies cannot be separated from cultural and social dynamics [7, 60, 172, 175]. As van Es et al. [224, n.p.] note, "algorithms and code reduce the complexity of the social world into a set of abstract instructions on how to deal with data and inputs coming from a messier reality." This process involves design decisions predicated on "selection, reduction, and categorization" [39] through which technologies come to reflect the values of certain worldviews [39, 212]. Without intentionally designing for equity, algorithmic systems reinforce and amplify social inequalities [60].

2.1.1 Identifying and anticipating harms in practice. With increased awareness of the need to anticipate harms early in product development [195], designers and researchers are central actors in pursuing harm reduction [40, 58, 97]. Anticipating harms requires considering how technological affordances shape their use and impact [86, 200]. It can be done in relation to the technology holistically or with a focus on certain features of the technology and its use by different groups [43]. This work requires thinking critically about the distribution of benefits and harms of algorithmic systems [33, 169] and existing social hierarchies [35]. It can be strengthened by bringing in different standpoints and epistemologies, such as feminism [73, 155], value-based design [17, 88, 116], design justice perspectives [60], and post-colonial theories [126, 148]. Importantly, the process requires attending to the constitutive role of social power in producing sociotechnical harms; "designers need to identify and struggle with, alongside the ongoing conversations about biases in data and code, to understand why algorithmic systems tend to become inaccurate, absurd, harmful, and oppressive" [7, p. 2]. Thus, in anticipating harms, practitioners need to account for computational harms as well as those arising through contextual use [40, 164, 191, 236].

2.2 Taxonomies of Harm, Risk, and Failure

Structured frameworks can aid practitioners' anticipation of harms throughout the product lifecycle [135, 239]. They encourage more rigorous analysis of social and ethical considerations [135], especially when operationalizing principles seems opaque [147]. Taxonomizing harms is, however, an exercise in classification, which has potential limitations: taxonomies can draw action to some issues over others, shaping how people navigate and act on information [39]. As such, the epistemological choices made in developing harm taxonomies focus attention on certain areas over others [40].

Many existing harm taxonomies address particular domains of use (e.g., [193, 217]) and how they are complex assemblages of actors, norms, practices, and technical systems, which can foster individual and collective harm [174]. Taxonomies have been developed related to online content [19, 193, 227], social media [157, 217, 218], users "at-risk" for experiencing online abuse [216, 234], and malicious uses of algorithmic systems [45], including cyber attacks [3] and cyberbullying [12]. Relatedly, they can focus on particular types of harms, such as misinformation [218] or representational harms co-produced through image tagging system inputs and outputs that reinforce social hierarchies [121, 228]. While domain-specific taxonomies draw attention to how context informs the emergent nature of harm, they are not easily applicable to a wide range of algorithmic systems. Many systems deploy across contexts, including, for example, ranking and recommendation systems (e.g., search engines or content sorting algorithms on social media platforms) and object detection models (e.g., video surveillance systems, self-driving cars, and accessibility technology).

Another common approach is to orient harm taxonomies around specific algorithmic or model functions (e.g., [83, 235]). Model-focused taxonomies have been developed for large language models [235], image captioning systems [121, 228], and so-called "foundational models," such as GPT-3 and BERT, which are applied in a wide range of downstream tasks [37]. Organizing harm by model function is highly useful when practitioners' focus is on a singular model because it draws attention to relevant computational concerns. It does, however, pose limitations to practitioners working downstream on products and features, where multiple model types operate simultaneously, such as in social media, search engines, and content moderation, and where contextual use significantly shapes potential harms.

Scholars have developed harm taxonomies related to system misbehaviors and failures [18, 198], particularly to aid algorithmic auditing [177]. These taxonomies focus on how algorithmic systems are sources of harm (e.g., faulty input/outputs, limited testing, proxy discrimination, and surveillance capitalism) [203]. Bandy [18] summarizes four problematic behaviors of algorithmic systems — discrimination, distortion, exploitation, and misjudgement. Using such taxonomies focus attention to how specific affordances, training data, and design choices can co-produce harm [22, 40]. Failure-based taxonomies are helpful when practitioners examine potential failure modes of a specific technology, but are often limited in terms of helping to anticipate who or what is harmed.

In sum, taxonomies can be helpful tools for appreciating and assessing how harms from algorithmic systems are sociotechnical. As they retain social and technical elements, they cannot be remedied by technical fixes [94] alone. They require social and cultural change [171]. The proposed taxonomy provides a holistic and systematic view of the current discourse on types of sociotechnical harms from algorithmic systems. As the scope of the taxonomy we propose is broad, and many topic- or application- specific taxonomies exist already, we refer to and build on these existing works when appropriate.

3 METHODOLOGY

In alignment with prior calls to anticipate computational and contextual harms [40, 151], we synthesize insights on harms from computing research to aid anticipation of sociotechnical harms from algorithmic systems. Our findings draw on a scoping review for data collection and a reflexive thematic analysis of computing research on harms.

3.1 Overview of Methodology

Our approach followed prior scoping reviews in HCI literature [74, 223], in alignment with the extension of the PRISMA checklist [133], the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) [220]. Scoping studies, as a knowledge synthesis methodology, map existing literature, and "clarify working definitions and conceptual boundaries of a topic or field" [168, p. 141]. They are especially appropriate when distilling and sharing research findings with practitioners [221], and are suited to identifying evidence on a topic and presenting it visually. Compared to systematic reviews, scoping reviews address a broader range of topics and incorporate different study designs [11]. A scoping review is an effective method for surfacing current "priorities for research, clarifying concepts and definitions, providing research frameworks or providing background, or contextual information on phenomena or concepts" [65, p. 2104]. We implemented a five-stage scoping review framework [11, 128]: (1) Identifying research questions; (2) Identifying relevant studies; (3) Study selection; (4) Charting the data; and (5) Collating, summarizing, and reporting results.

3.1.1 Identify research questions. To identify the types and range of sociotechnical harms, we developed the three aforementioned research questions (see: Section 1).

3.1.2 Identify and select relevant studies. We then employed multiple strategies to identify relevant resources through different sources: electronic scholarly databases, a citations-based review, and targeted keyword searches in relevant organizations, and conferences. Using the ACM Guide to Computing Literature as the primary search system – which reflects key computing research databases – we developed the following initial set of key concepts to search full text and metadata: "algorithmic harm", "sociotechnical harm", "AI harm", "ML harm", "data harm", "harm(s) taxonomy, "allocative harm", and "representational harm." Within scoping review methodology, keyword search strategies should be devised to surface relevant literature [11] and include terms common to the field [101]. We included allocative and representational harm as search terms because of their conceptual dominance in machine learning literature since 2017, popularized by responsible ML scholars (e.g.,

[20, 63]), enabling us to surface relevant literature in that sub-field. Iterative searching is a feature of scoping reviews [65]. Next, we reviewed each paper, and conducted a citations-based review to surface additional references (e.g., gray literature by nongovernmental organizations (NGOs)) that materially discuss harms, but may not use the specific terminology of the search terms. The citations-based review revealed highly-cited cross-disciplinary scholarship (e.g., articles from sociology, STS). Lastly, we relied on existing knowledge and networks to surface additional sources, including IEEE, NIST, Data and Society, the Aspen Institute, and the AI Incident Database.

Paper identification started February 2022. The initial search of the ACM database produced a set of 85 research articles (duplicates removed from 118 papers). The citations-based review and targeted keyword searches of NGO and professional organization outputs identified an additional 125 resources. We included articles that described or discussed: (1) algorithmic technologies and (2) harms or adverse impacts from algorithmic systems. We excluded 38 articles that: (1) did not meet the inclusion criteria, and (2) did not have full-text available. In total, 172 articles and frameworks were included in our corpus (see: Appendix Figure 2 and Table 7).

3.1.3 Data charting. We employed a descriptive-analytical method for charting data – a process of "synthesizing and interpreting qualitative data by sifting, charting and sorting material according to key issues and themes" [11, p. 26]. Two researchers independently charted the following data items extracted through reading of the full text of each source and organized them into a spreadsheet: (1) characteristics of sources: publication year and venue; and (2) description of harm: definition or conceptual framing. Discovery of a new concept or type of harm resulted in a new code, and repeat encounters with existing concepts or harms were documented to reach theoretical saturation – a point at which coding additional papers or resources do not yield additional themes [107, 190]. It is difficult to know when to stop searching for new sources when conducting a review [101]. Thus, relying on scoping reviews' iterative characteristic [168], we used theoretical saturation as a signal to stop sourcing new papers. The entire corpus was coded. Data charting concluded July 2022.

3.1.4 Collating and summarizing results. As collation of themes requires synthesis and qualitative analysis of articles, we used Braun and Clarke's reflexive thematic analysis [41, 42], a post-positivist approach to analysis that acknowledges researchers' standpoints influence data interpretation and encourages self-reflection. Within reflexive thematic analysis, coding is iterative as researchers are immersed in the data. As coding is an evolving, self-reflective process in reflexive thematic analysis, the authors engaged in deep data immersion, interpretation, and discussion, including sharing points of disagreement. First, we thematically sorted definitions of code and looked at the frequency at which harm definitions appeared to begin to identify dominant terms and definitions. Then, we conducted a first line-by-line pass reviewing associated phrasing and terminology of each specific kind of harm. In this initial phase, we identified codes that could be easily condensed. For instance, 'physical harm' and 'physical injury' were condensed into one code: physical harm. We then began to cluster harms based on the context or domain in which they were mentioned. For example, specific harms describing forms of harassment (e.g., non-consensual sharing of explicit images, or online stalking) were clustered under an initial theme of "hate, harassment, and violence." There were many conceptual overlaps among harm types; definitions were not always consistent. If there was a dominant term or definition in the cluster that could encompass different sub-types of harm (based on frequency of citation), that term was chosen as the primary category. Notably, we identified and coded more than one type of harm for approximately 80% of the articles in the corpus.

As RQ2 seeks to uncover where there was conceptual alignment across computing sub-fields, initial decisions about harm type and sub-type naming were made after raw coding the entire corpus and discussing emergent themes. From this clustering, and as we iterate from initial codes to final themes, we developed a first version of the harm taxonomy. Three of these harm types — allocative, representational, and quality-of-service — reflect where there was strong definitional and terminological consensus in pioneering responsible ML literature (see: [20, 63, 228]). As we iterated from initial codes to final themes we chose to anchor to these canonical harm types in alignment with the RQs. Social system harms and interpersonal harms took shape through the collating and summarizing process. Here, some of the sub-harm types, such as technology-facilitated violence [109] and information harms [232] are existing and well-established concepts/terms in different computing sub-fields to which we anchored in alignment with RQ2. See the Appendix for further details on the methodology and descriptive statistics of the corpus.

In scoping reviews, collating and summarizing findings requires researchers to make choices about what they want to prioritize. As the guiding purpose of this research was to develop an applied taxonomy, we prioritized keeping the number of major categories comprehensive yet manageable, envisioning a practitioner with minimal knowledge of harms as the primary user. With the goal of making the taxonomy accessible to practitioners with different disciplinary backgrounds, we repeated this process of clustering and synthesizing three times, refining language and examples of harms to ensure clarity and conceptual cohesion.

Importantly, while we have aligned to canonical concepts we found definitional variability within and across computing sub-fields, illuminating how understandings of harm are not rigidly fixed and can shift based on sub-field, context of use, technology type, and the evolving state of knowledge. Our descriptions of harm types and sub-types reflect the rich variability that exists in the broader field and is not intended to usurp specific harm definitions that hold specific meaning in different domains (e.g., law, engineering, policy, community work). As such this taxonomy navigates the challenging task of synthesizing multidisciplinary computing research with different priorities and concerns.

3.2 Limitations

In seeking to map how computing researchers conceptualize sociotechnical harms in algorithmic systems, our scoping review focused on academic outlets. The findings are reflective of existing scholarly knowledge for a particular bounded time period. Like all knowledge systems, computing research scholarship is not neutral; it is shaped by various influences, including researcher and institutional priorities, access to resources, thematic conferences, and

Figure 1: Sociotechnical harms taxonomy overview.

targeted calls that advance research in specific areas. Focusing on scholarly literature also means vital community-based advocacy addressing the design and use of algorithmic systems is not reflected in the citations. Surveying such work is an important and fruitful direction for future research.

In alignment with feminist standpoint theory [103, 104], we prioritize articulations of harm voiced by marginalized communities when possible and foreground these in our descriptions of harm in the taxonomy. We acknowledge articulations of harm described in computing scholarship may derive from work with individuals and communities who describe harms in ways that differ from scholarly discourse. Indeed, there may be many types of harm that are not recognized or articulated in scholarship. As research literatures are always partial and in-progress, the harms described in our taxonomy reflect the partial and in-progress nature of the field. These dynamics are especially relevant to the study of emergent technologies, where individual, collective, and societal impacts of these technologies may be anticipated but not fully known. We also acknowledge the literature reviewed here aligns primarily with Eurocentric worldviews, which undoubtedly shape the descriptions of harms. We are attentive to how these absences likely persist in our taxonomy, having engaged in discussion around how perceived and real gaps in the taxonomy should motivate future research.

Lastly, the potential benefits of structuring knowledge on sociotechnical harm fosters a paradox: while the taxonomy aids more systematic analysis and minimizes the limitation of relying on the mental models of those at the "decision-making table," it arguably can hinder practitioners' imagination. These kinds of politics related to knowledge creation have been long critiqued in STS [53, 91, 102, 104]. Without continued and active critical reflection, this taxonomy — or any structured process the taxonomy is incorporated into — can divert attention away from other possible harms. While we expect understandings of sociotechnical harm will continue to evolve, we encourage those working in this field to retain their critical imagination in considering novel harms.

4 TAXONOMY OF SOCIOTECHNICAL HARMS

Our thematic analysis brings together five major types of sociotechnical harms reflective of micro-, meso-, and macro-level impacts of algorithmic systems (see Figure 1 and Appendix Table 6). These categories emphasize (1) how socially constructed beliefs and unjust hierarchies about social groups are reflected in model inputs and outputs (*representational harms*); (2) how these representations shape model decisions and their distribution of resources (*allocative harms*); (3) how choices made to optimize models for particular imagined users result in performance disparities (*quality-of-service harms*); (4) how technological affordances adversely shape relations between people and communities (*interpersonal harms*); and (5) how algorithmic systems impact the emergent properties of social systems, leading to increased inequity and destabilization (*social system*). As our main aim is to provide a cohesive taxonomy for the community, wherever possible, we sought to build on and refer to existing taxonomies, classifications, and terminologies rather than to re-invent new terms. Notably, important concepts such as tech-facilitated violence [109, 142], coercive control [80], disinformation and misinformation [232], and environmental harms [24] are well-established terms studied in-depth within different computing sub-fields but often alienated from other harms literature.

In developing a framework that supports more systematic analysis of potential harms in algorithmic systems, we recognize the complex and often concurrent ways harms are experienced. Conceptualizations of harm do not always fit neatly within a compartmentalized structure. Accordingly, there may be gray areas within and across harm categories, and multiple harms may occur in a single use case or system. This taxonomy is thus not prescriptive in its ordering of harms. In suggesting its use as a tool, we encourage considering the multiple dimensions in which harms may play out rather than isolating them. In what follows, we discuss each major harm classification, including sub-types and how they emerge through the interplay of technical components and social dynamics.

4.1 Representational Harms: Unjust Hierarchies in Technology Inputs and Outputs

In our initial coding of the corpus, we located 14 different kinds of representational harms; through the thematic analysis we decided these were analogous to an existing taxonomy on representational harm of image tagging [121]. For terminological consistency of the community, we choose to use the same phrasing of the sub-types presented in [121]. In this section, we describe representational harms and its sub-types from a broader algorithmic systems perspective.

Katzman and colleagues describe representational harms as beliefs about different social groups that reproduce unjust societal hierarchies [121]. These harms occur when algorithmic systems reinforce the subordination of social groups along the lines of identity, such as disability, gender, race and ethnicity, religion, and sexuality [22]. Representational harms include instances where certain social groups experience both over- and under-exposure [27], leading to unequal visibility [242]. Prior work identifies representational harms in many algorithmic systems, including through classifiers [46], natural language processing [35], computer vision [28, 48, 244]. Representational harms reflect assumptions that algorithmic systems make about people, culture, and experiences, which perpetuate normative narratives that adversely shape people's sense of identity and belonging [118]. Andalibi and Garcia [8] characterize the lived experience of representational harms as *algorithmic symbolic annihilation* through which normative narratives built into technologies become power structures that shape people's experiences with algorithms. The communities likely to experience these harms are those already experiencing social marginalization. Representational harms thus entrench and exacerbate social stereotypes and patterns of erasure [26]. Specific dimensions of representational harm include stereotyping, demeaning, erasing, and alienating social groups, denying people the opportunity to self-identify, and reifying essentialist social categories (Table 1). See Appendix Table 8 for the full list of articles in the corpus that also articulate this harm type.

Table 1: Representational harms

Harm Sub-Type	Example
Stereotyping social groups	"Exclusionary norms [in language models] can manifest in 'subtle patterns' like referring to women doctors as if doctor itself entails not-woman" [235, p. 216]
Demeaning social groups	"A greater percentage of [online] ads having "arrest" in ad text appeared for Black identifying first names than for white identifying first names in searches" [213, p. 13]
Erasing social groups	"I'm in a lesbian partnership right now and wanting to get married and envisioning a wedding [...] and I'm so sick of [searching for 'lesbian wedding' and seeing] these straight weddings" [71, p. 13]
Alienating social groups	"[Lack of representation] further promotes the idea that you don't belong and perpetuates the sense of alienation" [71, p. 8]
Denying people opportunity to self-identify	"It's definitely frustrating having [classifiers] get integral parts of my identity wrong. And I find it frustrating that these sorts of apps only tend to recognize two binary genders" [28, p. 12]
Reifying essentialist social categories	"[Automatic gender recognition] aim(s) to capture the morphological sexual differences between male and female faces by comparing their shape differences to a defined face template. We assume that such differences change with the face gender" (quoted in [123, p. 8])

4.1.1 Stereotyping social groups. Stereotyping in an algorithmic system refers to how the system's outputs reflect "beliefs about the characteristics, attributes, and behaviors of members of certain groups....and about how and why certain attributes go together" [110, p. 240]. People marginalized in society face numerous explicit and implicit stereotypes conveyed in various forms of data and coding schema [165] and design choices [34] that drive algorithmic systems. Stereotyping often reflects repeated patterns of over- and under-representation — for instance, how gendered beliefs about women's submissiveness are reflected in digital assistants [50, 210, 231]. Research identifies narrow stereotypes about masculinity and femininity represented and expressed in natural language processing and computer vision systems, particularly in relation to professions [122], cooking and shopping [244], and sport [48]. While computing literature often describes stereotyping along single-axis dimensions of identity [48, 244], an intersectional approach draws attention to how harms play out for people whose lives are shaped by interlocking forms of oppression [46, 229] – for example, when a search for the term "unprofessional hairstyles" disproportionately returns images of Black women [6, n.p.].

4.1.2 Demeaning social groups. In 2013, Latanya Sweeney [213] drew attention to how algorithmic systems can lead to demeaning treatment of certain social groups. This harm sub-type was also popularized by Safiya Noble in *Algorithms of Oppression* [156]. Wang et al. describe demeaning of social groups to occur when they are "cast as being lower status and less deserving of respect" [228, p. 5]. This type of representational harm speaks to what sociologist Patricia Hill Collins [57] calls *controlling images*, referring to discourses, images, and language used to marginalize or oppress a social group. Controlling images include forms of human-animal confusion in image tagging systems [225], which reflect dehumanizing gendered and racialized discourses used to socially exclude and control Black, Indigenous, and other people of color [95]. Such controlling images have appeared in ranking and retrieval systems, including reinforcing false perceptions of criminality by displaying ads for bail bond businesses when searching for Black-sounding versus white-sounding names [213]. Similarly, patterns of demeaning imagery have been found in hateful natural language predictions about Muslim people [1], and toxicity and sentiment classifiers that are more likely to classify descriptions or mentions of disabilities [113, 213] and LGBTQ identities [215, 237] as toxic or negative. As these identities are often weaponized, models struggle with the social nuance and context required to distinguish between hateful and non-hateful speech [237].

4.1.3 Erasing social groups. Katzman et al. describe that in the context of image tagging, erasing social groups refers to "when a system fail to recognize—and ... fails to correctly tag people belonging [to] specific social groups or attributes and artifacts that are bound up with the identities of those groups" [121, p. 3-4]. For algorithmic systems more broadly, the erasure of social groups would mean that people, attributes, or artifacts associated with specific social groups are systematically absent or under-represented. Whereas stereotyping reflects systematic patterns of over- and

under-representation, erasure captures its extremes. In instances of erasure, certain social groups are not legible to algorithmic systems. Erasure, as Dosono and Semaan [78, p. 1] describe, reflects a kind of algorithmic hegemony, as the dominant "system of ideas, practices, and social relations that permeate the institutional and private domains of society" become normalized in sociotechnical systems. Design choices [143] and training data [212] influence which people and experiences are legible to an algorithmic system. Prior work examines erasure in the context of misgendering [68, 123], the systematic erasure of transgender and non-binary people [68, 123], disability and ableism in image descriptions [28], and the marginalization of non-Western and underrepresented religious identities in systems [121].

4.1.4 Alienating social groups. Katzman et al. describe alienating as "when an image tagging system does not acknowledge the relevance of someone's membership in a specific social group to what is depicted in one or more images." [121, p. 4]. We did not find other work in our corpus that articulate this harm sub-type. This dimension of representational harm diminishes human dignity [139] and is especially likely when "a system fails to recognize the injustices suffered by specific social groups" [121, p. 4]. A study of user-elicited identification of harms in image search describes the impacts of such failures as "further promot[ing] the idea that you don't belong and perpetuat[ing] a sense of alienation" [71, p. 8].

4.1.5 Denying people the opportunity to self-identify. Another way algorithmic systems present representational harm is through the complex and non-traditional ways in which humans are represented and classified automatically, and often at the cost of autonomy loss [54, 165]. As Katzman et al. expresses, in image classification contexts, this means to classify people's membership without their knowledge or consent [121], such as categorizing someone who identifies as non-binary into a gendered category they do not belong [229]. This dimension of representational harm reduces autonomy [100] that undermines people's ability to disclose aspects of their identity on their own terms [59]. This loss of autonomy reduces people's control over data collection, through which data about people, their bodies, and presumptions about their behavior can be extracted into big data flows [73]. As classification systems are used across many consequential domains, denying opportunities to self-identify can materially impact marginalized communities, ranging from nonconsensual inclusion in datasets to surveillance and wrongful arrest [28].

4.1.6 Reifying essentialist social categories. Our analysis of the corpus surfaced a type of harm that reinforce social categories as natural, or reinforces perceived classifications of people as truths (see Appendix Table 8). Broadening existing narrower description of this sub-type harm [21, 121], algorithmic systems that reify essentialist social categories can be understood as when systems that classify a person's membership in a social group based on narrow, socially constructed criteria that reinforce perceptions of human difference as inherent, static and seemingly natural [69, 123]. Reifying essentialist categories can contribute to "existential harm" in which people are "portrayed in overly reductive terms" [186, p. 162], often from a Western or Eurocentric perspective [69]. When such classification relies on phenotypes, this dimension of representational harm essentializes historically contingent identities [85] through which classification systems entrench and produce meaning about what they represent [100, 111]. The harms of reifying social categories are especially likely when ML models or human raters classify a person's attributes – for instance, their gender, race, or sexual orientation – by making assumptions based on their physical appearance.

4.2 Allocative Harms: Inequitable Distribution of Resources

Allocative harms were first discussed in the ML community by Solon Barocas, Kate Crawford, Aaron Shapiro, and Hanna Wallach (see: [20, 63]) and subsequently popularized by Virginia Eubanks in *Automating Inequality* [84]. Our corpus included 11 thematic codes for allocative harms, which encompass problems arising from how algorithmic decisions are distributed unevenly to different groups of people [22, 183]. These harms occur when a system withholds information, opportunities, or resources [22] from historically marginalized groups in domains that affect material well-being [146], such as housing [47], employment [201], social services [15, 201], finance [117], education [119], and healthcare [158]. Allocative harms "arc towards existing patterns of power" [66, p. 2] as they entrench material divisions between social groups [243]. When occurring in consequential domains, these harms reflect what Mimi Onuhoha [161, n.p.] describes as algorithmic violence, in which algorithmic systems "prevent people from meeting their basic needs." Scholarly literature describes two specific dimensions of allocative harm — opportunity loss and economic loss — reflecting and reinforcing existing social hierarchies along axes of disability, gender, race, or sexuality among others (Table 2). See Appendix Table 9 for the full list of articles in the corpus that also articulate this harm type.

4.2.1 Opportunity loss. The results of our analysis indicate a subtype of allocative harms that are conceptually captured by the term "opportunity loss" presented in a talk by Crawford (cited [22, n.p.]). Opportunity loss occurs when algorithmic systems enable disparate access to information and resources needed to equitably participate in society, including the withholding of housing through targeting ads based on race [10] and social services along lines of class [84]. Researchers contextualize how opportunity loss arises through algorithmic systems and existing patterns of inequality. In relation to housing, for instance, when advertisers target ads based on race and ethnicity, they provide minoritized people fewer options and opportunities to purchase or rent homes [10]. In the employment domain, recommender or ranking systems that match employers and potential candidates may prioritize the resumes of men over other genders [201, 224]. Relatedly, these systems may "codify algorithmic segregation" whereby Black candidates are systematically matched to Black-owned businesses and white candidates are systematically matched to white-owned businesses [241, p. 704]. In the government or social services domain, screening tools to identify children at-risk for maltreatment can amplify already-existing biases against poor parents [84, 241].

Table 2: Allocative harms

Harm Sub-Type	Example
Opportunity loss	"Systems…wrongfully deny welfare benefits, kidney transplants, and mortgages to individuals of color as compared to white counterparts" [61, p. 2]
Economic loss	"Language models may generate content that is not strictly in violation of copyright but harms artists by capitalizing on their ideas…this may undermine the profitability of creative or innovative work" [235, p. 221]

4.2.2 Economic loss. Apart from the loss of opportunity, many articles in our dataset articulate the loss of resources that have negative economic implications (see Appendix Table 9). We refer to these collectively as economic loss. Economic loss is often entwined with opportunity loss, though it relates directly to financial harms [52, 160] co-produced through algorithmic systems, especially as they relate to lived experiences of poverty and economic inequality. This harm reinforces "feedback loops" between existing socioeconomic inequalities and algorithmic systems [76, p. 14]. Researchers recognize economic loss as a harm that intersects with gendered, racialized, and globalized inequalities [13]. It may arise through different technologies, including demonetization algorithms that parse content titles, metadata, and text, and it may penalize words with multiple meanings [51, 81], disproportionately impacting queer, trans, and creators of color [81]. Differential pricing algorithms, where people are systematically shown different prices for the same products, also leads to economic loss [55]. These algorithms may be especially sensitive to feedback loops from existing inequities related to education level, income, and race, as these inequalities are likely reflected in the criteria algorithms use to make decisions [22, 163].

4.3 Quality-of-Service Harms: Performance Disparities Based on Identity

In our initial coding of the corpus, we located 10 different articulations of quality-of-service harms. Performance disparities across different user groups have been widely discussed as a concern in the machine learning community (e.g., [132, 214]). Bird et al. refers to these as quality-of-service harms [32]. These harms occur when algorithmic systems disproportionately underperform for certain groups of people along social categories of difference such as disability, ethnicity, gender identity, and race. DeVries et al. outline that these harms reflect how system training data are optimized for dominant groups [72]. Prior work has described how quality-of-service harms are especially likely when system inputs rely on biometric data (e.g., facial features, skin tone, or voice), such as computer vision [46, 176], natural language processing [113, 131, 173], and speech recognition systems [124, 143]. Quality-of-service harms are often conceptualized as experiences of directly interacting with an algorithmic system that fails based on identity characteristics, resulting in feelings of alienation, increased labor, and service or benefit loss (see Table 3). See Appendix Table 10 for the full list of articles in the corpus that also articulate this harm type.

4.3.1 Alienation. Alienation generally refers to "an individual's feeling of uneasiness or discomfort which reflects [one's] exclusion or self-exclusion from social and cultural participation. It is an expression of non-belonging or non-sharing, an uneasy awareness or perception of unwelcome contrast with others" [99, p. 758-759]. Whereas alienation as a form of representational harm diminishes human dignity and the sense of non-belonging (see Section 4.1.4), our corpus also surfaced alienation as a quality-of-service harm. In this sub-type, alienation is the specific self-estrangement experienced at the time of technology use, typically surfaced through interaction with systems that under-perform for marginalized individuals [143] or reinforce social alienation between humans [34]. In their work on automatic speech recognition systems, Mengesha et al. describe this harm as feelings of annoyance, disappointment, frustration, or anger when interacting with technologies that do not recognize one's identity characteristics: "Because of my race and location, I tend to speak in a certain way that some voice technology may not comprehend. When I don't speak in my certain dialect, I come to find out that there is a different result in using voice technology" [143, p. 5]. Research on trans and queer people's experiences with voice activated assistants, for instance, describes an awareness of limited representation, noting these technologies "were not designed for trans/or queer people" [184, p. 8]. Similarly, content creators from marginalized communities describe feelings of alienation as they navigate what Duffy and Meisner [81] refer to as *algorithmic invisibility*, whereby topics important to marginalized communities are rendered invisible by content moderation algorithms.

4.3.2 Increased labor. In our corpus, certain types of harm surfaced in the form of increased burden (e.g., time spent) or effort required by members of certain social groups to make systems or products work as well for them as others. Research on automatic speech recognition, for instance, has found substantial disparities in word error rates between Black and white speakers (0.35 and 0.19 respectively) [124]. Similar disparities have been found relative to sociolect [5], gender [5, 214], age [132], and region [5], among others. To correct for these limitations, speakers have to modify their speech to meet system expectations through linguistic accommodation [143].

4.3.3 Service or benefit loss. Service or benefit loss is the degraded or total loss of benefits of using algorithmic systems with inequitable system performance based on identity [143]. Accommodating technology shortcomings limits the potential benefits of technologies. However, when technologies with performance disparities are used in consequential domains — such as in job application videos — degraded service can not only stigmatize users but also lead to other types of harm, such as allocative harms [140].

4.4 Interpersonal Harms: Algorithmic Affordances Adversely Shape Relations

We initially located 66 thematic codes that we ultimately categorize broadly as interpersonal harms. Interpersonal harms capture instances when algorithmic systems adversely shape relations between people or communities. As algorithmic systems mediate interactions between people and institutions, interpersonal harms do not necessarily emerge from direct interactions between people, as is the more classic understanding of interpersonal relations,

Table 3: Quality-of-Service harms

Harm Sub-Type	Example
Alienation	"It [voice technology] needs to change because it doesn't feel inclusive when I have to change how I speak and who I am, just to talk to technology" [143, p. 8]
Increased labor	"I modify the way I talk to get a clear and concise response. I feel at times, voice recognition isn't programmed to understand people when they're not speaking in a certain way" [143, p. 7]
Service/benefit loss	"It conveyed the opposite message than what I had originally intended, and cost somebody else a lot (of time)" [143, p. 4]

but can emerge through the power dynamics of productionized ML models [108]. Like other sociotechnical harms, existing power asymmetries and patterns of structural inequality constitutively shape them. They have an intrapersonal element, however, through which people feel a diminished sense of self and agency. Prior work on algorithmic systems describe different types of interpersonal harm, including agency loss, technology-facilitated violence, diminished health and well-being, and privacy violations (Table 4). See Appendix Table 11 for the full list of articles in the corpus that articulate this harm type.

4.4.1 Loss of agency or control. Loss of agency occurs when the use [123, 137] or abuse [142] of algorithmic systems reduces autonomy. One dimension of agency loss is algorithmic profiling [138], through which people are subject to social sorting and discriminatory outcomes to access basic services [189]. Algorithmic profiling is amplified when there is insufficient ability to contest or remedy the decisions of algorithmic systems [10, 67, 205]. As algorithms increasingly curate the flows of information in digital spaces (i.e., recommender systems), Karizat, Delmonaco, Eslami, and Andalibi [118, p. 20] describe how the presentation of content may lead to "algorithmically informed identity change… including [promotion of] harmful person identities (e.g., interests in white supremacy, disordered eating, etc.)." Similarly, for content creators, desire to maintain visibility or prevent shadow banning, may lead to increased conforming of content [215].

4.4.2 Technology-facilitated violence. Technology-facilitated violence occurs when algorithmic features enable use of a system for harassment and violence [2, 16, 44, 80, 108], including creation of non-consensual sexual imagery in generative AI. Gender violence scholars have uncovered how algorithmic technologies can become conduits for stalking [87, 108], online sexual harassment and assault (e.g., sharing images of sexual coercion and violence, sextortion) [44], and coercive control backed by the threat of violence (e.g., accessing accounts, impersonating a partner, doxxing, sharing sexualized content) [80]. For example, abusers may misuse Wi-Fi enabled devices, including locking out and controlling devices to terrorize and harass users [44, 167], or use technology to generate or share non-consensual sexually explicit images [15, 142]. Beyond gender violence, other facets of technology-facilitated violence, include doxxing [79], trolling [14], cyberstalking [14], cyberbullying [14, 98, 204], monitoring and control [44], and online harassment and intimidation [98, 192, 199, 226], under the broader banner of online toxicity [98, 136]. Technology-facilitated violence leads to co-occurring harms, including feelings of distress, fear, and humiliation [44], while often infringing personal and bodily integrity, dignity, and privacy and inhibiting autonomy and expression [142].

4.4.3 Diminished health and well-being. Algorithmic systems can lead to diminished health and well-being of human users. Our corpus attribute the myriad sources of this harm including from algorithmic behavioral exploitation [18, 209], emotional manipulation [202] whereby algorithmic designs exploit user behavior, safety failures involving algorithms (e.g., collisions) [67], and when systems make incorrect health inferences [158]. They can lead to both physical harms [71, 79, 139, 181] emotional harms, such as distress [235], dignity loss [44, 139], misgendering [123], and reputational harms [152, 181]. Diminished health and well-being may accompany other identified sociotechnical harms – for example, experiences of representational harms, including algorithmic annihilation [8] or the internalization of stereotypes may spark other emotional or psychological effects, such as "epistemic doubt" [231], which affects overall health. As constructs of well-being are culturally relative [154], health ideologies operationalized into machine learning models may "not be relevant, or potentially even harmful, to users living differently to the ways assumed by situated designers" [77, p. 5]. Thus, builders of algorithmic systems must be attentive to forms of distress falling outside Eurocentric and Western care models [166].

4.4.4 Privacy violation. Privacy violation occurs when algorithmic systems diminish privacy, such as enabling the undesirable flow of private information [180], instilling the feeling of being watched or surveilled [181], and the collection of data without explicit and informed consent [117]. These violations have also been framed as "data harms" [149], which encompass the adverse effects of data that "impair, injure, or set back a person, entity, or society's interests" [181, n.p.]. Here, privacy violations may reflect more traditional conceptualizations of privacy attacks or security violations [79, 105] and privacy elements beyond what may be protected by regulations or under the traditional purview of a privacy officer [138, 180]. For instance, privacy violations may arise from algorithmic systems making predictive inference beyond what users openly disclose [222] or when data collected and algorithmic inferences made about people in one context is applied to another without the person's knowledge or consent through big data flows [138], even after those datasets or systems have been deprecated [59, 82]. Even if those inferences are false (e.g., the incorrect assessment of one's sexuality), people or systems can act on that information in ways that lead to discrimination and harm [235]. Privacy violations may also occur through ubiquitous surveillance, surveillance based on emotional/affective targeting [209], or coercive and exploitative data practices [117].

4.5 Societal Harms: System Destabilization and Exacerbating Inequalities

Our corpus included 68 thematic codes that we broadly classify as societal harms. Social system or societal harms reflect the adverse macro-level effects of new and reconfigurable algorithmic systems, such as systematizing bias and inequality [84] and accelerating the

Table 4: Interpersonal harms

Harm Sub-Type	Example
Loss of agency or control	"[A photo recommender shared a] picture of my deceased mother [and it] just kind of caught me, and I sat there and thought about different things for a little bit. Then I had to get back to work. But I was distracted the whole time" [134, p. 8]
Technology-facilitated violence	"[She] broke up with [him] due to his controlling behavior. After the break-up, he began to appear where she was…One day, while driving her [car], the air conditioner turned off.…After a few failed attempts, she figured the unit was broken…After a call with the [car's] customer support, she discovered a second person using the [car] app to connect" [167, p. 650]
Diminished health and well-being	"I was getting ads for maternity clothes. I was like, 'Oh please stop.' …there's no way to tell your app, 'I had a miscarriage. Please stop sending me these updates'" [8, p. 18]
Privacy violations	"[Shopping] analytics had correctly inferred what he had not known, that his daughter was pregnant." [222, p. 211]

scale of harm [137]. Social systems are instantiated through recurrent social practices, shaped by existing and intersecting power dynamics. As Dosono and Semaan [78, p. 2] summarize, "people with marginalized identities—those who are pushed to the boundaries of society based on various intersections of their identity such as race and gender—continue to experience oppression, exclusion, and harassment within sociotechnical systems." Compared to other harm types, social system harms are often indirectly felt and occur downstream; they do not necessarily arise from a single incident or problematic system behavior. Societal harms reflect the "widespread, repetitive or accumulative character" of algorithmic systems in the world [207, p. 10], which contribute to institutional exclusions [231]. Harm to social systems is thus about how algorithmic systems adversely shape the emergent properties [129] of social systems [162]. Prior research outlines such harms in relation to knowledge systems, culture, political and civic harms, socioeconomic systems, and environmental systems (Table 5). See Appendix Table 12 for articles in the corpus articulating this harm type.

4.5.1 Information harms. Knowledge systems can be conceived as localized processes through which social knowledge is produced, circulates, and is destabilized. Janzen, Orr, and Terp [115] use the term information-based harms to capture concerns of misinformation, disinformation, and malinformation. Algorithmic systems, especially generative models and recommender, systems can lead to these information harms. Misinformation refers to the spread of misleading information whether or not there is intention to deceive and disinformation is deliberately false information [153, 211, 219, 232]. Malinformation describes "genuine information that is shared with the intent to harm" [115, p. 2]. Information harms are often accompanied by co-occurring impacts, including physical, psychological or emotional, financial, and reputational harms [3, 218, 233, 240], which scale into broader societal harm. Beyond misinformation, disinformation, and malinformation, knowledge systems may be harmed through "subjugation," whereby dominant discourses proliferate through algorithmic systems — including in generative language models [235] — and foreclose alternative ways of knowing [93, 186, 187].

4.5.2 Cultural harms. Cultures are collectively and dynamically produced [114]. Cultural harm has been described as the development or use of algorithmic systems that affects cultural stability and safety, such as "loss of communication means, loss of cultural property, and harm to social values" [4, p. 30]. As algorithmic technologies can "foreclose alternative ways of understanding the world and restricting imaginations about possible futures" [186, p. 162], the nature of their harm can encompass adverse cultural impacts such as systemic erasure [71], Eurocentric ideas being exported to Global South [77, 148], harmful cultural beliefs [76], such as normalizing a culture of non-consensual sexual activity [142], or proliferating false ideas about cultural groups [78, 189].

4.5.3 Political and civic harms. Political harms emerge when "people are disenfranchised and deprived of appropriate political power and influence" [186, p. 162]. These harms focus on the domain of government, and focus on how algorithmic systems govern through individualized nudges or micro-directives [187], that may destabilize governance systems, erode human rights, be used as weapons of war [188], and enact surveillant regimes that disproportionately target and harm people of color [120]. More generally, these harms may erode democracy [97], through election interference or censorship [207]. Moreover, algorithmic systems may exacerbate social inequalities and reduction of civil liberties within legal systems [139, 181], such as unreasonable searches [152], wrongful arrest [61, 61, 124], or court transcription errors [124]. These harms adversely impact how a nation's institutions or services function [3] and increase societal polarization [207].

4.5.4 Macro socio-economic harms. Algorithmic systems can increase "power imbalances in socio-economic relations" at the societal level [4, 137, p. 182], including through exacerbating digital divides and entrenching systemic inequalities [114, 230]. The development of algorithmic systems may tap into and foster forms of labor exploitation [77, 148], such as unethical data collection, worsening worker conditions [26], or lead to technological unemployment [52], such as deskilling or devaluing human labor [170]. For instance, text-to-image models may undermine creative economies [235]. While big data flows reshape power within socio-economic systems [148, 189], when algorithmic financial systems fail at scale, these can lead to "flash crashes" and other adverse incidents with widespread impacts [137].

4.5.5 Environmental harms. Environmental harms entail ecological concerns, such as the depletion or contamination of natural resources [24, 92, 139, 148, 206, 207, 235], and damage to built environments [139]. Ecological harms concern adverse changes to the "ready availability and viability of environmental resources" [145, p. 738] that may occur throughout the lifecycle of digital technologies [170, 237] from "cradle (mining) to usage (consumption) to grave (waste)" [24, p. 169]. Similar to other sociotechnical harms, the "benefits and burdens of extractivism are unevenly distributed around the planet" whereby consumption in the economic core are contingent on extraction from the economic periphery [24, p. 170].

5 DISCUSSION

In this section, we reflect on the findings of our review, offering a discussion of how the taxonomy may support the anticipation of

Table 5: Social system / societal harms

Harm Sub-Type	Example
Information harms	"Users are increasingly exposed to information assembled and presented algorithmically, and many users lack the literacy to comprehend how algorithms influence what they can and cannot see" [78, p. 16]
Cultural harms	"[An image search for 'thug' showing predominantly Black men] …It damages all the Black community because if you're damaging Black men, then you're hurting Black families" [71, p. 8]
Political and civic harms	"Bots, automated programs, are used to spread computational propaganda. While bots can be used for legitimate functions ... [they] can be used to spam, harass, silence opponents, 'give the illusion of large-scale consensus', sway votes, defame critics, and spread disinformation campaigns" [181, p. 8]
Macro socio economic harms	"Harms associated with the labour and material supply chains of AI technologies, beta testing, and commercial exploitation" [170, p. 1]
Environmental harms	"The energy cost of training machine learning models...[and] harms from intensive water and fuel usage and server farms, consequent chemical and e-waste" [170, p. 5]

harms as well as tensions that might arise. We propose directions for continued research on sociotechnical harms to deepen the field's understanding of conditions that foster such harms.

5.1 Synthesizing methodological distinctions in studying harms

Harms from algorithmic systems encompass both computational and contextual harms [40, 164, 191, 236]. Through a scoping review and reflexive thematic analysis, we identify five harm categories, including representational, allocative harms, quality-of-service, interpersonal harms, and social system harms. Our analysis finds authors in the corpus vary widely in their approach to discussing and studying harms — an insight unsurprising given the multidisciplinary focus of the review. Notably, the discussion of harms frequently motivates research on technical aspects of algorithmic systems in the machine learning (ML) literature, but is less often a central analytic or variable. In contrast, research from HCI and related social scientific disciplines often centers harm, but may focus on one harm type, providing rich but narrow insight into that particular harm dimension (e.g., tech-facilitated violence [16, 80, 108]). Accordingly, individual scholarly analyses rarely capture the wide scope of harms that can arise from a given algorithmic system, which is a kind of anticipation work required for developing trustworthy and Responsible AI (see: [194]). By synthesizing a distributed body of computing research, this review offers insight into the current discourse and range of harms identified in the literature, which can support Responsible AI efforts to anticipate them in practice.

5.2 Towards a shared harms vocabulary with flexible structure

As structured frameworks support the work of anticipating harms and other challenges of algorithmic systems [135, 239], scoping literature from disparate computing research synthesizes insights that can be useful to practitioners and researchers alike. Here, we offer two findings of note. First, this review reveals dominant areas of concern within computing research on harm, such as the prospect of algorithmic systems exacerbating or scaling existing social inequalities (see Appendix Table 12). While concern for the relational complexities of social inequality is perhaps expected in social science research (where inequality is a core concept), its appearance in ML research might be unexpected given its historic emphasis on statistics. Our findings illuminate inequality as a normative concern of computing research on harm. Given methodological distinctions across computing disciplines, there are opportunities for deeper integration of social science insights into ML approaches to strengthen and enrich understanding of harms from algorithmic systems. There are examples of such work already (e.g., [31, 127]).

Second, this review reveals how computing researchers describe harms at varying levels of abstraction. For instance, some authors in the corpus simply refer to "representational harms" in relation to a type of likely harm (e.g., [66]), while others focus on mid-range articulations. Take, for example, deeper discussions of representational "erasure" (e.g., [121]) and the identification of specific ways in which erasure might manifest in an application (e.g., [8, 68]). The depth in which computing research describes harms is often an artifact of a given study's focus. This observation underscores the need to be able to discuss harms at varying levels of specificity and retain shared understanding. This need is particularly salient in Responsible AI settings where practitioners often interact with different audiences, and may simply refer to "*harms* broadly, without specifying...harms to who or what" [185, p. 9].

These two findings from the scoping review suggest the resulting taxonomy offers practical benefits, as it cultivates a shared language of harms while accommodating needs to discuss harms with varying specificity. This taxonomy enables what linguists call semantic "entailment" through which clear relationships are established between concepts [125], even though it draws together insights from different epistemological standpoints [103, 104]. It organizes harm types at cascading levels of conceptual detail, while allowing researchers and practitioners to narrow in on harms under those categories or to further operationalize them at a more granular level. This flexible knowledge structure also supports variable needs that arise when communicating about harms to different audiences. For instance, a practitioner working on policy may need higher levels of abstraction to provide generalized guidelines for an application; an engineer benchmarking harms within a model may desire more specificity to operationalize them within an evaluation dataset. A flexible harms taxonomy, such as the approach we suggest here, accommodates the varying needs of practitioners and researchers, while fostering common language to support collective efforts to reduce harms.

5.3 Navigating tensions between known and emergent harms

Encouraging practitioners to reflect on potential harms throughout the product life cycle can help proactively anticipate harms and limit reliance on reactionary responses. Anticipating harms is best conducted when grounded in a use case [86, 150, 200], because it provides deeper consideration of the domain of use, impacted downstream communities, and technological affordances [40]. Authors in the corpus identify how certain harms are inherent to

particular ML models (e.g., the relationship between recommender systems and allocative harms), pointing to some stability between certain algorithmic systems and the prospect of harm. For example, without interventions in place, algorithmic systems trained on text corpora from the social world are likely to contain representational harms across some aspect of identity, as text corpora often reflect the inequalities of the social world [49]. Even with recognition of the connections between certain ML models and potential harms, a harms taxonomy may still be useful in supporting systematic analyses, such as considering how harms might extend across categories, including how they might inform and contribute to other harms. Consider relationships between allocative and quality-of-service harms: when algorithmic systems fail based on identity, community groups often have to engage in additional labor to correct those failures, revealing how those harms are interrelated in practice. An opportunity thus arises to consider known harms and explore their interdependence [75], which may be useful when anticipating harms for novel systems.

Anticipating harms for novel systems is especially challenging [40]: there are more unknown variables, and practitioners may be asked to anticipate harms early in the development or production stage before there are users or even a prototype. When the type of algorithm is novel — for example, code generation or text-to-image models — there may be limited existing empirical harms research to refer to for guidance. The knowledge base offered by prior work on harms provides researchers and practitioners a generative starting point. The taxonomy synthesizes prior literature as an analytic and topic guide that can be interpreted alongside specific contextual features when looking at applied contexts.

5.4 Towards multidisciplinary proactive and reflexive harm anticipation

Our review underscores the diverse theoretical foundations and methodologies that the field of computer research employs in relation to sociotechnical harms. The breadth of harms covered in the taxonomy is a first step in supporting practitioners to more systematically reflect on adverse impacts of algorithmic systems. As we appreciate various practitioner standpoints and challenges, we do not offer normative guidance on identifying, evaluating, or controlling for harms. This taxonomy can supplement and enhance existing assessment processes an organization may have in place, providing a starting point for establishing a shared vocabulary on sociotechnical harms. Furthermore, we acknowledge that assessing the overall social impacts of an algorithmic system using only harm as a framing device can miss other negative implications of technology – for instance, inconveniences that arise from exercising the right to data portability or the right to be forgotten [30, 38].

In making these recommendations, we recognize they maintain both tensions and shortcomings. Given that harm is a broad concept experienced in myriad ways, any taxonomy is limited. Our scoping review, the corpus of which is comprised primarily from academic and gray literature published in English, presents inherent biases and does not necessarily resonate globally. The existing literature privileges Western perspectives [148, 170], leaving a dearth of perspectives from the majority of the world. This has bearing on what experiences become legible as harm. Since completing the scoping review, there have been refinements in how certain harms are conceptualized (e.g. [196]). It would be a mistake to consider this taxonomy a final, comprehensive list, or solely employ it to quantify the overall degree of harms a system may pose. Rather, it is a synthesis of knowledge that can be built upon and extended.

Rather than aim to flatten the diversity of methods and strategies to address harm by overprescribing how the taxonomy could be used, we hope various groups can draw on its insights to strengthen their methods. Developing a shared language can accelerate the capacity building of practitioners across organizations – a key objective in presenting these findings. In addition to the taxonomy, we hope to inspire practitioner communities to embrace and advance more systematic harm reduction methodologies, including 1) continued research to study and measure hams prior to launching a product; 2) increasing efforts to prioritize community-driven articulation of harms; and 3) strengthening multidisciplinary approaches. To ensure harm reduction practices and design strategies are comprehensive, future research should investigate understandings of harm and social benefit with communities traditionally marginalized and excluded from technology development [56].

6 CONCLUSION

Through a scoping review and reflexive thematic analysis of computing research on harms, we offer this taxonomy of sociotechnical harms as an initial guide to support practitioners and researchers in addressing a range of adverse impacts informed by algorithmic systems. We expect and hope it will evolve as research and engagement progress, particularly in terms of participatory and community-driven research methodologies (e.g., [68, 71, 89]). As a synthesis of computing research, this taxonomy offers a measure to assess areas and directions for future scholarly and practitioner discussions and research. It reveals there is greater consensus and depth of work in investigating particular harms, such as representational and allocative harms, as well as gaps where the range of possible harms is likely under articulated. Our interest in scoping sociotechnical harms remains motivated by cultivating methods to reduce their likelihood in algorithmic systems. It is our stance that developing a richer understanding of harms creates more generative paths towards harm reduction for all.

ABSTRACT

Machine Learning's proliferation in critical fields such as healthcare, banking, and criminal justice has motivated the creation of tools which ensure trust and transparency in ML models. One such tool is *Actionable Recourse* (AR) for negatively impacted users. AR describes recommendations of cost-efficient changes to a user's *actionable* features to help them obtain favorable outcomes. Existing approaches for providing recourse optimize for properties such as proximity, sparsity, validity, and distance-based costs. However, an often-overlooked but crucial requirement for actionability is a consideration of *User Preference* to guide the recourse generation process. In this work, we attempt to capture user preferences via soft constraints in three simple forms: *i) scoring continuous features, ii) bounding feature values* and *iii) ranking categorical features*. Finally, we propose a gradient-based approach to identify *User Preferred Actionable Recourse (UP-AR)*. We carried out extensive experiments to verify the effectiveness of our approach.

CCS CONCEPTS

• **Theory of computation → Actionable Recourse**; • **Computing methodologies** → *Knowledge representation and reasoning*; • **Human-centered computing → Human computer interaction (HCI)**.

1 INTRODUCTION

Actionable Recourse (AR) [30] refers to a list of actions an individual can take to obtain a desired outcome from a fixed Machine Learning (ML) model. Several domains such as lending [28], insurance [26], resource allocation [6, 27] and hiring decisions [1] are required to suggest recourses to ensure the trust of a decision system; in such scenarios, it is critical to ensure the actionability (the viability of taking a suggested action) of recourse, otherwise the suggestions are pointless. Consider an individual named Alice who applies for a loan, and a bank, which uses an ML-based classifier, who denies it. Naturally, Alice asks - *What can I do to get the loan?* The inherent question is what action she must take to obtain the loan in the future. *Counterfactual explanation* introduced in *Wachter* [31] provides a *what-if* scenario to alter the model's decision, but it does not account for actionability. AR aims to provide Alice with a *feasible* action set which is both actionable by Alice and which suggests as low-cost modifications as possible.

While some features (such as age or sex) are inherently inactionable for all individuals, Alice's personalized constraints may also limit her ability to take action on certain suggested recourses (such as a strong reluctance to secure a co-applicant). We call these localized constraints *User Preferences*, synonymous to user-level constraints introduced as *local feasibility* by Mahajan et al. [17]. Figure 1 illustrates the motivation behind UP-AR. Note that how similar individuals can prefer contrasting recourse.

Actionability, as we consider it, is centered explicitly around individual preferences, and similar recourses provided to two individuals (Alice and Bob) with identical feature vectors may not necessarily be equally actionable. Most existing methods of finding actionable recourse are restricted to *omissions* of features from the *actionable feature set* and *box constraints* [18] that bound actions.

In this study, we discuss three forms of user preferences and propose a user-provided score formulation for capturing these different idiosyncrasies. We believe that communicating in terms of preference scores (by say, providing a 1-10 rating on the actionability of specific features) improves the explainability of a recourse generation mechanism, which ultimately improves trust in the underlying model. Such a system could also be easily re-run with different preference scores, allowing for diversifiable recourse. We surveyed 40 individuals and found that an overwhelming 60% majority preferred to provide their preferences on individual features for influencing a recourse mechanism, as opposed to receiving multiple "stock" recourse options or simply receiving a single option. Additional details of our survey are included in Section 7. We provide a hypothetical example of UP-AR's ability to adapt to preferences in Table 1.

Motivated by the above considerations, we capture soft user preferences along with hard constraints and identify recourse based on local desires without affecting the success rate of identifying recourse. For example, consider Alice prefers to have 80% of the recourse "cost" from loan duration and only 20% from the loan amount, meaning she prefers to have recourse with a minor reduction in the loan amount. Such recourse enables Alice to get the benefits of a loan on her terms, and can easily be calculated to Alice's desire. We study the problem of providing *user preferred recourse* by solving a custom optimization for individual user-based preferences. Our contributions include:

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604708

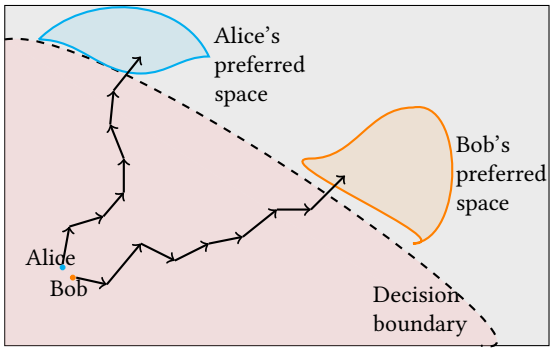

Figure 1: Illustration of UP-AR. Similar individuals Alice and Bob with contrasting preferences can have different regions of desired feature space for a recourse.

Table 1: A hypothetical actionable feature set of adversely affected individuals sharing similar features and corresponding suggested actions by AR and UP-AR. UP-AR provides personalized recourses based on individual user preferences.

Actionable Features	Curr. val.	UP-AR values	
		Alice	Bob
LoanDuration	18	8	17
LoanAmount	$1940	$1840	$1200
HasGuarantor	0	0	1
HasCoapplicant	0	1	0

- We start by enabling Alice to provide three types of user preferences: i) *Scoring*, ii) *Ranking*, and iii) *Bounding*. We embed them into an optimization function to guide the recourse generation mechanism.
- We then present *User Preferred Actionable Recourse (UP-AR)* to identify a recourse tailored to her liking. Our approach highlights a cost correction step to address the *redundancy* induced by our method.
- We consolidate performance metrics with empirical results of UP-AR across multiple datasets and compare them with state-of-art techniques.

1.1 Related Works

Several methods exist to identify counterfactual explanations, such as FACE [22], which uses the shortest path to identify counterfactual explanations from high-density regions, and Growing Spheres (GS) [16] which employs random sampling within increasing hyperspheres for finding counterfactuals. CLUE [3] identifies counterfactuals with low uncertainty in terms of the classifier's entropy within the data distribution. Similarly, manifold-based CCHVAE [21] generates high-density counterfactuals through the use of a latent space model. However, there is often no guarantee that the *what-if* scenarios identified by these methods are attainable.

Existing research focuses on providing feasible recourses, yet comprehensive literature on understanding and incorporating user preferences within the recourse generation mechanism is lacking. It is worth mentioning that instead of understanding user preferences, Mothilal et al. [18] provides a user with diverse recourse options and hopes that the user will benefit from at least one. The importance of diverse recourse recommendations has also been explored in recent works [18, 25, 31], which can be summarized as increasing the chances of actionability as intuitively observed in the domain of unknown user preferences [13]. Karimi et al. [14] and Cheng et al. [5] also resolve uncertainty in a user's cost function by inducing *diversity* in the suggested recourses. Interestingly, only 16 out of the 60 recourse methods explored in the survey by Karimi et al. [13] include diversity as a constraint where diversity is measured in terms of distance metrics. Alternatively, studies like Cui et al. [7], Rawal and Lakkaraju [23], Ustun et al. [30] optimize on a universal cost function. This does not capture individual idiosyncrasies and preferences crucial for actionability.

Efforts of eliciting user preferences include recent work by De Toni et al. [8]. The authors provide interactive human-in-the-loop approach, where a user continuously interacts with the system. However, learning user preferences by asking them to select from one of the *partial interventions* provided is a derivative of providing a diverse set of recourse candidates. In this work, we consider fractional cost as a means to communicate with Alice, where fractional cost of a feature refers to *fraction of cost incurred from a feature i out of the total cost of the required intervention.*

The notion of user preference or user-level constraints was previously studied as *local feasibility* [17]. Since users can not precisely quantify the cost function [23], Yadav et al. [32] diverged from the assumption of a universal cost function and optimizes over the distribution of cost functions. We argue that the inherent problem of feasibility can be solved more accurately by capturing and understanding Alice's recourse preference and adhering to her constraints which can vary between *Hard Rules* such as unable to bring a co-applicant and *Soft Rules* such as hesitation to reduce the amount, which should not be interpreted as unwillingness. This is the first study to capture individual idiosyncrasies in the recourse generation optimization to improve feasibility.

2 PROBLEM FORMULATION

Consider a binary classification problem where each instance represents an individual's feature vector $\mathbf{x} = [\mathbf{x}_1, \mathbf{x}_2, \cdot, \mathbf{x}_D]$ and associated binary label $\mathbf{y} \in \{-1, +1\}$. We are given a model $f(\mathbf{x})$ to classify $\mathbf{x}$ into either -1 or $+1$. Let $f(\mathbf{x}) = +1$ be the desirable output of $f(\mathbf{x})$ for Alice. However, Alice was assigned an undesirable label of -1 by f. We consider the problem of suggesting action $\mathbf{r} = [\mathbf{r}_1, \mathbf{r}_2, \cdot, \mathbf{r}_D]$ such that $f(\mathbf{x} + \mathbf{r}) = +1$. Since suggested recourse only requires actions to be taken on *actionable features* denoted by F_A, we have $\mathbf{r}_i \equiv 0 : \forall i \notin F_A$. We further split F_A into *continuous actionable features* F_{con} and *categorical actionable features* F_{cat} based on feature domain. Action $\mathbf{r}$ is obtained by solving the following optimization, where $userCost(\mathbf{r}, \mathbf{x})$ is any predefined cost function of taking an

action $\mathbf{r}$ such that:

$$\min_{\mathbf{r}} \ userCost(\mathbf{r}, \mathbf{x}) \tag{1}$$

$$s.t. \ userCost(\mathbf{r}, \mathbf{x}) = \sum_{i \in F_A} userCost(\mathbf{r}_i, \mathbf{x}_i) \tag{2}$$

$$\text{and } f(\mathbf{x} + \mathbf{r}) = +1. \tag{3}$$

2.1 Capturing individual idiosyncrasies

A crucial step for generating recourse is identifying *local feasibility* constraints captured in terms of individual user preferences. In this study, we assume that every user provides their preferences in three forms. Every continuous actionable feature $i \in F_{con}$ is associated with a *preference score* Γ_i obtained from the affected individual. Additional preferences in the form of feature value bounds and ranking for preferential treatment of categorical features are also requested from the user.

User Preference Type I (Scoring continuous features): User preference for continuous features are captured in $\Gamma_i \in [0, 1] : \forall i \in F_{con}$ subject to $\sum_{i \in F_{con}} \Gamma_i = 1$. Such *soft constraints* capture the user's preference without omitting the feature from the actionable feature set. Γ_i refers to the fractional cost of action Alice prefers to incur from a continuous feature i. For example, consider $F_{con} = \{LoanDuration, LoanAmount\}$ with corresponding user-provided scores $\Gamma = \{0.8, 0.2\}$ implying that Alice prefers to incur 80% of fractional feature cost from taking action on *LoanDuration*, while only 20% of fractional cost from taking action on *LoanAmount*. Here, Alice prefers reducing *LoanDuration* to *LoanAmount* and providing recourse in accordance improves actionability.

User Preference Type II (Bounding feature values): Users can also provide constraints on values for individual features in F_A. These constraints are in the form of lower and upper bounds for individual feature values represented by $\underline{\delta_i}$ and $\overline{\delta_i}$ for any feature i respectively. These constraints are used to discretize the steps. For a continuous feature i, action steps can be discretized into pre-specified step sizes of $\Delta_i = \{s : s \in [\underline{\delta_i}, \overline{\delta_i}]\}$. For categorical features, steps are defined as the feasible values a feature can take. For all categorical features we define, $\Delta_i = \{\underline{\delta_i}, \ldots, \overline{\delta_i}\} : \forall i \in F_{cat}$ representing the possible values for categorical feature i.

User Preference Type III (Ranking categorical features): Users are also asked to provide a ranking function $\mathcal{R} : F_{cat} \rightarrow \mathbb{Z}^{+1}$ on F_{cat}. Let $\mathcal{R}_i$ refers to the corresponding rank for a categorical feature i. Our framework identifies recourse by updating the candidate action based on the ranking provided. For example, consider $F_{cat} = \{HasCoapplicant, HasGuarantor, CriticalAccountOrLoansElsewhere\}$ for which Alice ranks them by $\{3, 2, 1\}$. The recourse generation system considers suggesting an action on *HasGuarantor* before *HasCoapplicant*. Ranking preferences can be easily guaranteed by a simple override in case of discrepancies while finding a recourse.

2.1.1 Cognitive simplicity of preference scores. The user preferences proposed are highly beneficial for guiding the recourse generation process. Please note that in the absence of these preferences, the recourse procedure falls back to the default values set by a domain expert. Additionally, the users can be first presented with the default preferences, and asked to adjust as per their individual preferences. A simple user interface can help them interact with the system intuitively. For example, adjusting a feature score automatically adjusts the corresponding preference type scores.

2.2 Proposed optimization

We depart from capturing a user's cost of feature action and instead obtain their preferences for each feature. We elicit three forms of preferences detailed in the previous section and iteratively take steps in the action space. We propose the following optimization over the basic predefined steps based on the *user preferences*. Let us denote the inherent hardness of feature action $\mathbf{r}_i$ for feature value $\mathbf{x}_i$ using $cost(\mathbf{r}, \mathbf{x})$ which can be any cost function easily communicable to Alice. Here, $cost\left(\mathbf{r}_i^{(t)}, \mathbf{x}_i\right)$ refers to a "universal" cost of taking an action $\mathbf{r}_i^{(t)}$ for feature value $\mathbf{x}_i$ at step t. Note that this cost function or quantity differs from the $userCost(\cdot, \cdot)$ function specified earlier. This quantity is capturing the inherent difficulty of taking an action.

$$\max_{\mathbf{r}} \sum_{i \in F_A} \frac{\Gamma_i}{cost(\mathbf{r}_i, \mathbf{x}_i)} \qquad \text{(Type I)}$$

$$s.t. \ f(\mathbf{x} + \mathbf{r}) = +1$$

$$\Gamma_i = 0 : \ \forall i \notin F_A \qquad \text{(actionability)}$$

$$\Gamma_j = 1 : \ \forall j \in F_{cat}$$

$$\mathbf{r}_i \in \Delta_i : \ i \in F_A \qquad \text{(Type II)}$$

$$\mathbf{1}\{\mathbf{r}_i > 0\} \geq \mathbf{1}\{\mathbf{r}_j > 0\} : \mathcal{R}_i \geq \mathcal{R}_j \ \forall i, j \in F_{cat} \qquad \text{(Type III)}$$

The proposed method minimizes the cost of a recourse weighted by Γ_i for all actionable features. We discuss the details of our considerations of cost function in Section 3.1. The order preference of categorical feature actions can be constrained by restrictions while finding a recourse. The next section introduces UP-AR as a stochastic solution to the proposed optimization.

3 USER PREFERRED ACTIONABLE RECOURSE (UP-AR)

Our proposed solution, User Preferred Actionable Recourse (UP-AR), consists of two stages. The first stage generates a candidate recourse by following a connected gradient-based iterative approach. The second stage then improves upon the *redundancy* metric of the generated recourse for better actionability. The details of UP-AR are consolidated in Algorithm 1 and visualized in Figure 2.

3.1 Stage 1: Stochastic gradient-based approach

Poyiadzi et al. [22] identifies a counterfactual by following a high-density connected path from the feature vector $\mathbf{x}$. With a similar idea, we follow a connected path guided by the user's preference to identify a feasible recourse. We propose incrementally updating the candidate action with a predefined step size to solve the optimization. At each step t, a candidate intervention is generated, where any feature i is updated based on a Bernoulli trial with probability $I_i^{(t)}$ derived from user preference scores and the cost of taking a

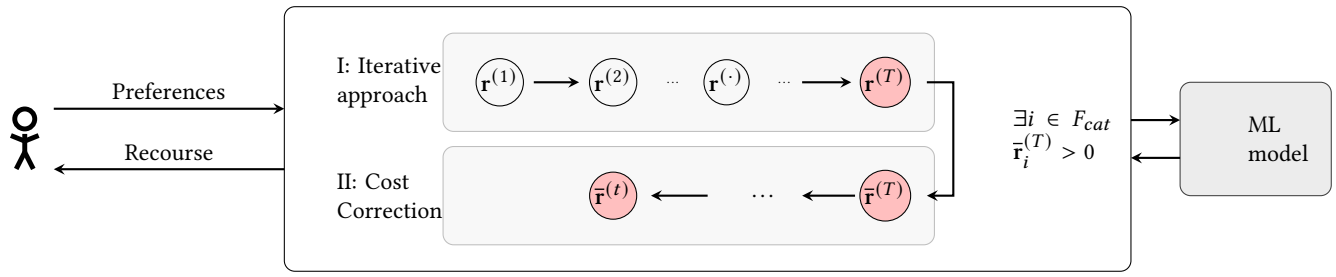

Figure 2: Framework of UP-AR. Successful recourse candidates; $\mathbf{r}^{(\cdot)}$, $\bar{\mathbf{r}}^{(\cdot)}$ are colored in pink.

predefined step $\delta_i^{(t)}$ using the following procedure:

$$I_i^{(t)} \sim Bernoulli\left(\sigma\left(z_i^{(t)}\right)\right) \tag{4}$$

$$\text{where } \sigma\left(z_i^{(t)}\right) = \frac{e^{z_i^{(t)}/\tau}}{\sum_{j\in F_A} e^{z^{(t)}/\tau}},\ z_i^{(t)} = \frac{\Gamma_i}{cost\left(\mathbf{r}_i^{(t)}, \mathbf{x}_i\right)} \tag{5}$$

With precomputed costs for each step, *weighted inverse cost* is computed for each feature, and these values are mapped to a probability distribution using a function like softmax. *Softmax* gives a probabilistic interpretation $P\left(I_i^{(t)} = 1 | z_i^{(t)}\right) = \sigma\left(z_i^{(t)}\right)$ by converting $z_i^{(t)}$ scores into probabilities.

We leverage the idea of *log percentile shift* from AR to determine the cost of action since it is easier to communicate with the users in terms of percentile shifts. Specifically, we follow the idea and formulation in [30] to define the cost:

$$cost\left(\mathbf{r}_i, \mathbf{x}_i\right) = log\left(\frac{1 - Q_i\left(\mathbf{x}_i + \mathbf{r}_i\right)}{1 - Q_i\left(\mathbf{x}_i\right)}\right) \tag{6}$$

were $Q_i\left(\mathbf{x}_i\right)$ representing the *percentile* of feature i with value $\mathbf{x}_i$ is a score below which $Q_i\left(\mathbf{x}_i\right)$ percentage of scores fall in the frequency distribution of feature values in the target population.

We adapt and extend the idea that counterfactual explanations and adversarial examples [29] have a similar goal but with contrasting intention [19]. A popular approach to generating adversarial examples [10] is by using a gradient-based method. We employ the learning of adversarial example generation to determine the direction of feature modification in UP-AR: the Jacobian matrix is used to measure the local sensitivity of outputs with respect to each input feature. Consider that $f : \mathbb{R}^D \rightarrow \mathbb{R}^K$ maps a D-dimensional feature vector to a K-dimensional vector, such that each of the partial derivatives exists. For a given $\mathbf{x} = [\mathbf{x}_1, \ldots, \mathbf{x}_i, \ldots, \mathbf{x}_D]$ and $f(\mathbf{x}) = [f_{[1]}(\mathbf{x}), \ldots, f_{[j]}(\mathbf{x}), \ldots, f_{[K]}(\mathbf{x})]$, the Jacobian matrix of f is defined to be a $D \times K$ matrix denoted by $\mathbf{J}$, where each (j, i) entry is $\mathbf{J}_{j,i} = \frac{\partial f_{[j]}(\mathbf{x})}{\partial \mathbf{x}_i}$. For a neural network (NN) with at least one hidden layer, $\mathbf{J}_{j,i}$ is obtained using the chain rule during backpropagation. For an NN with one hidden layer represented by *weights* $\{w\}$, we have:

$$\mathbf{J}_{j,i} = \frac{\partial f_{[j]}(\mathbf{x})}{\partial \mathbf{x}_i} = \sum_l \frac{\partial f_{[l]}(\mathbf{x})}{\partial a_l} \frac{\partial a_l}{\partial \mathbf{x}_i} \text{ where } a_l = \sum_i w_{li}\mathbf{x}_i \tag{7}$$

Where in Equation 7, a_l is the output (with possible activation) of the hidden layer and w_l is the weight of the node l. Notice line 4 in Algorithm 1 which *updates the candidate* action for a feature i at step t as:

$$\mathbf{r}_i^{(t)} = \mathbf{r}_i^{(t-1)} + Sign\left(\mathbf{J}_{+1,i}^{(t)}\right) \cdot I_i^{(t)} \cdot \delta_i^{(t)} \tag{8}$$

Following the traditional notation of a binary classification problem and with a bit of abuse of notation $-1 \rightarrow 1, +1 \rightarrow +1$, $Sign\left(\mathbf{J}_{+1,i}^{(t)}\right)$ captures the direction of the feature change at step t. This direction is iteratively calculated, and additional constraints such as non-increasing or non-decreasing features can be placed at this stage.

Algorithm 1 User Preferred Actionable Recourse (UP-AR)

Input: Model f, user feature vector $\mathbf{x}$, cost function $cost(\cdot, \cdot)$, step size $\Delta_i : \forall i \in F_A$, maximum steps T, action $\mathbf{r}$ initialized to $\mathbf{r}^{(0)}$, fixed τ, $t = 1$.

1: **while** $t \leq T$ or $f\left(\mathbf{x} + \mathbf{r}^{(t)}\right) \neq +1$ **do**
2: $\quad z_i^{(t)} = \frac{\Gamma_i}{cost\left(\mathbf{r}_i^{(t)}, \mathbf{x}_i\right)} : \forall i$
3: $\quad I_i^{(t)} \sim Bern(\sigma(z_i^{(t)})) : \forall i$, where $\sigma(z_i^{(t)}) = \frac{e^{z_i^{(t)}/\tau}}{\sum_{j\in F_A} e^{z^{(t)}/\tau}}$
4: $\quad \mathbf{r}_i^{(t)} = \mathbf{r}_i^{(t-1)} + Sign\left(\mathbf{J}_{+1,i}^{(t)}\right) \cdot I_i^{(t)} \cdot \delta_i^{(t)} : \forall i \in F_A$
5: $\quad t = t + 1$
6: Let $\hat{t}$ be the smallest step such that $f(\mathbf{x} + \mathbf{r}^{(\hat{t})}) = +1$ and initialize $t = \hat{t}$
7: **if** $\exists i \in F_{cat} : \mathbf{r}_i^{(t)} > 0$ **then**
8: $\quad$ **while** $f\left(\mathbf{x} + \bar{\mathbf{r}}^{(t)}\right) = +1$ **do**
9: $\quad\quad \bar{\mathbf{r}}^{(t)} = \mathbf{r}^{(t)}$
10: $\quad\quad \bar{\mathbf{r}}_i^{(t)} = \mathbf{r}_i^{(\hat{t})} : \forall i \in F_{cat}$
11: $\quad\quad t = t - 1$
12: **return** $\bar{\mathbf{r}}^{(t)}$ as action $\mathbf{r}$

3.1.1 Calibrating frequency of categorical actions. We employ *temperature scaling* [11] parameter τ observed in Equation 5 to calibrate UP-AR's recourse generation cost. Updates on categorical features with fixed step sizes are expensive, especially for binary categorical values. Hence, tuning the frequency of categorical suggestions can significantly impact the overall cost of a recourse. τ controls the frequency with which categorical actions are suggested. Additionally, if a user prefers updates on categorical features over continuous features, UP-AR has the flexibility to address this with a smaller τ.

To study the effect of τ on overall cost, we train a Logistic Regression (LR) model on a processed version of *German* [4] dataset and

generate recourses for the 155 individuals who were denied credit. The cost gradually decreases with decreasing τ since the marginal probability of suggesting a categorical feature change is diminished and the corresponding experiment is deferred to the Appendix. Hence, without affecting the success rate of recourse generation, the overall cost of generating recourses can be brought down by decreasing τ. In simple terms, with a higher τ, UP-AR frequently suggests recourses with expensive categorical actions. We note that τ can also be informed by a user upon seeing an initial recourse. After the strategic generation of an intervention, we implement a cost correction to improve upon the potential redundancy of actions in a recourse option.

3.2 Stage 2: Redundancy & Cost Correction (CC)

In our experiments, we observe that once an expensive action is recommended for a categorical feature, some of the previous action steps might become redundant. Consider an LR model trained on the processed *german* dataset. Let $F_A = \{$*LoanDuration*, *LoanAmount*, *HasGuarantor*$\}$ out of all the 26 features, where *HasGuarantor* is a binary feature which represents the user's ability to get a guarantor for the loan. Stage 1 takes several steps over *LoanAmount* and *LoanDuration* before recommending to update *HasGuarantor*. These steps are based on the feature action probability from Equation 5. Since categorical feature updates are expensive and occur with relatively low probability, Stage 1 finds a low-cost recourse by suggesting low-cost steps more frequently in comparison with high-cost steps.

Table 2: Redundancy corrected recourse for a hypothetical individual.

Features to change	Current values	Stage 1 values	Stage 2 values
LoanDuration	18	8	12
LoanAmount	$1940	$1040	$1540
HasGuarantor	0	1	1

Once an update to a categorical feature is recommended, some of the previous low-cost steps may be redundant, which can be rectified by tracing back previous continuous steps. Consider a scenario such that $\exists i \in F_{cat} : \mathbf{r}_i^{(T)} > 0$ for a recourse obtained after T steps in Stage 1. The CC procedure updates all the intermediary recourse candidates to reflect the categorical changes i.e., $\forall i \in F_{cat} : \mathbf{r}_i^{(T)} > 0$, we update $\mathbf{r}_i^{(t)} = \mathbf{r}_i^{(T)} : \forall t \in \{1, 2, \ldots, T-1\}$ to obtain $\bar{\mathbf{r}}^{(t)}$. We then perform a linear retracing procedure to return $\bar{\mathbf{r}}^{(t)}$ such that $f\left(\mathbf{x} + \bar{\mathbf{r}}^{(t)}\right) = +1$ for the smallest t.

4 DISCUSSION AND ANALYSIS

In this section, we analyze the user preference performance of UP-AR. For simplicity, a user understands cost in terms of log percentile shift from her initial feature vector described in Section 3. Let $\hat{\Gamma}_i$ be the observed fractional cost for feature i formally defined in Equation 11. Any cost function can be plugged into UP-AR with no restrictions. A user prefers to have Γ_i fraction of the total desired percentile shift from feature i. Consider $F_A = \{$*LoanDuration*, *LoanAmount*$\}$ and let the corresponding user scores provided by all the adversely affected individuals be: $\Gamma = \{0.8, 0.2\}$. Here, "Denied loan applicants prefers reducing *LoanDuration* to *LoanAmount* by 8 : 2." Figure 3 shows the frequency plot of feature cost ratio for feature *LoanDuration* out of total incurred cost from *LoanDuration* and *LoanAmount*. i.e., $y-$axis represents $\hat{\Gamma}_i$. Also, Figure 4 further shows the fractional cost of feature *DebtRatio* for recourses obtained for a NN based model trained on *Give Me Some Credit (GMSC)* dataset. These experiments signify the adaptability of UP-AR to user preferences and provides evidence that distribution of $\hat{\Gamma}_i$ is centered around Γ_i.

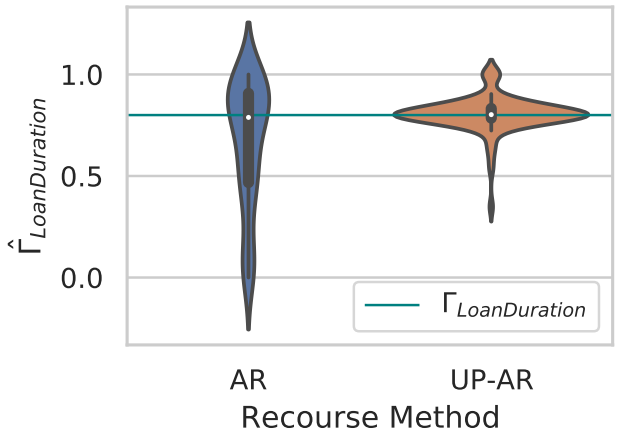

Figure 3: AR and UP-AR's distribution of $\hat{\Gamma}_{LoanDuration}$ for a *Logistic Regression* model trained on *German*.

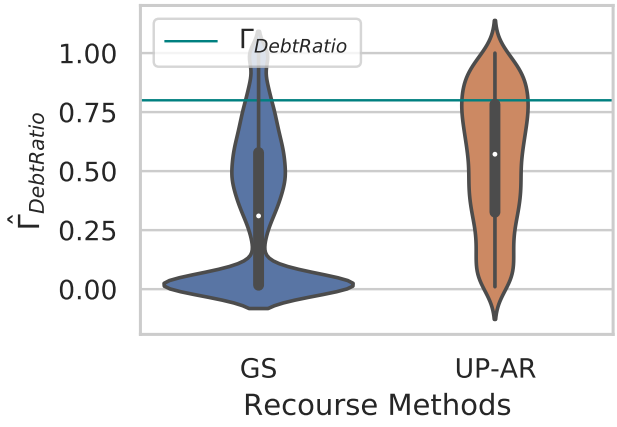

Figure 4: GS and UP-AR's distribution of $\hat{\Gamma}_{DebtRatio}$ for a *Neural Network* model trained on *GMSC*.

Lemma 4.1. *Consider UP-AR identified recourse* $\mathbf{r}$ *for an individual* $\mathbf{x}$. *If* $C_{i,min}^{(T^*)}$ *and* $C_{i,max}^{(T^*)}$ *represent the minimum and maximum cost*

of any step for feature i until T^*, then:

$$\mathbb{E}\left[cost\left(\mathbf{r}_i, \mathbf{x}_i\right)\right] \leq T^* \sigma\left(\frac{\Gamma_i}{C_{i,min}^{(T^*)}}\right) C_{i,max}^{(T^*)}. \tag{9}$$

Lemma 4.1 implies that the expected cost $\mathbb{E}\left[cost\left(\mathbf{r}_i, \mathbf{x}_i\right)\right]$, specifically for a continuous feature action is positively correlated to the probabilistic interpretation of user preference scores. Hence $\mathbf{r}$ satisfies users critical Type I constraints in expectation. Recall that Type II and III constraints are also applied at each step t. Lemma 4.1 signifies that UP-AR adheres to user preferences and thereby increases the actionability of a suggested recourse.

Corollary 4.2. *For UP-AR with a linear $\sigma(\cdot)$, predefined steps with equal costs and $cost\left(\mathbf{r}, \mathbf{x}\right) = \sum_{i \in F_A} cost\left(\mathbf{r}_i, \mathbf{x}_i\right)$, total expected cost after T^* steps is:*

$$\mathbb{E}\left[cost\left(\mathbf{r}, \mathbf{x}\right)\right] \leq T^* \sum_{i \in F_A} \sigma\left(\Gamma_i\right). \tag{10}$$

Corollary 4.2 states that with strategic selection of $\sigma(\cdot)$, $\delta^{(\cdot)}$ and $cost\left(\cdot, \cdot\right)$, UP-AR can also tune the total cost of suggested actions. In the next section, we will compare multiple recourses based on individual user preferences for a randomly selected adversely affected individual.

4.1 Case study of individuals with similar features but disparate preferences

Given an LR model trained on *german* dataset and Alice, Bob and Chris be three adversely affected individuals. $F_A = \{$*LoanDuration*, *LoanAmount*, *HasGuarantor*$\}$ and corresponding user preferences are provided by the users. In Table 3, we consolidate the corresponding recourses generated for the specified disparate sets of preferences.

From Table 3 we emphasize the ability of UP-AR to generate a variety of user-preferred recourses based on their preferences, whereas AR always provides the same low-cost recourse for all the individuals. The customizability of feature actions for individual users can be found in the table. When the Type I score for *LoanAmount* is 0.8, UP-AR prefers decreasing loan amount to loan duration. Hence, the loan amount is much lesser for Chris than for Alice and Bob.

5 EMPIRICAL EVALUATION

In this section, we demonstrate empirically: 1) that UP-AR respects Γ_i-fractional user preferences at the population level, and 2) that UP-AR also performs favorably on traditional evaluate metrics drawn from CARLA [20]. We used the native CARLA catalog for the `Give Me Some Credit (GMSC)` [12], `Adult Income (Adult)` [9] and `Correctional Offender Management Profiling for Alternative Sanctions (COMPAS)` [2] data sets as well as pre-trained models (both the **Neural Network** (NN) and **Logistic Regression** (LR)). NN has three hidden layers of size [18, 9, 3], and the LR is a single input layer leading to a Softmax function. Although AR is proposed for *linear models*, it can be extended to *nonlinear models* by the local linear decision boundary approximation method LIME [24] (referred as AR-LIME).

PERFORMANCE METRICS:. For UP-AR, we evaluate:

(1) *Success Rate (Succ. Rate)*: The percentage of adversely affected individuals for whom recourse was found.
(2) *Average Time Taken (Avg.Tim.)*: The average time (in seconds) to generate recourse for a single individual.
(3) *Constraint Violations (Con. Vio.)*: The average number of non-actionable features modified.
(4) *Redundancy (Red.)*: A metric that tracks superfluous feature changes. For each successful recourse calculated on a univariate basis, features are flipped to their original value. The redundancy for recourse is the number of flips that do not change the model's classification decision.
(5) *Proximity (Pro.)*: The normalized l_2 distance of recourse to its original point.
(6) *Sparsity (Spa.)*: The average number of features modified.

We provide comparative results for UP-AR against state-of-the-art counterfactual/recourse generation techniques such as GS, Wachter, AR(-LIME), CCHAVE and FACE. These methods were selected based on their popularity and their representation of both independence and dependence based methods, as defined in CARLA. In addition to the traditional performance metrics, we also measure *Preference-Root mean squared error (pRMSE)* between the user preference score and the fractional cost of the suggested recourses. We calculate $pRMSE_i$ for a randomly selected continuous valued feature i using:

$$pRMSE_i = \sqrt{\frac{1}{n}\sum_{j=1}^{n}\left(\hat{\Gamma}_i^{(j)} - \Gamma_i^{(j)}\right)^2} \tag{11}$$

$$\text{where } \hat{\Gamma}_i^{(j)} = \frac{cost\left(\mathbf{r}_i, \mathbf{x}_i\right)}{\sum_{k \in F_{con}} cost\left(\mathbf{r}_k, \mathbf{x}_k\right)} \tag{12}$$

Here $\Gamma_i^{(j)}$ and $\hat{\Gamma}_i^{(j)}$ are user provided and observed preference scores of feature i for an individual j. In Table 4, we summarize *pRMSE*, which is the average error across continuous features such that:

$$pRMSE = \frac{1}{|F_{con}|}\sum_{i \in F_{con}} pRMSE_i. \tag{13}$$

DATASETS:. We train an LR model on the processed version of `german` [4] credit dataset from *sklearn's linear_model* module. We replicate Ustun et al. [30]'s model training and recourse generation on `german`. The dataset contains 1000 data points with 26 features for a loan application. The model decides if an applicant's credit request should be approved or not. Consider $F_{con} = \{$*LoanDuration*, *LoanAmount*$\}$, and $F_{cat} = \{$*CriticalAccountOrLoansElsewhere*, *HasGuarantor*, *HasCoapplicant*$\}$. Let the user scores for F_{con} be $\Gamma = \{0.8, 0.2\}$ and ranking for F_{cat} be $\{3, 1, 2\}$ for all the denied individuals. For this experiment, we set $\tau^{-1} = 4$. Out of 155 individuals with denied credit, AR and UP-AR provided recourses to 135 individuals.

Cost Correction: Out of all the denied individuals for whom categorical actions were suggested, an average of $\sim$ \$400 in *LoanAmount* was recovered by cost correction.

For the following datasets, for traditional metrics, user preferences were set to be uniform for all actionable features to not bias the results to one feature preference over another:

(1) **GMSC:** The data set from the 2011 Kaggle competition is a credit underwriting dataset with 11 features where the

target is the presence of delinquency. Here, we measure what feature changes would lower the likelihood of delinquency. We again used the default protected features (*age* and *number of dependents*). The baseline accuracy for the NN model is 81%, while the baseline accuracy for the LR is 76%.

(2) **Adult Income:** This dataset originates from 1994 census database with 14 attributes. The model decides whether an individual's income is higher than 50,000 USD/year. The baseline accuracy for the NN model is 85%, while the baseline accuracy for the LR is 83%. Our experiment is conducted on a sample of 1000 data points.

(3) **COMPAS:** The data set consists of 7 features describing offenders and a target representing predictions. Here, we measure what feature changes would change an automated recidivism prediction.

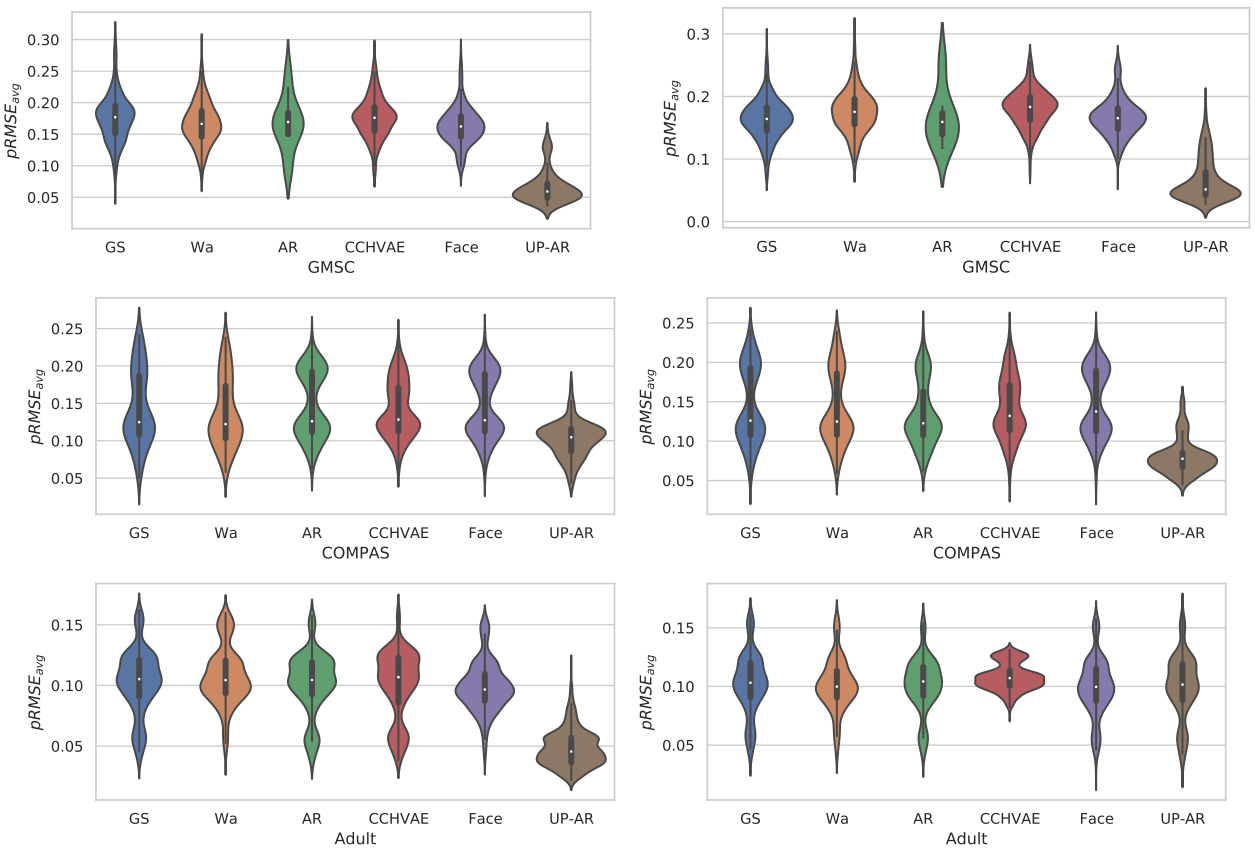
The baseline accuracy for NN is 78%, while baseline accuracy for LR is 71%.

PERFORMANCE ANALYSIS OF UP-AR:. We find UP-AR holistically performs favorably to its counterparts. Critically, it respects feature constraints (which we believe is fundamental to actionable recourse) while maintaining a significantly low redundancy and sparsity. This indicates that it tends to change fewer necessary features. Its speed makes it tractable for real-world use, while its proximity values show that it recovers relatively low-cost recourse. These results highlight the promise of UP-AR as a performative, low-cost option for calculating recourse when user preferences are paramount. UP-AR shows consistent improvements over all the performance metrics. The occasional lower success rate for a NN model is attributed to 0 constraint violations.

*pRMSE***:** We analyze user preference performance in terms of *pRMSE*. From Table 4, we observe that UP-AR's *pRMSE* is consistently better than the state of art recourse methods. The corresponding experimental details and visual representation of the distribution of *pRMSE* is deferred to Appendix 5.1.

5.1 Random user preference study

We performed an experiment with increasing step sizes on *German* dataset. We observed that, with increasing step sizes, $pRMSE_i$ increased from 0.09 to 0.13, whereas it was consistent for AR.



(a) Logistic Regression model **(b) Neural Network model**

Figure 5: Distribution of the average *pRMSE* of UP-AR and other recourse methodologies.

In the next experiment, we randomly choose user preference for *LoanDuration* from $[0.4, 0.5, 0.6, 0.7, 0.8]$. The rest of the experimental setup is identical to the setup discussed in Section 4. In this experiment, we observe *pRMSE* with non-universal user preference for adversely affected individuals. Here the average *pRMSE* of both *LoanDuration* and *LoadAmount* for UP-AR is 0.19, whereas for AR it is 0.34.

Further, using the CARLA package, we generated recourses for a set of 1000 individuals and Γ for two continuous features was randomly selected from $[0.3, 0.6, 0.9]$. Figure 5 provides a visual analysis of the distribution of average *pRMSE* using violin plots. The experiments were performed on the 3 datasets discussed in Section 5 for both the LR and NN models. For *GMSC* dataset, F_{con} = {*DebtRatio, MonthlyIncome*} and F_A = {*RevolvingUtilizationOf UnsecuredLines, NumberOfTime30-59DaysPastDueNotWorse, DebtRatio, MonthlyIncome, NumberOfOpenCreditLinesAndLoans, NumberOfTimes90DaysLate, NumberRealEstateLoansOrLines, NumberOfTime60-89DaysPastDueNotWorse*}. For *COMPAS* dataset, F_{con} = {*priors-count, length-of-stay*} and F_A = {*two-year-recid, priors-count' length-of-stay*}. For *Adult* dataset, F_{con} = {*education-num, capital-gain*} and F_A = {*education-num, capital-gain, capital-loss, hours-per-week, workclass-Non-Private, workclass-Private, marital-status-Married, marital-status-Non-Married, occupation-Managerial-Specialist, occupation-Other*}.

With these experiments we conclude that UP-AR's $\hat{\Gamma}$ deviation from the user's Γ is consistently lower than the existing recourse generation methodologies. We observe that AR is unaffected by the varying user preference due to the fact that AR and other state-of-the-art recourse methodologies lack the capability of capturing such idiosyncrasies. On the other hand, UP-AR is driven by those preferences and has significantly better *pRMSE* in comparison to AR.

5.2 Cost Correction analysis

In Table 5 we explore the effect of UP-AR's cost correction procedure on the Adult and COMPAS datasets. We do not include the GMSC dataset as it does not include binary features, and therefore does not utilize the cost correction procedure. In Table 5 we show the number of factuals, the percentage of factuals for which recourse was found, the percentage of recourse found which contained at least one binary action, the percent of recourse found which underwent cost correction, the average percentage of steps saved by the cost correction procedure, and the average percent of cost savings, measured as the percent reduction in continuous cost

Table 5: The Frequency and Effect of Cost Correction

Metrics	Adult	COMPAS
Number of Factuals	1000	568
Success Rate	79.3%	99.6%
Percent of Recourse with a Binary Action	71.9%	82.6%
Percent of Recourse with Cost Correction	38.4%	25.5%
Average Percentage of Steps Saved	67.9%	63.5%
Average Percentage of Continuous Cost Saved	83.1%	76.0%

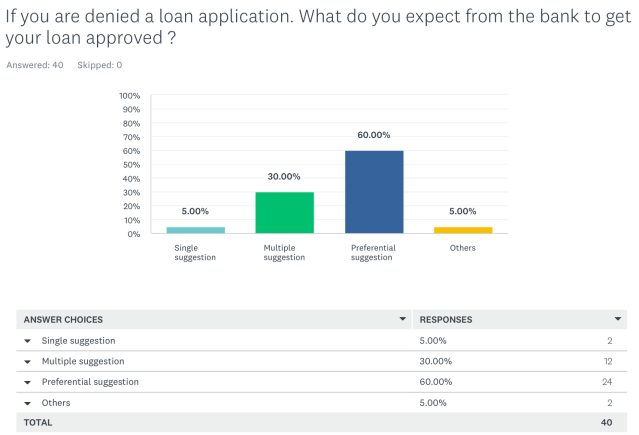


Figure 6: Snapshot of the human acceptance survey.

(l_2 distance) between a factual and its recourse before and after the cost-correction procedure.

6 CONCLUDING REMARKS

In this study, we propose to capture different forms of user preferences and propose an optimization function to generate actionable recourse adhering to such constraints. We further provide an approach to generate a connected [15] recourse guided by the user. We show how UP-AR adheres to soft constraints by evaluating user satisfaction in fractional cost ratio. We emphasize the need to capture various user preferences and communicate with the user in comprehensible form. This work motivates further research on how truthful reporting of preferences can help improve overall user satisfaction.

7 USER ACCEPTANCE SURVEY

We surveyed 40 random students and employees from a mailing list. The goal of this survey is to establish whether people preferred to provide specific preferences over other mechanism. The survey included one question with four options as follows:

If you are denied a loan application. What do you expect from bank to get your loan approved ?

(1) *Single list of suggestions to your profile. Ex: (increase income by 100$ & reduce loan duration by 1 year)*
(2) *A set with multiple lists of suggestions to your profile. Ex: (i) increase income by 100$ and reduce loan duration by 1 year OR ii) increase income by 500$ OR iii) reduce loan duration by 3 year OR iv) bring a co-applicant)*
(3) *Influence bank's suggestions by providing preferential scores for actions you can take. Ex: (preferring to increase loan duration more than loan amount by 8:2, or preferring to bring a guarantor before a co-applicant)*
(4) *Any other form of preferences*

Every individual in the survey was asked to select one of the four choices provided. In this survey, it is identified that majority of 60% of individuals preferred influencing the bank's decision by providing preference scores for individual features, followed by 30% of individuals who wanted multiple recourses from the bank. The remaining 10% of individuals preferred a single recourse or any other form of preference.

ABSTRACT

Supervised learning systems are trained using historical data and, if the data was tainted by discrimination, they may unintentionally learn to discriminate against protected groups. We propose that fair learning methods, despite training on potentially discriminatory datasets, shall perform well on fair test datasets. Such dataset shifts crystallize application scenarios for specific fair learning methods. For instance, the removal of direct discrimination can be represented as a particular dataset shift problem. For this scenario, we propose a learning method that provably minimizes model error on fair datasets, while blindly training on datasets poisoned with direct additive discrimination. The method is compatible with existing legal systems and provides a solution to the widely discussed issue of protected groups' intersectionality by striking a balance between the protected groups. Technically, the method applies probabilistic interventions, has causal and counterfactual formulations, and is computationally lightweight — it can be used with any supervised learning model to prevent direct and indirect discrimination via proxies while maximizing model accuracy for business necessity.

1 INTRODUCTION

With the growth of algorithmic decision-making systems in highly consequential domains such as finance and criminal justice, lawmakers have refocused their broader equity agendas to now include assurances that such algorithms do not discriminate [11]. That is, algorithmic decision-making systems should not treat someone unfavorably because of their membership to a particular group, characterized by a *protected attribute* such as race or gender. Therefore, new guidelines and orders that aim to prevent algorithmic discrimination have been increasingly proposed in recent years, e.g., the U.S. blueprint for an "A.I. Bill of Rights" in 2022 [6]. These proposals are typically based on legal [51, 52] and social science [1, 32, 53] contexts, where the key basis for identifying algorithmic discrimination is whether there is a disparate treatment or unjustified disparate impact on the members of some protected group. To prevent disparate treatment, the law often forbids the use of certain protected attributes, Z, such as race or gender, in decision-making, e.g., in hiring [52]. Thus, these decisions, Y, should be based on a set of relevant attributes, $\boldsymbol{X}$, and should not depend on the protected attribute, Z, i.e., $P(y|\boldsymbol{x}, z) = P(y|\boldsymbol{x}, z')$ for any z, z', ensuring that there is no *disparate treatment*.[1] We refer to this kind of discrimination as *direct discrimination* (or lack thereof), because of the direct use of the protected attribute Z.

Despite the introduction of laws prohibiting direct discrimination in the 20th century, such protections were sometimes circumvented by the use of attributes correlated with the protected attribute as proxies. One example of this is the practice of "redlining" done by U.S. financial institutions. That is, these institutions systematically denied loans and services to customers residing in neighborhoods with populations largely comprised of racial and ethnic minorities [24, 64]. In order to prevent such *inducement of discrimination* via proxy attributes, legal systems have established that the

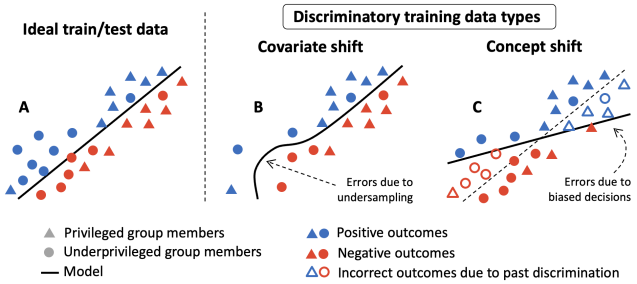

Figure 1: Training data can be tainted in two ways: individuals belonging to underprivileged groups may be undersampled and, hence, models trained on this data may make larger errors for these groups (B), some of the labels in the training data may be incorrect due to historic discrimination and, hence, models trained on this data may be biased against the underprivileged groups (C). These two dataset issues represent a covariate shift and concept shift, respectively. This paper addresses discriminatory concept shifts.

[1] Throughout the manuscript we use a shorthand notation for probability: $P(y|\boldsymbol{x}, z) \equiv P(Y = y|\boldsymbol{X} = \boldsymbol{x}, Z = z)$, where $\boldsymbol{X}, Y, Z$ are random variables, $\boldsymbol{x}, y, z$ are their instances, and P is a probability distribution or density.

probability of a positive decision should be the same among individuals belonging to different protected groups [1, 32, 51, 52], i.e., $P(y|z_1) = P(y|z_2)$. Such protections are also legally necessary for decision-making systems [43], especially since data-rich machine learning systems can often find accurate surrogates for protected attributes when a large enough set of legitimate-looking variables is available, resulting in discrimination via association [55]. However, these laws often have provisions allowing for such *disparate impact* across groups if there is a "justified reason" or "business necessity clause" [52]. For instance, in the 1970s it was found that females were less likely to be admitted than males in graduate admissions to University of California Berkeley [5]. However, females applied to departments with lower admission rates than males and the overall admissions process was judged legal. The provisions allowing for *disparate impact* conflict with the statistical notions of fairness, the fairness definitions most common in algorithmic fairness literature [34]. These notions typically call for parity of a statistical measure, e.g., impact parity: $P(y|z_1) = P(y|z_2)$ [2], which prevents the usage of attributes related to the protected-attribute. To address the challenge of handling business necessity and proxy attributes, and to develop a method that is transparent and communicable to lawmakers and courtroom officials, our prior work employed explainability measures to remove direct discrimination without the inducement of discrimination [19]. Our prior work, however, did not discuss the real-world setting of multiple protected attributes, did not specify the training dataset issues, and was not optimally accurate — we address these gaps in this study.

In legal texts, the prevention of discrimination spans across many groups defined over multiple protected attributes, e.g, race, gender, and religion [6, 51, 52]. Despite this, there rarely exists any legal mechanisms accounting for discrimination based on the intersection of the protected attributes an individual may have — a concept known as "intersectionality" which has been famously spotlighted by social experts in recent decades [9]. The need for such mechanisms can be seen in criminal justice settings such as COMPAS [31], where it is well documented that certain intersections of age, race, and sex experience more discriminatory outcomes than others, e.g, young Black males [48]. With the lack of legal support on preventing discrimination on these intersections, it is unsurprising that many fair learning methods do not operate in such settings and even fewer report results in them [56]. In this work, we address this setting. Doing so is crucial for algorithmic fairness, as prior studies have shown that learning methods can be fair with respect to protected attributes separately, such as race and sex, while being discriminatory to intersections of attributes, e.g., Black females or Black males [26].

Another crucial challenge is how to clarify application scenarios of algorithmic fairness methods. With this clarification, policymakers could utilize the information about such scenarios to shape future legislature regulating consequential algorithmic decision-making [18]. Therefore, we propose to distinguish between various data issues and tie them with the methods that address these issues. This task has received much less research attention than the fair learning methods themselves. Unfortunately, the research community that studies the data issues for supervised learning, so-called dataset shifts [36, 39, 57], is largely disconnected from the algorithmic fairness community [2]. In supervised learning, models are trained to perform well on training data and are evaluated on test data, where both are typically created by splitting a dataset into two subsets. In contrast, dataset shifts refer to data issues where there are systematic differences between train and test datasets. To our knowledge, we are the first to note that different algorithmic fairness problems can be formalized as different kinds of dataset shifts. Firstly, if one of the protected groups is underrepresented in the training set, this commonly results in larger model errors for underprivileged group (Figure 1B) [21]. This problem can be formalized as a covariate shift, i.e., $P_{\text{train}}(Z) \neq P_{\text{test}}(Z)$, and it can be solved via sample reweighing or subsampling of the majority group [49]. Secondly, if the training dataset includes examples of discriminating decisions (Figure 1C), then we posit that the model should be evaluated on a non-discriminatory test dataset (Figure 1A). Formally, this is a concept shift problem, i.e., $P_{\text{train}}(Y|\boldsymbol{X}, Z) \neq P_{\text{test}}(Y|\boldsymbol{X}, Z)$, that we address in this work.

Problem summary. Consider decisions Y that are outcomes of a process acting on non-protected variables $\boldsymbol{X}$ and protected variables $\boldsymbol{Z}$, where $\boldsymbol{x} \in \mathcal{X}$, $\boldsymbol{z} \in \mathcal{Z}$, $y \in \mathcal{Y}$, i.e., the variables can take values from any set, e.g., binary or real. Protected and non-protected features are indexed, e.g., X_i corresponds to the i'th feature (component). We are interested in training a model on available dataset D_{train} sampled from $P_{\text{train}}(\boldsymbol{X}, \boldsymbol{Z}, Y)$. This model can represent any decision-making process, e.g., assigning a credit score for a customer, given their financial record $\boldsymbol{x}$ and their ethnicity and gender $\boldsymbol{z}$. The goal of a standard supervised learning algorithm is to obtain a function $\hat{y} : \mathcal{X} \to \mathcal{Y}$ that optimizes a given objective, e.g., the expected loss, $\mathbb{E}_{D_{\text{train}}}[\ell(Y, \hat{y}(\boldsymbol{X}))]$, where the expectation is over the samples in D_{train} and ℓ is a loss function, e.g., quadratic loss, $\ell(y, \hat{y}) = (y - \hat{y})^2$.

However, if the training dataset is tainted by discrimination, then a data science practitioner may desire, and, in principle, be obliged by law to apply an algorithm that does not perpetuate this discrimination. For clarity, we distinguish between discriminatory decisions $T \in \mathcal{Y}$ that are causally and unfairly influenced by Z (Figure 1C) and non-discriminatory $U \in \mathcal{Y}$ that are are not unfairly influenced by Z (Figure 1A). These two kinds of decisions may co-exist in the same context, e.g., a company's hiring team can include both discriminating and non-discriminating members who determine hires in parallel following nearly the same decision-making process. Unfortunately, the practitioner may have no information whether the training dataset was tainted by discrimination, $D_{\text{train}} = \tilde{D} = \{(\boldsymbol{x}^i, \boldsymbol{z}^i, t^i)\}$, where $i \in \{1, ..., n\}$ is a sample index, or was *not*, $D_{\text{train}} = D = \{(\boldsymbol{x}^i, \boldsymbol{z}^i, u^i)\}$, nor how it was tainted, so supervised algorithms that aim to prevent discrimination operate in a blind setting. The problem that we aim to address is to provide a learning algorithm that in such a blind setting yields models that are as close to non-discriminatory data as possible.

Contributions. To address this problem, independently of the given training data type, we propose that the *objective* of fair supervised learning methods is to minimize the expected *cross-loss*, $\mathbb{E}_{D_{\text{test}}}[\ell(U, \hat{y}(\boldsymbol{X}))]$, on the non-discriminatory test dataset D_{test} drawn from $P_{\text{test}}(\boldsymbol{X}, \boldsymbol{Z}, U)$, while training on a potentially discriminatory data D_{train} (§3), as in Figure 2A. Achieving that objective may sound infeasible, given lack of any assumptions about the concept shift, i.e., we are in the blind setting, but the information

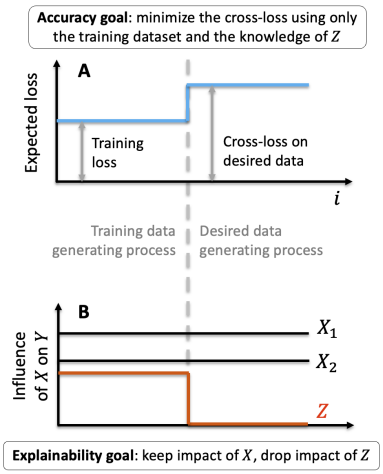

Figure 2: Illustration of the two related goals for fair algorithmic learning, grounded in dataset shifts (top) and explainability literature (bottom). This work focuses on the former, while our prior work focused on the latter.

that the attribute Z should not directly influence the model outcomes $\hat{Y}$ is the reason why this problem is solvable. We show that a learning algorithm averaging probabilistic interventions on the protected attribute optimizes cross-loss under additive directly discriminatory dataset shifts (§4). Such interventions previously were applied to compute explainability measures [10, 25], and were used in the context of discrimination prevention only recently by our work [19]. In that study, we proposed that the goal of a fair learning algorithm is to nullify the influence of the protected attribute, while preserving the influence of remaining attributes (explainability goal in Figure 2), which is achieved by *marginal interventional mixtures*. In this work, we introduce a novel "accuracy" goal of cross-loss minimization, which is achieved by *optimal interventional mixtures*, and show that the two methods are equivalent in certain conditions. We evaluate and compare the optimal interventional mixture with the state-of-the-art algorithms addressing discrimination (§5) on synthetic datasets simulating direct discrimination and proxy variables (§6), and on real-world datasets (§7), including those with multiple protected attributes, finding that the *optimal interventional mixture* leverages parity measures and accuracy, and can accurately recover the unbiased ground truth. Our method is included in the publicly released `FaX-AI` Python library (https://github.com/social-info-lab/FaX-AI).

2 RELATED WORKS

Causal notions of fairness. One can define direct and indirect discrimination as direct and indirect causal influence of Z on Y, respectively [38, 65, 66]. While this notion of direct discrimination is consistent with the concept of disparate treatment in legal systems, the corresponding indirect discrimination is not, since the business necessity clause allows the use of an attribute that depends on the protected feature (causally or otherwise) if only the attribute is judged relevant to the decisions made, e.g., as in the seminal court case of Ricci v. DeStefano [42]. This issue is addressed by *path-specific* notions of causal fairness [7, 40, 59]. However, if there is no limit on the influence that can pass through fair paths, then the path can be used for inducing discrimination, as in the aforementioned case of *redlining*. Hence, causal accounts of discrimination [7, 27, 30, 40, 50, 59, 65] do not capture induced discrimination, which is common in machine learning and is the focus of this work. To address this issue, our recent work defines induced discrimination as a change in the causal influence of non-protected features associated with the protected attributes and proposes a marginal interventional mixture to inhibit direct and induced discrimination [19]. However, that work does not discuss multiple protect attributes and it does not consider discriminatory concept shifts.

Dataset shifts. There is a growing interest in the machine learning community in dataset shifts, since they are surprisingly common in reality and often negatively impact the performance of supervised models on deployment [29, 49]. The most common dataset shift is a covariate shift, where the distribution of features or decisions changes between the training and test datasets, i.e., $P_{\text{train}}(\boldsymbol{x}, z) \neq P_{\text{train}}(\boldsymbol{x}, z)$, or $P_{\text{train}}(y) \neq P_{\text{test}}(y)$, respectively [39]. In the context of fair machine learning, outcome perturbations were first proposed as random swaps of labels in binary classification, i.e., $y \sim P(y|u)$, where y is a perturbed version of u [16]. That study, however, assumed no access to the protected attribute, so the random swaps correspond to adding i.i.d. noise in the output variable. Here, we propose to use a different type of dataset shift, known as concept shift, i.e., $P_{\text{train}}(y|\boldsymbol{x}, z) \neq P_{\text{test}}(y|\boldsymbol{x}, z)$, to simulate discriminatory perturbations of data and evaluate the resilience of learning methods to such perturbations.

3 PROBLEM FORMULATION

Before we formalize the problem of discrimination prevention based on dataset shifts, we must first define discrimination in the context of decision making. While many other studies focus on statistical notions of fairness [2, 13, 22, 47, 58, 62], our dataset shift-based notions are drawn from abstractions of legal concepts and causal influence notions.

3.1 Fairness and discrimination

Our prior work defines unfair influence and fair relationship between protected attributes $\boldsymbol{Z}$ and decisions Y by tying them to legal texts and instruments [19].

Definition 1. ***Unfair influence*** *is an influence of protected feature(s) $\boldsymbol{Z}$ on specified type of decisions Y that is judged illegal via some legal instrument, e.g., Title VII of the U.S. Civil Rights Act [52].*

Definition 2. ***Fair relationship*** *of protected feature(s) $\boldsymbol{Z}$ with non-protected feature(s) $\boldsymbol{X}$ is a relationship that is judged legal when making decisions Y, e.g., due to the U.S. business necessity clause.*

In real-world contexts, many models can generate decisions Y without directly using the protected attribute $\boldsymbol{Z}$, while using non-protected features $\boldsymbol{X}$ which may be associated with the protected attribute. Even though these features may be related to the protected attribute, they may be legally admissible for use in the decision-making if they are not *unfairly influenced* by the protected feature(s), i.e., they are relevant to the decisions and fulfil a business purpose recognized by legal agencies. For instance, in the case of Ricci v. DeStefano [42], the U.S. Supreme Court ruled that the feature in

question, a promotion exam, did not violate business necessity despite its association with race. Thus according to the court, there was a *fair relationship* between the exam and race.

With these definitions of unfair influence and fair relationship, discrimination can be defined through measures of causal influence. Formal frameworks for causal models include classic potential outcomes (PO) and structural causal models (SCM) [44]. In this notation, the potential outcome for variable Y after intervention $do(\boldsymbol{X} = \boldsymbol{x}, \boldsymbol{Z} = \boldsymbol{z})$ is written as $Y_{\boldsymbol{x},\boldsymbol{z}}$, which is the outcome we would have observed had the variables $\boldsymbol{X}$ and $\boldsymbol{Z}$ been set to the values $\boldsymbol{x}$ and $\boldsymbol{z}$ via an intervention. It is assumed that there are direct causal links from $\boldsymbol{X}$ and $\boldsymbol{Z}$ to Y, that all variables are observed, and there are no assumptions about the relations between $\boldsymbol{X}$ and $\boldsymbol{Z}$ and their components. These assumptions hold at the very least for a model $\hat{Y}$ of Y that uses $\boldsymbol{X}$ and $\boldsymbol{Z}$ as features. This foundational point enables explainability measures, e.g., various feature influence definitions [25]. Hence, in our prior work we argue that if the intentions and reasoning behind the development process of the model $\hat{Y}$ *was* legally admissible, e.g., proxies were not used as a replacement for the protected attribute, then despite the unknowingly incorrect epistemic state represented by the model, e.g., partially incorrect causal representation, legal systems may acquit model developers of discrimination [19]. Under these assumptions, the causal *controlled direct effect* (CDE) on Y of changing the value of $\boldsymbol{Z}$ from a reference value $\boldsymbol{z}$ to $\boldsymbol{z}'$ given that $\boldsymbol{X}$ is set to $\boldsymbol{x}$ [44] is

$$\mathrm{CDE}_Y(\boldsymbol{z}', \boldsymbol{z}|\boldsymbol{x}) = \mathbb{E}[Y_{\boldsymbol{x},\boldsymbol{z}'} - Y_{\boldsymbol{x},\boldsymbol{z}}]. \quad (1)$$

By tying the causal concept of controlled direct effect to the notions of *fair influence* and *unfair relationship*, we define three concepts of discrimination – direct, indirect, and induced [19].

Definition 3. ***Direct discrimination*** *is an unfair influence of protected attribute(s), $\boldsymbol{Z}$, on the decisions Y, i.e., $\exists_{z,z'}\exists_{\boldsymbol{x}} CDE_Y(\boldsymbol{z}, \boldsymbol{z}'|\boldsymbol{x}) \neq 0$.*

Definition 4. ***Indirect discrimination*** *is an influence on the decisions Y of feature(s) $\boldsymbol{X}$ whose relationship with $\boldsymbol{Z}$ is not fair, i.e., $\exists_{x,x'}\exists_{\boldsymbol{z}} CDE_Y(\boldsymbol{x}, \boldsymbol{x}'|\boldsymbol{z}) \neq 0$.*

Definition 5. ***Discrimination induced*** *via X_i is a transformation of the process generating decisions U not affected by direct and indirect discrimination into a new process generating Y that modifies the influence on the decisions of certain X_i depending on $\boldsymbol{Z}$ between the processes U and Y, i.e., $\exists_{\boldsymbol{z}}\exists_{\boldsymbol{x},\boldsymbol{x}'} CDE_U(\boldsymbol{x}, \boldsymbol{x}'|\boldsymbol{z}) \neq CDE_Y(\boldsymbol{x}, \boldsymbol{x}'|\boldsymbol{z})$ given that $P(\boldsymbol{x}|\boldsymbol{z}) \neq P(\boldsymbol{x})$ or $P(\boldsymbol{x}'|\boldsymbol{z}) \neq P(\boldsymbol{x}')$.*

To remove direct discrimination, one can construct a model $\hat{Y}$ that does not use $\boldsymbol{Z}$. However, this may induce discrimination indirectly via the attributes X_i associated with the protected attributes $\boldsymbol{Z}$, even if there is no causal link from $\boldsymbol{Z}$ to X_i. Methods inhibiting discrimination should do so without inducing discrimination.

Example 1. *Consider a hypothetical linear model of loan interest rate, Y. Using similar models, prior works suggest that interest rates differ by race, Z [3, 54]. Some loan-granting clerks may produce non-discriminatory decisions, $u = \beta_0 - x_1$, while other clerks may discriminate directly, $y_{dir} = \beta_0 - x_1 + z$, where β_0 is a fixed base interest rate, x_1 is a relative salary of a loan applicant, while z encodes race and takes some negative (positive) value for White (non-White) applicants. If the protected attribute is not available, e.g., loan applications are submitted online, then a discriminating clerk may induce discrimination in the interest rate, by using a proxy for race, $y_{ind} = \beta_0 - x_1 + x_2$, where x_2 is the proxy, e.g., an encoding of the zip code (as in the redlining) or the first name (as in the seminal work of Bertrand and Mullainathan) of the applicant.*

3.2 Discriminatory concept shifts

Distinct from our prior work, we introduce an additional goal in discrimination prevention from the perspective of dataset shifts. That is, we propose to use discriminatory perturbations dependent on the protected attribute (or all possible intersections of multiple protected attributes) to simulate a concept shift, i.e., $P_{\text{train}}(y|\boldsymbol{x}, z) \neq P_{\text{test}}(y|\boldsymbol{x}, z)$, and to evaluate the cross-loss of learning methods w.r.t. to such concept shifts [39] (accuracy goal in Figure 2). These concept shifts reflect bias in a historical data-generating process, rather than a sampling bias which typically is associated with covariate shifts.

Definition 6. ***Discriminatory concept shift*** *is a transformation of the process generating U that is not affected by direct, indirect, and induced discrimination into a new process generating Y that is affected by discrimination.*

Example 2. *We continue the prior example. The transformation from $u = \beta_0 - x_1$ to $y_{dir} = \beta_0 - x_1 + z$ via a directly discriminatory additive perturbation of z (race) is a discriminatory concept shift. This gives two datasets, $\tilde{D} = \{(x_1^i, x_2^i, z^i, y_{dir}^i)\}$ for training and $D = \{(x_1^i, x_2^i, z^i, u^i)\}$ for testing.*

We do not assume that the perfectly fair decision-making process, illustrated in Figure 1A, exists already in all real-world contexts. In stark contrast, we posit that its knowledge should not be required to prevent discrimination in supervised learning. The above constructs enable us to formalize the goal for fair learning methods on the grounds of dataset shifts and specify the idealized real-world scenarios that the methods achieving this goal address. Next, we define the cross-loss of a supervised learning algorithm to discriminatory concept shifts, which measure how well an algorithm trained on *potentially* discriminatory training dataset, i.e., $D_{\text{train}} = \tilde{D}$ or $D_{\text{train}} = D$, performs when it is evaluated on a non-discriminatory $D_{\text{test}} = D$.

Definition 7. ***Cross-loss.*** *The solution of supervised learning algorithm a, $\hat{y}_a(\boldsymbol{x}|D_{train})$, is a model obtained by training on the potentially discriminatory dataset D_{train}. The empirical cross-loss function is an expected loss of this model w.r.t. the non-discriminatory data D, $\mathbb{E}_D\left[\ell\left(U, \hat{y}_a(\boldsymbol{X}|D_{train})\right)\right]$.*

The cross-loss measures how well the model learned by an algorithm training on the discriminatory data predicts the fair data, i.e., how well it performs under a discriminatory concept shift.

Example 3. *We continue the prior example. For simplicity, assume that all variables have zero mean, no correlation between X_1 and Z, and a positive correlation $r > 0$ between X_2 and Z. Let the training dataset be $\tilde{D} = \{(x_1, x_2, z, y_{dir})\}$. If we applied standard supervised learning under the quadratic loss, then asymptotically with the number of samples we would learn the model $\hat{y}_1 = \beta_0 - x_1 + z$, which is directly discriminatory and results in high cross-loss $\mathbb{E}_D\left[\ell\left(U, \hat{y}_1(\boldsymbol{X}|\tilde{D})\right)\right] = \mathbb{E}_Z Z^2$. If we dropped the protected attribute, Z, before regressing Y_{dir} on the attributes X_1 and X_2, then*

we would learn the model $\hat{y}_2 = \beta_0 - x_1 + rx_2$, which also yields a sub-optimal cross-loss, $\mathbb{E}_D\left[\ell\left(U, \hat{y}_2(\boldsymbol{X}|\tilde{D})\right)\right] = r^2\,\mathbb{E}_{X_2}X_2^2$, that increases with r due to the growing discrimination induced via X_2.

4 OPTIMAL INTERVENTIONAL MIXTURE

Next, we introduce a supervised learning method based on probabilistic interventions that aims to prevent direct discrimination in Y without inducing any discrimination. We prove that it minimizes cross-loss, up to a constant, under the assumption of the concept shift coming from additive directly discriminatory perturbations (§4.1). In addition, if Y is impacted by *indirect discrimination*, i.e., $\boldsymbol{Z}$ unfairly influences $\boldsymbol{X}$, we can address it as *direct discrimination* in $\boldsymbol{X}$. To prevent *indirect discrimination* one can apply our method in a nested way (§4.2) that resembles the path-specific counterfactual fairness [7].

4.1 Removal of direct discrimination

The proposed method is a post-processing approach and has two optimisation steps. In the first step, we train the model $\hat{y}(\boldsymbol{x}, z)$ using all features, both protected Z and relevant $\boldsymbol{X}$, without any consideration of fairness, by minimizing the corresponding expected loss $\mathbb{E}_{D_{\text{train}}}[\ell(Y, \hat{y}(\boldsymbol{X}))]$. Most importantly, the protected attribute is available during the training, so the model does not need to use third variables as surrogates of the protected attribute and avoids inducing discrimination via $\boldsymbol{X}$ (we provide theoretical and empirical evidence for this statement in Proposition 1 and Section 6.1, respectively). In the second step, we eliminate the influence of the protected attribute. This is achieved by intervening probabilistically on the full model trained with all features and mixing the interventions on the protected attribute independent from other variables via a mixing distribution $\pi(Z')$, yielding $\hat{y}_\pi(\boldsymbol{x}) = \sum_{z'}\hat{y}(\boldsymbol{x}, z')\pi(z')$. Here, we search for the optimal mixing distribution, $\pi^*(z')$, that minimizes the expected loss, $\mathbb{E}_{D_{\text{train}}}[\ell(Y, \hat{y}_\pi(\boldsymbol{X}))]$, while all parameters of the full model $\hat{y}(\boldsymbol{x}, z)$ are fixed, i.e., $\pi^* = \arg\min_\pi \mathbb{E}_{D_{\text{train}}}[\ell(Y, \hat{y}_\pi(\boldsymbol{X}))]$. This optimization problem is convex for quadratic and negative log-likelihood loss functions. Thus, the optimal weighting distribution can be found by applying disciplined convex programming with constraints ensuring that $\pi(z')$ is a distribution, i.e., $\sum_{z'}\pi(z') = 1$ and $\pi(z') \geq 0$ for all z' [12]. Once the optimal mixing distribution is known, the *optimal interventional mixture (OIM)* can be computed, $\hat{y}^*(\boldsymbol{x}) = \sum_{z'}\hat{y}(\boldsymbol{x}, z')\pi^*(z')$, which constitutes the solution of the proposed learning algorithm.

Unlike many methods achieving statistical fairness objectives, our method is seamlessly applicable to scenarios with multiple protected attributes or numeric attributes such as age. This is accomplished by mixing the interventions on all combinations of the protected attributes in the second optimization step. Next, for discriminatory data transformations that have a simple additive form, i.e., $y = u + h(z)$, we prove that optimal interventional mixture minimizes cross-loss on non-discriminatory data and show that for ℓ^2 loss the accuracy and explainability goals of fair machine learning (Figure 2) lead to the same solution.

Proposition 1. *Let the non-discriminatory data have $u = f(\boldsymbol{x}) + v$ and the data following a discriminatory concept shift have $y = f(\boldsymbol{x}) + h(z) + v$, where f and h are some functions and v is i.i.d. noise independent from $\boldsymbol{X}$ and Z. Assume that the same ℓ^p loss, either ℓ^1 or ℓ^2, is used for model learning and the computation of cross-loss. If the estimation model is well specified w.r.t. the discriminatory data-generating process and the estimation method is consistent, then the OIM, asymptotically with the number of samples, is $\hat{y}^*(\boldsymbol{x}) = f(\boldsymbol{x}) + C_p$, and it minimizes the expected cross loss $\mathbb{E}_D\left[\ell\left(U, \hat{y}_a(\boldsymbol{X}|\tilde{D})\right)\right]$ up to the constant C_p that depends on the unknown $h(\boldsymbol{Z})$.*

Example 4. *We continue the loan interest rate example. The full model is $\hat{y}(\boldsymbol{x}, \boldsymbol{z}) = \beta_0 - x_1 + \boldsymbol{z}$. The optimal interventional mixture is $\hat{y}^* = \beta_0 - x_1 + \beta_\pi$, where the intercept β_π is the result of mixing over the optimal $\pi^*(\boldsymbol{z}')$. In this case, $\beta_\pi = \mathbb{E}_Z\, Z = 0$ due to the optimization. Thus, the algorithm recovers the non-discriminatory ground truth.*

The proof follows from the definition of consistent estimator (full proof in Appendix A). For a particular dataset that does not meet the condition $C_p = 0$, one can propose a better model than the OIM by subtracting C_p from model's intercept, which is a sum of C_p and a component of $f(x)$, but C_p depends on the unknown $h(Z)$ and, without knowing $h(Z)$, we do not know what to subtract, so there is no learning strategy that improves the cross-loss. Furthermore, the case of nonzero C_p is practically irrelevant, because it represents a data perturbation that affects all individuals in the same way, e.g., it introduces across the board more positive outcomes y without changing their dependence on $\boldsymbol{x}$, i.e., $\mathbb{E}[Y|\boldsymbol{x}] = \mathbb{E}[U|\boldsymbol{x}] + C_p$. The above proposition is valid for well-specified models. Next, we prove analogue result for universal approximators such as deep learning models.

Corollary 1. *Let the same assumptions hold as in Proposition 1, but now the estimation model is a universal approximator. Then the OIM is an arbitrarily close approximation of $f(\boldsymbol{x}) + C_p$, which according to Proposition 1 minimizes the expected loss $\mathbb{E}_D\left[\ell\left(U, \hat{y}_a(\boldsymbol{X}|\tilde{D})\right)\right]$ up to C_p.*

The proof follows from universal approximator theorems and Proposition 1 (see Appendix A). These guarantees do not universally hold for our prior work, which is the only work that proposes a similar interventional mixtures for inhibiting discrimination [19]. Rather than finding an optimal mixture, we previously proposed to utilize the marginal distribution of the protected attribute to build a marginal interventional mixture (MIM), i.e., $\hat{y}_{\text{MIM}}(\boldsymbol{x}) = \mathbb{E}_Z[\hat{y}(\boldsymbol{x}, Z)]$.

Proposition 2. *Let the same assumptions hold as in Proposition 1. Then the marginal interventional mixture (MIM), asymptotically with the number of samples, is $\hat{y}_{MIM}(\boldsymbol{x}) = \mathbb{E}_Z[\hat{y}(\boldsymbol{x}, Z)] = f(\boldsymbol{x}) + \mathbb{E}[h(Z) + v]$, and minimizes the expected cross loss $\mathbb{E}_D\left[\ell\left(U, \hat{y}_a(\boldsymbol{X}|\tilde{D})\right)\right]$ for ℓ^2 loss up to the constant $\mathbb{E}[h(\boldsymbol{Z}) + v]$.*

4.2 Removal of indirect discrimination via optimal counterfactual mixture

In real-world scenarios, a non-protected feature, X_i, can be unfairly influenced by $\boldsymbol{Z}$. If decisions Y were influenced by such X_i, then Y would be indirectly discriminatory. To prevent this, one can apply a nested multi-stage version of OIM. More precisely, say that we have X_1, X_2, and $\boldsymbol{Z}$, where X_1 is unfairly influenced by $\boldsymbol{Z}$, and all are used

to make decisions Y. We first create a model $\hat{Y}$ using X_1, X_2, and $\boldsymbol{Z}$. Then, we create a model $\hat{X}_1$, using X_2 and $\boldsymbol{Z}$ and other relevant features that we have access to, and apply the OIM to create a "fair" model $\hat{X}_1^*$. Lastly, to create $\hat{Y}^*$, we replace X_1 with $\hat{X}_1^*$ in the model $\hat{Y}$, and apply the OIM. This is a reasonable solution, but in situations where we know the value of a variable for which we apply OIM, such as X_1 here, we can do better through counterfactual analysis.

4.2.1 Counterfactual mixtures. Causality literature posits a causal hierarchy and distinguishes between interventional and counterfactual estimates [45]. The latter differ from former in that they assume that everything stays the same, including any exogenous noise values, when estimating the effect of an intervention. In contrast, the interventional mixture calculates the value of $\hat{X}_1$ had the causal influence of $\boldsymbol{Z}$ been removed from it given the values of all *observed* variables, but not the values of exogenous noise. Each variable can contain *exogenous* noise, i.e., unobserved intrinsic noise not associated with any other variable. In the situations where we know the value of the variable for which we want to develop a fair model, we can use that value to infer that variable's exogenous noise. For such situations, we propose an *optimal counterfactual mixture* (OCM), which merges the three canonical counterfactual reasoning steps with the OIM step: (*abduction*) infer exogenous noise for a variable, (*intervention*) apply the OIM to remove the influence of the protected attribute on that variable, and (*counterfactual prediction*) estimate the counterfactual value of the variable given the exogenous noise and intervention.

4.2.2 Counterfactual mixtures comparison. We compare the interventional (OIM) and counterfactual (OCM) versions of our method as well as the related path-specific counterfactual fairness (PSCF) using a multi-stage linear model introduced in the PSCF paper [7]:

$$M = \theta^m + \theta_z^m Z + \theta_c^m C + \epsilon_m, \tag{2}$$

$$L = \theta^l + \theta_z^l Z + \theta_c^l C + \theta_m^l M + \epsilon_l, \tag{3}$$

$$Y = \theta^y + \theta_z^y Z + \theta_c^y C + \theta_m^y M + \theta_l^y L + \epsilon_y, \tag{4}$$

where C, M, L are components of $\boldsymbol{X}$, $\boldsymbol{Z}$ is the protected attribute, and ϵ_c, ϵ_m, ϵ_l are exogenous noise variables. The causal influence of Z on decisions Y and the mediator M is assumed unfair and all other influences are fair. In other words, Y is affected by direct discrimination via Z *and* indirect discrimination via M. This means that our method needs to be applied first to M and then to Y.

For simplicity, without loss of generality, let us consider a scenario where we have enough samples to have perfect estimates of a well-specified model's parameters, so that the estimated model is $\hat{m} = \theta^m + \theta_z^m z + \theta_c^m c$. In this scenario, the *abduction* step corresponds to computing $\epsilon_m = m - \hat{m}$; the *intervention* step to applying OIM to $\hat{m}$, yielding $\hat{m}^* = \theta^m + \theta_z^m z^* + \theta_c^m c$; and the *counterfactual prediction* to injecting the abducted noise into the estimated model, $\hat{m}^c = \theta^m + \theta_z^m z^* + \theta_c^m c + \epsilon_m$. Overall, we refer to these three steps as the single-stage OCM. Same as the PSCF, the multi-stage OCM corrects the decision through a correction on all the variables that are influenced by the protected attribute along unfair pathways. Thus, we first apply the OCM to get a non-discriminatory counterfactual $\hat{m}^c$, then we propagate $\hat{m}^c$ to its descendants and apply the OCM to yield a fair counterfactual $\hat{l}^c$, and finally we propagate the two counterfactuals to $\hat{y}$ and apply the OIM (not OCM, since we do not observe Y) to get $\hat{y}^c$:

$$\hat{m}^c = \theta^m + \theta_z^m z^* + \theta_c^m c + \epsilon_m = m - \theta_z^m (z - z^*), \tag{5}$$

$$\hat{l}^c = \theta^l + \theta_z^l z + \theta_c^l c + \theta_m^l \hat{m}^c + \epsilon_l = l - \theta_m^l (m - \hat{m}^c), \tag{6}$$

$$\hat{y}^c = \theta^y + \theta_z^y z^* + \theta_c^y c + \theta_m^y \hat{m}^c + \theta_l^y \hat{l}^c, \tag{7}$$

where z^* is the expected value of Z resulting from the optimal mixing distribution for Z. Conversely, applying solely the OIM to obtain $\hat{m}^*$, $\hat{l}^*$, and $\hat{y}^*$ does not take advantage of estimating the noise terms ϵ_m and ϵ_l, and results in estimators

$$\hat{m}^* = \theta^m + \theta_z^m z^* + \theta_c^m c, \tag{8}$$

$$\hat{l}^* = \theta^l + \theta_z^l z + \theta_c^l c + \theta_m^l \hat{m}^*, \tag{9}$$

$$\hat{y}^* = \theta^y + \theta_z^y z^* + \theta_c^y c + \theta_m^y \hat{m}^* + \theta_l^y \hat{l}^*. \tag{10}$$

When comparing $\hat{y}^*$ and $\hat{y}^c$ we observe that difference in estimating ϵ_m unsurprisingly yields the noise terms, $\hat{y}^c = \hat{y}^* + \theta_m^y \epsilon_m + \theta_l^y \theta_m^l \epsilon_m$, which results in a larger error w.r.t. Y for the OIM than the OCM,

$$\mathbb{E}(Y - \hat{Y}^*)^2 = \mathbb{E}(Y - \hat{Y}^c)^2 + (\theta_m^y \epsilon_m + \theta_l^y \theta_m^l \epsilon_m)^2. \tag{11}$$

A comparison with the PSCF reveals that $\hat{y}^c = \hat{y}^{\text{PSCF}} + \Delta$, where $\Delta = z^*(\theta_z^y + \theta_m^y \theta_z^m + \theta_l^y \theta_m^l \theta_z^m)$. The mean squared error w.r.t. Y is larger for the PSCF than for the OCM by the square of the difference, i.e., $\mathbb{E}(Y - \hat{Y}^{\text{PSCF}})^2 = \mathbb{E}(Y - \hat{Y}^c)^2 + \Delta^2$. Overall, the OCM is more accurate than the PSCF, because the PSCF relies on a choice of reference value, z', also known as baseline, which is assumed $z' = 0$ in the PSCF paper and above example. However, this choice is arbitrary and it is not clear what the baseline should be for non-binary $\boldsymbol{Z}$. By contrast, the OCM introduces a distribution $\pi(z')$ and optimizes it for accuracy. In addition, it follows from Proposition 1 and Corollary 1, that the OIM and by extension the OCM, are the most accurate interventional and counterfactual models on the non-discriminatory test datasets (up to the unlearnable constant C_p).

5 EVALUATION METHOD AND EVALUATED METHODS

In the remaining sections, we measure the *resilience* of various learning methods to discriminatory concept shifts that have more complex functional forms than the additive shifts described in the previous section. We begin by introducing the notion of resilience and the evaluated learning methods addressing discrimination.

5.1 Resilience

Note that the range of cross-loss values depends on the dataset and loss function. To make comparisons across datasets, we introduce the measure of resilience by normalizing the inverse of cross-loss, so that the resilience is a number between 0 and 1. For a specific pair of datasets D_{train} and D, the larger the cross-loss, the lower the resilience of the learning algorithm to the concept shift from training data D_{train}.

Definition 8. ***Resilience.*** *The resilience of algorithm a to a discriminatory concept shift from non-discriminatory data D to potentialy discriminatory D_{train} is a ratio of the expected loss of the standard algorithm training on D and the cross-loss of algorithm a training on D_{train}:*

$$\Omega_a = \mathop{\mathbb{E}}_{D}\left[\ell\left(U, \hat{u}(\boldsymbol{X}|D)\right)\right] / \mathop{\mathbb{E}}_{D}\left[\ell\left(U, \hat{y}_a(\boldsymbol{X}|D_{train})\right)\right], \tag{12}$$

where $\hat{u}(\boldsymbol{x}|D)$ is a model of the non-discriminatory ground truth trained on dataset D.

The enumerator of resilience takes into account that U can be intrinsically random and unpredictable.[2] The resilience is confined, $0 \leq \Omega \leq 1$. This property is ensured if both learning algorithms yielding the models $\hat{u}(\boldsymbol{x}|D)$ and $\hat{y}_a(\boldsymbol{x}|\tilde{D})$ optimise the same vanilla objective function, e.g., both optimize expected loss, where the algorithm a adds an extra component to address discrimination. An algorithm that is perfectly resilient to the discriminatory concept shift yields $\Omega = 1$, and $\Omega = 0$ otherwise.

5.2 Evaluated learning methods

A number of algorithms addressing discrimination have been developed by adding a constraint or a regularization to the objective function [13, 15, 22, 46, 47, 58, 61–63]. Most of these algorithms prevent direct discrimination, but it should come as no surprise that some of them do not prevent the induction of discrimination. For instance, the algorithms that put constraints on the aforementioned disparities in treatment and impact [15, 46, 61] induce "reverse" discrimination, by affecting the members of advantaged group and the people similar to them in a non-desirable manner when training on a non-discriminatory dataset D [33]. As an example, such "reverse" discrimination would result in less job opportunities for similarly qualified short-haired women than long-haired women, because short hair is associated with males and there is a historical correlation between hiring and gender [33]. Other studies propose interesting statistical notions of fairness, such as equalized opportunity, $P(\hat{y}|y = 1, z = 0) = P(\hat{y}|y = 1, z = 1)$, equalized odds, $P(\hat{y}|y, z = 0) = P(\hat{y}|y, z = 1)$ [13, 22, 47, 58], or parity mistreatment, $P(\hat{y} \neq y|z = 0) = P(\hat{y} \neq y|z = 1)$ [62]. However, prior works reveals the impossibility of simultaneously satisfying multiple non-discriminatory objectives, such as equalized opportunity and parity mistreatment [8, 17, 28]. There is a need to compare them.

We evaluate several of such methods in the next section. For this evaluation, we select a diverse set of algorithms that aim to prevent discrimination through different objectives: disparate impact [60, 61], disparate mistreatment [62], preferential fairness [63], equalized odds [22], a convex surrogate of equalized odds [13], game-theoretic envy-freeness [63], and a causal database repair [50]. We also evaluate a scenario where we prevent discrimination over multiple protected attributes. Here, the only fair-learning method we evaluate against is the method introduced in the fairness gerrymandering paper [26], as it considers fairness, based on the best subgroup-fair distribution over classifiers, across infinitely many subgroups. In all cases but one, we use implementations of these algorithms as provided by the authors. We re-implemented one of these methods [61] so that it works for the case of continuous Y. In Appendix B, we report these methods' parameters we select.

6 EVALUATION ON SYNTHETIC DATA

In the synthetic setting, we generate random non-discriminatory datasets D, containing samples of U, and perform a concept shift to create datasets $\tilde{D}$, containing samples of Y. Then, datasets $D_{\text{train}} = \tilde{D}$ are used for training, datasets D are used for testing, and we measure the resilience and the feature influence of various learning algorithms preventing discrimination, including the OIM. Next, we make these measurements as a function of the correlation between the protected and non-protected attributes, which often causes learning algorithms to induce discrimination via association. We also study the setting where there is no discriminatory concept shift, $D_{\text{train}} = D'$ (a dataset drawn from the same distribution as the test dataset D), but there is a feature correlated with the protected attributes that is fair to use, i.e., permitted by law. The learning algorithms operate in a blind setting, i.e., they have no information whether $D_{\text{train}} = D'$ or $D_{\text{train}} = \tilde{D}$. Other scenarios where we randomize the parameters of our data generating process or have a discriminatory concept shift under a complex non-linear functional form are available in Appendix E and H, respectively, and yield qualitatively the same results for resilience.

6.1 Resilience captures induced discrimination

Data generation. Without loss of generality, the data generating process of U can yield $\mathbb{E}[U|\boldsymbol{x}] = \sigma(f(\boldsymbol{x}))$, where f is a potentially non-linear function, and σ is a function establishing the respective support for U. For instance, for classification problems σ can be a logistic or softmax function, while for regression it can be identity. Next, we simulate discrimination as a concept shift from U that in general can be represented as $\mathbb{E}[Y|\boldsymbol{x}] = \sigma(g(\boldsymbol{x}, z))$, where g is some function. These concept shifts may or may not be discriminatory, depending on how expected outcomes were shifted: i) no discrimination, if $g(\boldsymbol{x}, z) = f(\boldsymbol{x})$, ii) direct discrimination, if $g(\boldsymbol{x}, z)$ depends on z, iii) induced discrimination, if $g(\boldsymbol{x}, z) = \tilde{f}(\boldsymbol{x}) \neq f(\boldsymbol{x}) + \text{const}$. We study simple forms of $f(\boldsymbol{x})$ and $g(\boldsymbol{x}, z)$ that are linear combinations of its arguments, i.e., $f(\boldsymbol{x}) = \boldsymbol{\alpha}^\intercal \boldsymbol{x}$ and $g(\boldsymbol{x}, z) = \tilde{\boldsymbol{\alpha}}^\intercal \boldsymbol{x} + \beta z$, and σ is the logistic function.

Results. We focus first on a data-generating process that extends the loan-interest Example to binary dependent variables, which are prevalent in real-world decision-making. Specifically, $u \sim \text{Bernoulli}[\mathbb{E}[U|\boldsymbol{x}]]$ and $y \sim \text{Bernoulli}[\mathbb{E}[Y|\boldsymbol{x}]]$, where $f(\boldsymbol{x}) = x_1$ and $g(\boldsymbol{x}, z) = x_1 + \beta z$. We model this data with logistic regression and measure how the resilience and the expected value of influence of each feature changes with the increasing correlation between X_1 and Z. We measure influence using SHAP (SHapley Additive exPlanations), a popular explainability measure [37].

We study two cases of the training dataset $\tilde{D}$: (i) without any concept shift (no discrimination, $\beta = 0$, left Figures 3 & 4) and (ii) with a discriminatory concept shift ($\beta = 5$, right Figures 3 & 4). In both cases, the resilience of most learning algorithms is sub-optimal and for several methods it drops with the correlation.

For the non-discriminatory case (i), Lipton et al. [33] demonstrates that the algorithms fighting the disparities in treatment and impact [15, 46, 61] induce "reverse" discrimination. Our measurements of resilience and input influence captures this result and extend it to methods based on equalized odds and disparate mistreatment (the orange and brown lines in the left Figure 3 and orange line in Figures 4a), including methods equalizing overall misclassification rate, false negative rate, and related measures (Appendix D). The only methods that do not bias the models in this scenario are: traditional supervised learning and the two methods

[2] If U is not intrinsically unpredictable, then $\mathbb{E}_D\left[\ell\left(U, \hat{u}(\boldsymbol{X}|D)\right)\right]$ can be zero. In such cases, a small value could be added to the enumerator and denominator of resilience, to prevent it from taking the value of zero. This scenario is uncommon in practice.

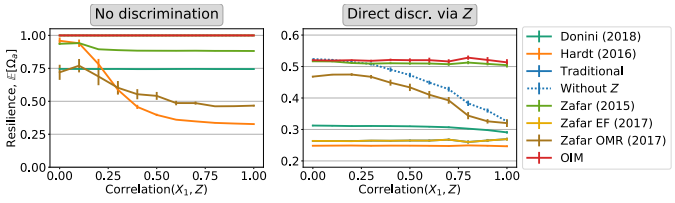

Figure 3: Average resilience to potentially discriminatory concept shifts decreases with the correlation between X_1 and Z. The coefficient that scales the discrimination in the training data is $\beta = 0$ for the case of no discrimination (left) and $\beta = 5$ for direct discrimination (right). Each point is an average over 100 random datasets. Error bars show 95% confidence intervals.

that fall back to it if there is no direct discrimination in the data, i.e., the game-theoretic method based on envy-freeness (yellow line overlaps with the red line in the left Figure 3) and the OIM.

For the discriminatory case (ii), we observe that with the growing correlation the resilience of the OIM stays high, whereas of three other algorithms decreases, suggesting that they induce discrimination via association [55], i.e., they replace the protected attribute with its proxy thus replicating "redlining", which causes a drop in resilience (e.g., the blue dotted line in the right Figure 3 & in Figure 4b). Therefore, it is not sufficient to simply drop the protected attribute in traditional learning. Some methods perform poorly irrespective of the correlations, e.g., "Hardt", because it allows direct discrimination (orange lines in Figure 3 & 4). Overall, the two cases show that many learning algorithms induce discrimination or directly discriminate, i.e., they yield biased models by changing the impact of $\boldsymbol{X}$ on $\hat{Y}$ or are directly impacted by $\boldsymbol{Z}$.

7 EVALUATION ON REAL-WORLD DATASETS

In the synthetic settings, we experimented in an idealized environment where we had full information on the discriminatory concept shift and, therefore, knew the non-discriminatory ground truth. However, with real-world scenarios it is often the case that we only have access to a potentially discriminatory dataset without any information about the concept shift or we have a concept shift under a complex non-linear function. Therefore, we analyze the OIM in two types of real-world settings. Firstly, on tabular datasets commonly found in algorithmic fairness research where we have multiple protected attributes and no information on the concept shift. Then, on the CelebA image dataset [35] where we have non-discriminatory labels and introduce a discriminatory concept shift, while working with a highly non-linear deep neural net.

7.1 Concept shift information unknown

Datasets. We focus on two datasets that are prevalent in the literature on fairness: the COMPAS dataset of recidivism risk [31] and the German Credit dataset of creditworthiness [14], and their respective binary classification tasks.

The ProPublica COMPAS dataset [31] contains the records of 7214 offenders in Broward County, Florida in 2013 and 2014. As target, y, we use the binary label describing whether an individual recommitted a crime ($y = 1$). For comparison with the original study [31], we follow their labeling of recidivism as the positive outcome. In our single-protected attribute scenario we use the race (African American, Caucasian) as the protected feature, Z. We use race and sex (male, female) in the multiple protected attribute scenario. This dataset also includes information about the severity of charge, the number of prior crimes, and the age of individuals.

The German Credit Dataset [14] provides information about 1000 individuals and the corresponding binary labels describing them as creditworthy ($y = 1$) or not ($y = 0$). Each variable $\boldsymbol{x}$ includes 20 attributes with both continuous and categorical data. We use the binary gender of individuals as the protected feature. This dataset also includes information aboutthe age, job type, housing type, and total amount in bank accounts of applicants and the total amount in credit, the duration, and the purpose of loan applications.

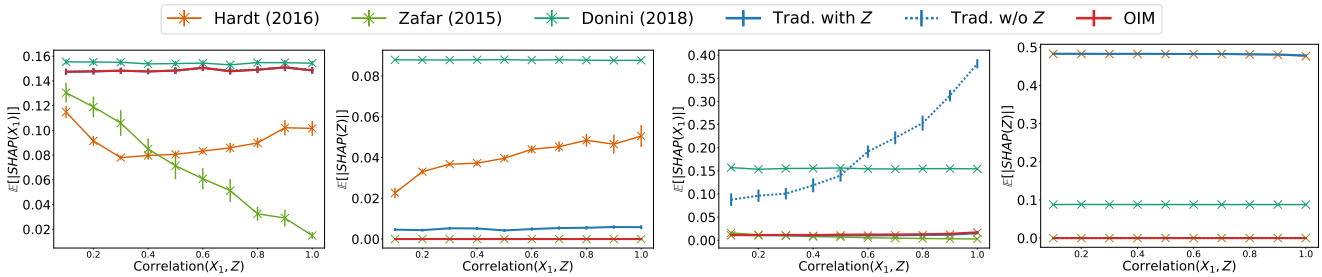
Measures. Since the non-discriminatory ground truth is unknown for these datasets, we use standard accuracy and demographic disparity to compare the learning algorithms. Demographic disparity measures disparate impact: DD = $|P(\hat{y} = 1|z = 0) - P(\hat{y} = 1|z = 1)|$ [50, 61]. While other measures have been proposed and used in the real-world context of applications [31], such as disparity in false positive rate (FPD = $|P(\hat{y} = 1|y = 0, z = 0) - P(\hat{y} = 1|y = 0, z = 1)|$) or positive predictive value (PPD = $|P(y = 1|\hat{y} = 1, z = 0) - P(y = 1|\hat{y} = 1, z = 1)|$), both of which we report, these and other measures derived from the confusion matrix are determined by accuracy and demographic disparity [8, 17, 28, 41]. For the multiple protected attribute scenario, we report disparity for each combination of sex and race w.r.t. the largest and, across each measure, the most disadvantaged group in COMPAS, Black males.

Results. We report the mean of the accuracy and disparities for the single-protected attribute scenarios and the multi-protected attribute COMPAS scenario in Figures 5 & 6 respectively.

For the German Credit data, the OIM achieves the lowest demographic disparity and the highest accuracy (right panels of Figure 5). For the COMPAS data on one protected attribute it also achieves the top accuracy, while yielding medium demographic disparity. The method that achieves much lower demographic disparity than the OIM directly constrains disparate impact at the expense of drastically lower accuracy and higher other disparities ("Zafar" in the top left panel of Figure 5). The OIM also performs well in terms of false positive disparity and has medium performance for positive predictive disparity (four bottom panels in Figure 5).

In the multiple protected attribute scenario, the OIM performed better than the traditional and the fair-learning method, "GerryFair" [26], in demographic and false positive disparities, while maintaining high accuracy (Figure 5 & 6). Therefore, the OIM addresses the substantial disparities in false positive rates by race reported in ProPublica's analysis of COMPAS over all intersections of race and sex [31]. Even though the OIM resulted in marginally worse positive predictive disparity than the traditional method, as revealed in ProPublica's analysis and our results, this disparity is minimal to begin with. Note that tuning the "GerryFair" method's parameters either increased accuracy with more disparity or vise-versa.

In both datasets and protected attribute scenarios, the OIM performs similarly to the traditional method that drops the protected attributes, "Without Z", and select state-of-the-art methods; however, these methods does not offer any protections, nor guarantees, against induced discrimination, as described in §4, and for the other datasets we studied they induce discrimination and/or directly discriminate (see §6 and §7.2).



(a) No direct discrimination, $g(\boldsymbol{x}, z) = x_1 + 0 * z$

(b) Directly discriminatory, $g(\boldsymbol{x}, z) = x_1 + 5 * z$

Figure 4: Average absolute value of SHAP values for X_1 and Z as the correlation between X_1 and Z increases. Each point is an average over 100 random datasets. Error bars show 95% confidence intervals.

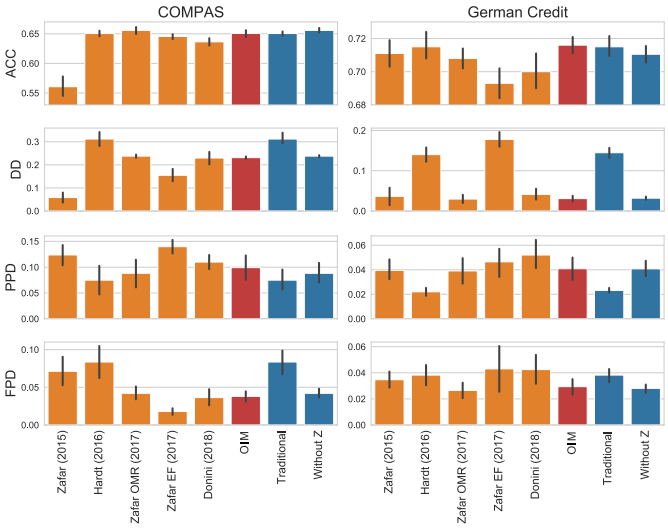


Figure 5: Performance of learning algorithms inhibiting discrimination over COMPAS and German Credit datasets. Higher accuracy (ACC) and lower demographic disparity (DD), positive predictive disparity (PPD), and false positive disparity (FPD) are better.

7.2 Concept shift information known

Dataset. We focus on the CelebA dataset [35] commonly found in computer vision and deep learning literature. Here, the task is to classify the hair color of celebrities in photos, so the target labels are unlikely to be affected by any discrimination. That is, the non-discriminatory U is known and we can simulate discriminatory concept shift by swapping hair color labels to generate a discriminatory Y, which enable the measurements of cross-loss in real-world scenarios.

CelebA is composed of celebrity images, each with 40 attribute annotations. Each image is transformed to 128*128 pixels, constituting the features $\boldsymbol{X}$. We use the official train-val-test split from Liu et al. [35] with blond ($y = 1$) or not blond hair ($y = 0$) as the target and binary gender as the protected attribute. To avoid sampling bias w.r.t. the hair-gender groups, we balance the dataset based on the smallest group (blond males). The balanced training and testing sets have 5,548 and 720 samples. To simulate a discriminatory concept shift, we randomly swap the labels of 50% of blond males to not blond in the training data. We train the methods on this discriminatory data, except for the traditional method trained on the non-discriminatory data (green in Figure 7 & 8).

Models and training. As our base model architecture we use a Pytorch implementation of ResNet-18 [23]. In addition to the OIM, only one of the evaluated learning methods' implementation, Hardt et al. [22], can handle deep learning models, since both of them are post-processing methods. Therefore, all the methods train ResNet-18 on the images without annotations, then both fair learning methods use the gender annotations in their post-processing step. The OIM also requires the addition of the protected attribute to the feature set when training ResNet-18. To avoid any changes to the architecture, we encode gender in the images via special markings (e.g., 10 pixel wide green and blue boxes shown in Figure 7a). First, we train ResNet-18 on the photos with markings. Then, we estimate the optimal mixing distribution, π^*, on the training data. At the test time, we first compute the ResNet-18 predictions on the photos with either value of the gender mark, and then we average these predictions using the learned mixing distribution. Note that we do not use the ground-truth gender for making predictions in the test set, but rather the counterfactual values of the gender markings. Other methods train without these markings.

Results. We measure the expected cross-loss, demographic disparity (DD), false positive disparity (FPD), and positive predictive disparity (PPD). Despite training on the discriminatory data like the traditional biased method (blue in Figure 7), the OIM reduces the expected cross-loss and the disparities close to that of the traditional unbiased method (red and green in Figure 7). By contrast, when trained on discriminatory data, the traditional learning without Z (without markings) performs poorly both in terms of disparities and the cross-loss, especially for blond males whose label was swapped (blue in Figure 7). Without the gender encoding, the model uses visual features of the images, such as hair and face shape, as proxies for gender. The method by Hardt et al. [22] results in the lowest DD and PPD (orange bars in Figure 7). However, it yields the highest expected cross-loss, in particular for the group with biased labels, i.e., blond males, and its female counterpart. In addition, this method tends to be further away (than the OIM) from the vanilla Resnet-18 training on the non-discriminatory data in terms of disparities. The presented OIM results use 10 pixel wide green boxes on the corners of images of females with same sized blue markings on male pictures (Figure 7a). The results for similar markings as Figure 7a are nearly the same (Appendix I). The expected cross-loss and the disparities of the OIM initially decrease monotonically with the width of the markings (Figure 8). At the width of about 10 pixels this trend flattens, both in terms of expected cross-loss and disparities, suggesting that the markings are sufficiently large already for the

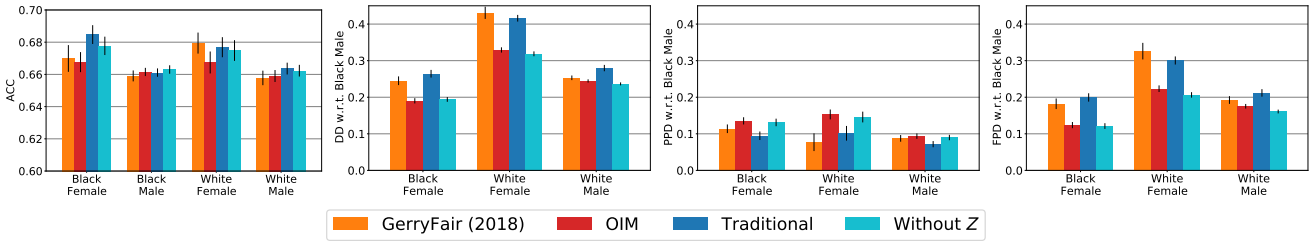

Figure 6: Performance of learning algorithms inhibiting discrimination over all combinations of race & sex on COMPAS. Disparity measures are on each given group w.r.t. Black Males. Higher accuracy (ACC) and lower disparities (DD, PPD, FPD) are better.

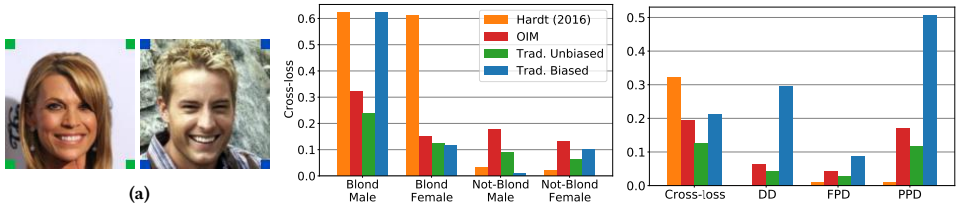

Figure 7: The expected cross-loss by hair-gender group (left plot) and the overall performance (right plot) of learning algorithms trained on the biased data following a discriminatory concept shift, except for the traditional trained on unbiased data (green bar). Marker style are shown in the photos on the left and have width of 10 pixels. Lower values are better. "Traditional" is ResNet-18.

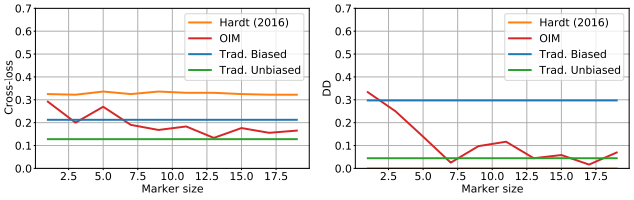

Figure 8: Overall expected cross-loss and demographic disparity of learning algorithms as marking pixel size increases. Marker style as in 7a. Lower values are better. "Traditional" is ResNet-18.

model to use them. We note that, in real-world application domains where cross-loss cannot be measured, the size of markings can be established based on the disparity measures.

8 CONCLUSION

Discussion. Our results shed a new light on the problem of discrimination prevention in supervised learning. First, we propose a new objective for discrimination prevention in supervised learning seeking methods that are resilient to discriminatory dataset shifts. Dataset shifts clarify the dataset issues that can lead to discriminatory models. Different dataset shifts can be identified and tackled with different learning methods, so the remaining big question is whether these methods can be combined or are conflicting.

Second, we show that the optimal interventional mixtures do not produce "reverse" discrimination nor induce discrimination. In the scenarios where training data is not discriminatory, the proposed learning method falls back to a traditional learning, and hence it is safer for general use than other approaches. While we do not provide resilience guarantees for discriminatory concept shifts with other perturbations than additive perturbations, to our knowledge this is the first study to provide such guarantees. Future research can study other dataset shifts to clarify the limits of this approach.

Third, we show that the proposed method is applicable to real-world settings with multiple protected groups and meets the explainability goal of removing their discriminatory impact, while remaining compatible with existing legal systems. The method provides a solution to the widely-discussed issue of protected groups' intersectionality and strikes a balance between protected groups, i.e., it does not correspond to affirmative actions advantageous to certain groups. The method overall is transparent and relatively easy to communicate to policymakers and courtroom officials.

Limitations. We studied a variety of datasets and models, finding support for our methods, but a wider set of scenarios could be considered. In future, discriminatory concept shifts could be measured via randomized human subject experiments or observational studies, and fair learning methods could be evaluated on resulting datasets and benchmarks. For instance, one could identify the groups of discriminating and fair members of hiring teams, as in our running Example, via population-level mixture models without identifying the individuals that belong to them [20]. Then, mixture components could be used to simulate realistic discriminatory and fair decisions. Such evaluation techniques would facilitate the comparisons and bolster the credibility of fair learning methods.

All fairness objectives run the risk of being misused by practitioners to justify that their decision-making systems are fair. In any decision-making scenario, our method requires understanding whether the relationships in the causal model are fair and not. However, a practitioner may neglect the proper understanding of the causal processes and their fairness, e.g., they may overlook indirect discrimination §4.2. While our method will eliminate direct discrimination, it would not remove indirect discrimination, unless it is applied in an appropriate way. Thus, we emphasize the utmost importance of collaboration with domain experts to better understand the underlying causal process and their interpretation when applying our method and any other fair-learning methods in consequential decision-making systems.

ABSTRACT

To address the growing concern of unfairness in Artificial Intelligence (AI), several bias mitigation algorithms have been introduced in prior research. Their capabilities are often evaluated on certain overly-used datasets without rigorously stress-testing them under simultaneous train and test distribution shifts. To address this, we investigate the fairness vulnerabilities of these algorithms across several distribution shift scenarios using synthetic data, to highlight scenarios where these algorithms do and don't work to encourage their trustworthy use. The paper makes three important contributions. Firstly, we propose a flexible pipeline called the Fairness Auditor to systematically stress-test bias mitigation algorithms using multiple synthetic datasets with shifts. Secondly, we introduce the Deviation Metric for measuring the fairness and utility performance of these algorithms under such shifts. Thirdly, we propose an interactive reporting tool for comparing algorithmic performance across various synthetic datasets, mitigation algorithms and metrics called the Fairness Report.

1 INTRODUCTION

Artificial Intelligence (AI) models enable data-driven decisions in applications such as job hiring, loan granting, college admission screening and more [19]. Despite their wide applicability, recent research has revealed that such models can be biased, often discriminating against certain groups of individuals [7, 23]. For example, an automated screening of individuals based on historic data was found to correlate race, address, and birthplace to poorer rates of acceptance [19]. Such correlations can be concerning if they lead to disparate outcomes or if the screening is sensitive to these attributes even when other attributes are fixed. Such biases are observed due to biased datasets or the models developed on them. For example, ImageNet, a popular image dataset, disproportionately represents images from various countries. 45% of the images come from the United States while only 3.1% images are from China and India [23]. This translates to poorer model performance, where the authors found that the prediction of groom/bride images had higher confidence on US-based images than Ethiopia or Pakistan. In another study, the authors found that commercially available facial recognition systems misclassified dark-skinned women four times more often than light-skin males [7].

With the growing concern that datasets and Machine Learning (ML) models have biases, there is a need for using "bias mitigation algorithms" [3] which are developed to mitigate unwanted bias for fair and trustworthy ML models. However, these algorithms are typically evaluated on a few overly-used datasets without discussing their strengths and weaknesses under simultaneous train and test distribution shifts. Recent research has shown that shifts in data are common. For example, in [6, 10], the authors discussed how covariate shifts occur in real applications where source and target datasets have different distributions. Another study discussed the fairness properties of models and mitigation algorithms from a causal perspective [22] under shifts. Typically, bias mitigation algorithms are evaluated on unique train-test distributions. However, to rigorously evaluate the fairness capabilities of these algorithms, we must evaluate them on many potential distribution shifts to identify fairness vulnerabilities. We define "fairness vulnerabilities" as distribution shifts where the bias mitigation algorithm struggles to remove unwanted bias and/or increases bias.

However, datasets with different distribution shifts are not easily accessible. For example, the Adult Income dataset [2] is based on a 1994 US Census database. However, a potentially shifted dataset for a recent study is hard to identify as there is no 2023 US Census dataset available to conduct a similar study. Furthermore, in the healthcare domain, access to health data is limited by privacy laws such as the Health Insurance Portability and Accountability Act (HIPAA) in the United States [9] and General Data Protection

Regulation (GDPR) in the European Union [11]. Lack of access to shifted data is likely to hinder trust in AI models as an algorithm trained and evaluated on a dataset cannot directly be used on a shifted dataset without testing. To address this, in this study, we propose the rigorous evaluation of bias mitigation algorithms using synthetically generated datasets with distribution shifts, referred to as "scenarios". These scenarios are deliberately biased (resulting in distribution shifts) towards certain populations and thus, expose whether the bias mitigation algorithms struggle to recover from these unwanted biases. The approach replicates shifts without the need for getting access to new data. It can systematically generate many different scenarios so the potential vulnerabilities of bias mitigation algorithms can be understood. We believe that more rigorous and complete evaluation can lead to better bias mitigation algorithms and create greater trust in them.

The contributions of this study are as follows:

- We propose Fairness Auditor, a flexible pipeline to systematically stress-test bias mitigation algorithms using multiple synthetic datasets with distribution shifts derived from a limited number of real datasets for understanding fairness vulnerabilities.
- We introduce the Deviation Metric that summarizes a suite of scores for a fairness or utility metric to evaluate bias mitigation algorithms under shifts. It quantifies the scores across many scenarios using empirical Cumulative Distribution Functions (eCDFs).
- To efficiently communicate the results and vulnerabilities found in the fairness audit, we propose an interactive reporting tool for comparing algorithmic performance across various synthetic datasets, bias mitigation algorithms, and metrics called the Fairness Report.

The synthetic scenarios are generated using stratified sampling of the Adult Income dataset [2] and using Generative Adversarial Networks (GANs) on datasets derived from the Medical Information Mart for Intensive Care (MIMIC-III) dataset [13, 16, 17]. We measure the utility and fairness of the ML models trained with four bias mitigation algorithms on these datasets to identify fairness vulnerabilities across many scenarios.

2 METHODOLOGY

2.1 Notation and Preliminaries

Let us consider three random variables A, X, and Y such that A is one or more protected attributes (such as ethnicity, race, gender), X is the remaining set of attributes (such as admission location, HbA1c test levels) and Y is the outcome variable (such as having higher or lower income, having a disease or not). Then, we can describe a given real dataset D^0 as $D^0 = \{A, X, Y\}$, representing a classification task where features A and X are used to predict Y using an ML model M. We define the values predicted by this model M using $\hat{Y}$. For simplicity, we consider A to be a binary protected attribute such that $A = 1$ represents one group while the rest of the population is described by $A = 0$, thus, $A \in \{0, 1\}$. Similarly, Y is also assumed to be a binary outcome variable such that $Y \in \{0, 1\}$.

We assume that A and Y are both binary random variables with a Bernoulli marginal distribution. Their joint distribution can be represented as a contingency table where the cells represent the proportions of combinations of protected attribute A and outcome variable Y, with the row and column sums as the marginal proportions. Denoting the proportions for the dataset D^0 with different subscripts, the contingency table is shown in Table 1. We note that in Table 1, $p^0_{A=0} + p^0_{A=1} = p^0_{Y=0} + p^0_{Y=1} = 100\%$. Also, this can be extended straightforwardly to multinomial A and Y.

Table 1: Contingency Table for Protected Attribute A and Outcome Y

	$A=0$	$A=1$	
$Y=0$	$p^0_{A=0,Y=0}$	$p^0_{A=1,Y=0}$	$p^0_{Y=0}$
$Y=1$	$p^0_{A=0,Y=1}$	$p^0_{A=1,Y=1}$	$p^0_{Y=1}$
	$p^0_{A=0}$	$p^0_{A=1}$	

2.2 Generating Synthetic Scenarios with Shifts

There are four types of distribution shifts (see [22] for more discussion): (a) Demographic shift (change in distribution of A), (b) Covariate shift (change in distribution of X), (c) Label shift (change in distribution of Y) and (d) Compound shift (two or more shifts). Compound shifts are most common as seen in the healthcare example in Schrouff et al. [22] where the data sources for training and deployment are different. Thus, for a rigorous evaluation of bias mitigation algorithms and their potential vulnerabilities, we propose to evaluate them on synthetically generated datasets with compound shifts. We introduce compound shifts in the datasets with simultaneous demographic shift and label shift by changing the proportions of the protected attribute A and outcome Y.

To create these scenarios, we use the Iterative Proportional Fitting (IPF) algorithm, which has been used across many applications including the identification of missing values by estimation and population count scaling [18]. We start with the original dataset distribution represented by a contingency table such as in Table 1. For each desired new synthetic data with distribution shift (scenario), we define the desired marginal distribution of the outcome and protected attribute. IPF is then used to generate an updated joint distribution that matches the desired marginal while in some sense keeping the desired distribution as close as possible to the original distribution. The resulting table is the joint probability distribution of maximum likelihood estimates based on probability convergence limits [20] while maintaining cross-product ratios.

Let us consider that we want to generate a synthetic dataset D^1 with compound shift such that the proportions are represented by p^1 with different subscripts. Thus, the protected attribute proportions are defined by $p^1_{A=0}$ and $p^1_{A=1}$ while the outcome marginals are defined by $p^1_{Y=0}$ and $p^1_{Y=1}$ such that $p^1_{A=0} + p^1_{A=1} = p^1_{Y=0} + p^1_{Y=1} = 100\%$. If the total records are defined as $\hat{N}^1_{total}$, then counts are represented as $\hat{N}^1_{Z=a} = p^1_{Z=a}\hat{N}^1_{total}$, where Z can be A or Y with $a \in \{0, 1\}$. These values are then input as the new marginals into the IPF algorithm along with the original contingency Table 1. These cell values are iteratively updated such that the row and column sums closely match the marginals specified and IPF returns the cell values $\hat{N}^1_{A=0,Y=0}$, $\hat{N}^1_{A=0,Y=1}$, $\hat{N}^1_{A=1,Y=0}$, and $\hat{N}^1_{A=1,Y=1}$. In this dataset, $\hat{N}^1_{A=0,Y=0} + \hat{N}^1_{A=0,Y=1} + \hat{N}^1_{A=1,Y=0} + \hat{N}^1_{A=1,Y=1} = \hat{N}^1_{total}$. In essence, IPF generates a plan of how to create the dataset D^1 from

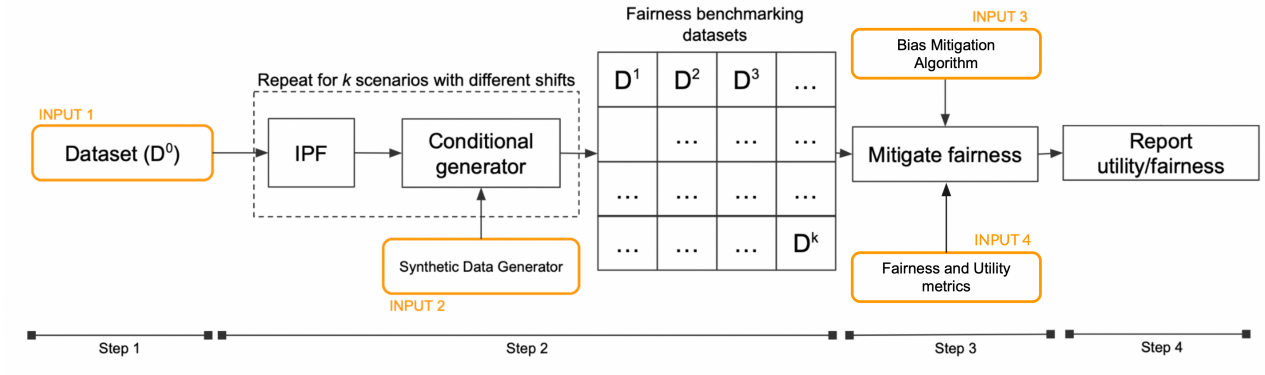

Figure 1: Design of the Fairness Auditor. The auditor includes four steps for evaluating bias mitigation algorithms based on the inputs: (1) Dataset, (2) Synthetic Data Generator, (3) Bias Mitigation Algorithm, and (4) Fairness and Utility metrics.

Table 2: Contingency Table representing the original proportions of protected attribute and outcome in the Adult Income dataset

	Females	Males	
Low-inc	13,026(28.8%)	20,988(46.41%)	75.22%
High-inc	1,669(3.69%)	9,539(21.09%)	24.78%
	32.5%	67.5%	

Table 3: Contingency Table representing the updated proportions of protected attribute and outcome in the Adult Income dataset in the synthetic scenario with higher number of high-income Females

	Females	Males	
Low-inc	967(9.67%)	33(0.33%)	10.0%
High-inc	8,033(80.33%)	967(9.67%)	90.0%
	90.0%	10.0%	

the original dataset D^0. Each scenario is a shifted dataset generated by stratified sampling according to this plan. Thus, IPF enables the transformation of a source distribution in the real data to a target distribution for the desired scenarios by changing the proportions of A and Y. This process can be used to create many synthetic scenarios with shifts derived from limited real datasets where both train and test distributions are shifted.

For instance, let Table 2 represent the contingency table for the Adult Income dataset (the pre-processing steps are described in the supplementary material). From the source distribution which has a higher population of high-income Males, we can create a synthetic scenario having a higher population of high-income Females. Thus, we set the marginal proportions of protected attribute A to 10-90 Male-to-Female, and the proportions of outcome Y to 10-90 Low-income-to-High-income, as shown in Table 3. IPF then returns the four cell values in the contingency table. This table is used as the basis for stratified sampling to create the target synthetic scenario, against which the bias mitigation algorithm should be evaluated.

After identification of the target synthetic data distribution using IPF, the synthetic scenario is achieved by conditionally sampling records based on protected attribute and outcome counts $(\hat{N}^1_{A=0,Y=0}, \hat{N}^1_{A=0,Y=1}, \hat{N}^1_{A=1,Y=0}, \hat{N}^1_{A=1,Y=1})$, either by bootstrapping from D^0, using synthetic data generators of D^0 created by Generative Adversarial Networks [14] or other methods. In this paper, we specifically discuss two methods for conditional sampling based on the proportions identified by IPF.

The first process (referred to here as Bootstrap) samples the real data with replacement according to different shifted proportions. This results in scenarios created by biased sampling of the original data. For the second process, we use a privacy-preserving Generative Adversarial Network (GAN), HealthGAN [25]. HealthGAN has been shown to be effective for generating high-utility, resemblance- and privacy-preserving data for public and private healthcare datasets [24]. Synthetic scenarios are generated using HealthGAN without conditioning and then, bootstrapped with replacement using the values identified by IPF. The two scenario sampling methods have different strengths and weaknesses. Bootstrap has the advantage that while being efficient and effective, it precisely preserves the distribution of $p(X|A, Y)$. But bootstrapping has the disadvantage that it requires the distribution of the original data and is limited by the size of the original dataset. The advantage of using advanced synthetic data generators such as HealthGAN is the ability to generate a large amount of data from small datasets while preserving privacy of the original dataset. The disadvantage is that the GANs require training and may introduce additional shifts and biases in the data beyond the desired ones.

2.3 Fairness Auditor

We propose the Fairness Auditor as a pipeline for evaluating bias mitigation algorithms under distribution shifts by using the synthetic data generation process described in the previous sub-section. The auditor generates a grid of scenarios with possible shifts and then evaluates the algorithm across this set of scenarios to highlight where these algorithms do and don't work for identifying potential fairness vulnerabilities and encouraging their trustworthy use. The proposed design for the auditor is shown in Figure 1. The auditor

is flexible to accommodate any dataset, synthetic data generator, bias mitigation algorithm, and fairness-utility metrics. The auditor conducts a rigorous evaluation for any given bias mitigation algorithm with the steps described below:

- **Step 1:** Select base dataset $D^0 = \{A, X, Y\}$ to be used for evaluation. The dataset should represent a classification problem with outcome Y and a protected attribute A which needs to be tested for biases. The starting contingency table is created with proportions p^0 and counts N^0 with various subscripts similar to Table 1.
- **Step 2:** Define various combinations of the proportions of protected attribute A and outcome Y to form a grid with k scenarios. These specify the new marginal totals for the contingency table and constraints for IPF. After running IPF, a synthetic data generator is used to generate data conditioned on each cell (e.g. $A = 0$ and $Y = 0$) with the number of samples found using IPF. The synthetic data generation process can either directly generate synthetic data conditioned on the counts or non-conditionally generate data to be conditioned later using bootstrapping. This is repeated for different compound shifts, resulting in k different datasets $D^1, D^2, D^3 ... D^k$, each representing a synthetic scenario in a grid of possible scenarios.
- **Step 3:** The bias mitigation algorithm is then applied to each scenario where the train and test data have the same shifted distribution, to measure reduction in bias as measured by a fairness metric f and changes in utility as measured by a utility metric u. The results are reported using the Deviation Metric (DM) as described in Section 2.4. Based on the type of algorithm, the mitigation is performed before, during, or after ML model training for outcome prediction $\hat{Y}$.
- **Step 4:** The resulting metric scores are reported in a report called Fairness Report, highlighting shifts where the bias mitigation algorithm struggled to reduce and/or remove bias and thus, is vulnerable. The report is described in detail in Section 3.3.

For each scenario $D^i, i \in 1, 2, ...k$, the dataset is split into train D^i_{train} and test D^i_{test}, where each train-test pair's distribution is different from the other pairs.. The ML model M^i is trained along with the bias mitigation algorithm on D^i_{train}. The resulting model is then evaluated on the test dataset D^i_{test} which has the same distribution as D^i_{train}. Based on the user-specified fairness metric f and utility metric u, the results are reported to the user through the report. For each dataset D^i, the experiment is repeated s times by changing the *random_seed* for train-test split from $1, 2, ...s$. Mean and 95% Confidence Interval (95% CI) scores are reported across the s experiments for each of the k scenarios.

2.4 Metrics

As each algorithm is evaluated $k \times s$ times, a metric is needed to capture all the scores for doing a single-value comparison with others. To accommodate this, we propose the Deviation Metric (DM). The Deviation Metric summarizes a suite of scores measured using a metric m across many scenarios as a single-value. The underlying metric m can be a fairness metric f, a utility metric u, or others. Here, the analysis is performed by calculating the Deviation Metric for m by evaluating it on all k scenarios and s repetitions.

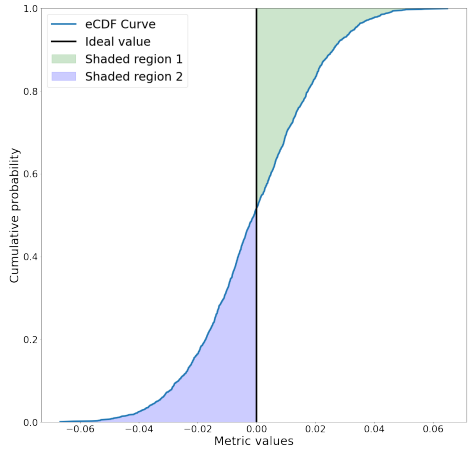

Figure 2: Example scenario describing the eCDF curve for the metric m. Shaded region 1 (green) and Shaded region 2 (purple) refer to the areas defining the deviation from ideal value 0. The Deviation Metric (DM) measures this deviation.

For this work, fairness is evaluated using group fairness [3] where different groups, such as those defined by protected attribute A ($A = 0$ or $A = 1$), receive similar scores. Additionally, utility is defined as the ML model's performance on the test data. These metrics are evaluated on all scenarios and then summarized to fairness and utility Deviation Metrics.

The metric m is evaluated across all k scenarios for s experiments each, resulting in a suite of scores ($k \times s$ values) for that metric. Additionally, each metric m has an ideal value V_{ideal} corresponding to the best possible performance for the algorithm. For example, for a fairness metric f, if no-bias implies a value of 0, then the ideal value for this metric is 0. However, this hinders a direct one-to-one comparison between algorithms as each algorithm's performance is now described by a list of scores. The Deviation Metric captures all these scores as a single value by aggregating the scores using the empirical Cumulative Distribution Function (eCDF) which characterizes the percentage of results observed in metric m below a specific value.

All the scores for the metric m and the ideal value V_{ideal} are plotted as curve C and line L respectively. The area between the curve C and the line L is then calculated to represent DM which summarizes all scores with one single value. To demonstrate, let's consider the example scenario represented by the eCDF curve C (blue) for metric m in Figure 2. The ideal value V_{ideal} is marked as a black line with value $x = 0$. For DM, the area between L and C is defined by the two shaded regions (green and purple) as shown in Figure 2. Put simply, DM measures how far away are the scores from the ideal value for the metric.

Thus a lower value of DM for metric m represents a better model. DM creates a single value to represent the vulnerabilities of the bias mitigation algorithm across all $k \times s$ experiments. The lower the DM

score, the better the algorithm and is thus, less vulnerable to shifts as compared to other algorithms for the given dataset and model. DM generalizes robust evaluation methods such as Receiver Operator Characteristic (ROC) method with AUC (Area Under Curve) [15] and Regression Error Curves (REC) [5]. Like AUC, the advantage of DM is that it allows different bias mitigation algorithms to be rigorously compared both visually and empirically across the grid of scenarios.

2.5 Experimental Design

In this study, we discuss the results on two datasets. The first dataset is the Adult Income dataset [2] which includes information about individuals and whether they earn more than $50K per year or not. The raw data is pre-processed to remove NaN values and categorical columns are one-hot encoded resulting in a total of 32 columns and 45,222 records. Based on the protected attribute, we define two versions of this dataset: (a) Adult Income (v1) that measures bias in Gender (Male-Female populations) and (b) Adult Income (v2) that measures bias in Marital-Status (Married-Single populations). For the second dataset, we define a Mortality dataset derived from a synthetic version of the MIMIC-III [13, 16, 17], dataset in a manner similar to previous studies [25]. In the Mortality dataset, we address the bias in Race (White-Black populations) while predicting mortality within 30 days of ICU admission. During pre-processing, we selected records for only Black and White individuals and perform one-hot and label encoding on the columns. Based on the selection of feature columns, we define three versions of the dataset: (a) Mortality dataset (v1) which includes features specific to Diabetic patients (16 columns and 3,365 records), (b) Mortality dataset (v2) which includes features for all patients (17 columns and 10,788 records) and (c) Mortality dataset (v3) which includes features as defined in a previous study [25] (13 columns and 11,173 records). The complete list of features for each dataset is described in the supplementary.

To create the shifts, we traverse the proportion of protected attribute A and outcome Y from 10% to 90%, each with a step of 10%. This creates a 9×9 grid of 81 scenarios. To create these scenarios, we synthetically generate datasets using bootstrapping of the real data with replacement based on the IPF counts. The total data size for each synthetic scenario is set to 100K records. For the Adult datasets, we conditionally sample using bootstrapping with replacement to create the 81 scenarios based on the IPF values. On the other hand, to ensure privacy preservation of the records in the Mortality dataset, we used the HealthGAN model [14, 25]. As HealthGAN does not generate data conditionally, we first generate 1M synthetic records and then we perform stratified sampling based on the IPF counts to create the 81 synthetic scenarios. For each of the k scenarios, the data is first split into 70-30 train-test data and then 30% of the train data is used as the validation set.

A classification model is trained on the training data and then, the probability threshold is set using hyper-parameter tuning using the validation data for best Balanced Accuracy. The resulting model and threshold are used to evaluate the fairness and utility metrics on the test data, each repeated 10 times ($s = 10$) for each scenario. While any classifier can be used, we present the results using two classification models: (a) Random Forest and (b) XGBoost. The model parameters are detailed in the supplementary.

For comprehensive testing, we evaluate mitigation algorithms from all three categories. We select two pre-processing algorithms, namely, Reweighing [8] and Disparate Impact Remover [12]. As an in-processing algorithm, we consider the Reductions algorithm [1]. As reductions can trade-off between fairness and utility, we discuss three versions here, each with a different value of the parameter *constraint_weight*: (a) Reduction (Utility focused): while balancing between utility and Equalized Odds, more weight is given to utility (*constraint_weight = 0.1*), (b) Reduction (Balanced): equal weight is used (*constraint_weight = 0.5*), and (c) Reduction (Fairness focused): more weight is given to the fairness metric (set to Equalized Odds) (*constraint_weight = 0.9*). Finally, we explore the Calibrated Equalized Odds [21] post-processing algorithm. Note that the hyper-parameter tuning during model training isn't used for Calibrated Equalized Odds as the algorithm is applied on the probability scores rather than actual predictions. The results for all bias mitigation algorithms are compared with the Baseline in which the ML models are trained on all 81 scenarios without the application of any bias mitigation algorithm.

In this study, we measure fairness using Equalized Odds. If the protected attribute A is comprised of two sub-groups, $A = 0$ and $A = 1$, then Equalized Odds is defined as:

$$EO = \max(|FPR_{A=0} - FPR_{A=1}|, |TPR_{A=0} - TPR_{A=1}|) \quad (1)$$

TPR refers to True Positive Rate and FPR refers to False Positive Rate. The regions of values considered to be fair are set as in Bhanot et al. [4]. As Equalized Odds measures the bias in the models in terms of both True Positive Rate (TPR) and False Positive Rate (FPR), it provides a comprehensive picture of the bias. For utility, the Balanced Accuracy is used. For imbalanced datasets, using a metric like Balanced Accuracy ensures that the model's performance for all classes is captured. The users have the flexibility to select the fairness and utility metrics based on previous knowledge, expertise in the field, or the characteristics of the dataset.

Equalized Odds has an ideal value of 0 since completely fair models have no bias. The Equalized Odds scores are always positive. However, as the ideal value is 0, the eCDF plot will only have the green shaded region of Figure 2 while measuring Deviation Metric for Equalized Odds. Balanced Accuracy has an ideal value of 1 as the best model is completely accurate across all classes. The Balanced Accuracy scores are also always positive but lie in the range of 0 to 1. While measuring Deviation Metric for Balanced Accuracy, the eCDF plot will only have the purple shaded region of Figure 2.

3 RESULTS AND DISCUSSION

3.1 Identifying Fairness Vulnerabilities

For each scenario, using the 10 scores (s=10) calculated for fairness metric f, we measure the mean value. This mean value for the bias mitigation algorithm is calculated and compared with the Baseline to identify vulnerable distribution shifts. For Equalized Odds, if the scores are equal or higher than Baseline, the algorithm is vulnerable to that distribution shift as on average, it didn't reduce the bias. To capture the vulnerability across all shifts, we plot a heatmap where

Figure 3: Heatmap comparing the performance of Reduction (Fairness Focused) on Mortality dataset (v1) while evaluating Equalized Odds for Race bias.

each tile represents one shifted scenario. If the mean value for the bias mitigation algorithm is lower than Baseline, it is marked with Better (green) else it is marked with Similar or Worse (red).

Let's consider the case study of identifying vulnerabilities of Reduction (Fairness Focused) when evaluating Equalized Odds for Race bias in Mortality dataset (v1) as shown in Figure 3.

The heatmap in Figure 3 plots each scenario as a tile, representing a unique distribution shift. The first tile represents the Black-White population ratio as 10-90 and the population survived to not-survived as 10-90 (proportion of the outcome). If we move to the next tile below, the ratio of the Black-White population changes to 20-80 while keeping the outcome proportions the same, and so on. From the results, we find that Reduction (Fairness Focused) performed Better (green) than the Baseline as measured by the averaged Equalized Odds scores in a few scenarios but not all. In other scenarios, the algorithm suffers from fairness vulnerabilities as indicated by the red tiles on the heatmap. For example, when Black-White population proportions are 50-50 and the outcome proportions are 10-90 (tile marked with a black box), Reduction (Fairness Focused) is performing Similar to or Worse than the Baseline based on the averaged scores. We find that there are many such scenarios, each identified by a red tile, where the algorithm is vulnerable to distribution shifts in this dataset.

This is insightful as the user knows the various shifts where the algorithm is struggling and where it is performing well. This shall enable a robust understanding of the algorithm's performance and can guide a trustworthy use under shifts.

3.2 Comparing Bias Mitigation Algorithms

Let's consider two case studies to understand how the stress-testing performed by the Fairness Auditor and the scores summarized using the Deviation Metric can enable informed decision-making for algorithm comparison.

3.2.1 Case Study 1: Gender Bias in Adult Income dataset (v1). For the first case study, we measure Gender bias in Random Forest models trained on the Adult Income dataset. The mitigation algorithms are compared with the Baseline across all synthetic scenarios generated

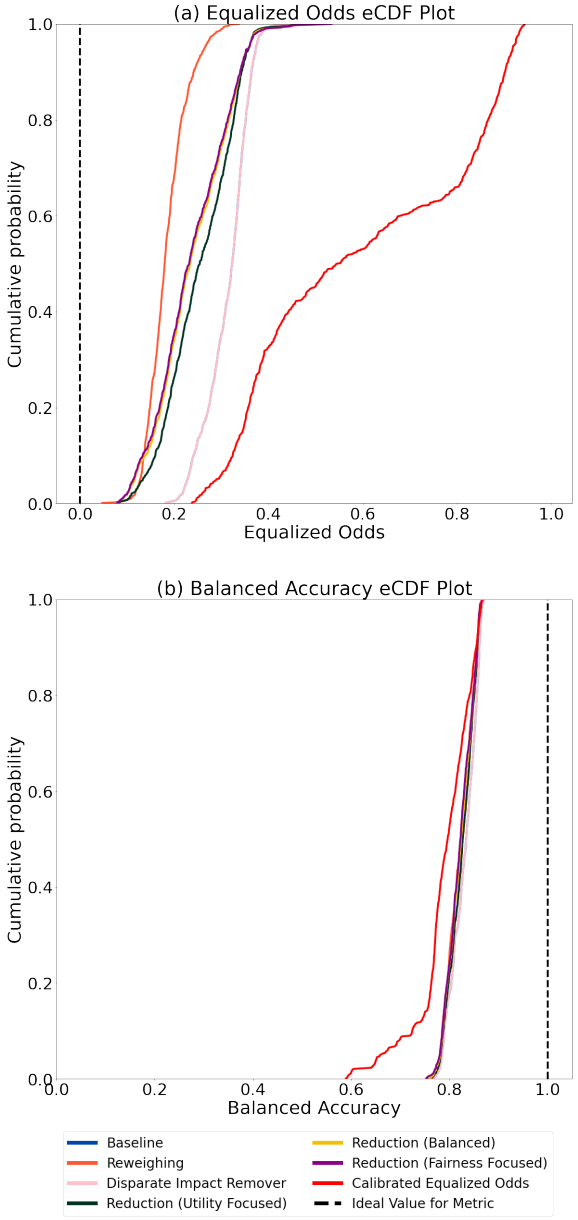

Figure 4: Empirical Cumulative Distribution Functions (eCDFs) for (a) Equalized Odds and (b) Balanced Accuracy for Random Forest models trained with mitigation algorithms on the Adult Income dataset (v1) addressing Gender bias.

using bootstrapping with replacement. The Equalized Odds and Balanced Accuracy scores for all $81 \times 10 = 810$ scenarios are used for generating the eCDF plot as shown in Figure 4.

Figure 4 (a) shows the eCDF plot the Equalized Odds. We observe that the curve for Reweighing (orange) is closest to the ideal value of 0 and is improving upon the fairness scores for the Baseline (blue) which coincides with Disparate Impact Remover (pink). The range of values for Reweighing lies between 0 and 0.3. In contrast,

Table 4: Deviation Metric for Equalized Odds and Balanced Accuracy scores measured for Random Forest and XGBoost models trained on the Adult Income dataset. The best mitigation algorithm is highlighted in bold while the second best is underlined for each pair of dataset and model combination.

Dataset	Machine Learning model	Mitigation	Deviation Metric for Balanced Accuracy	Deviation Metric for Equalized Odds
Adult Income dataset (v1)	Random Forest	Baseline	**0.1703**	0.3125
		Reweighing	0.1782	**0.1843**
		Disparate Impact Remover	**0.1703**	0.3125
		Reduction (Utility Focused)	<u>0.1752</u>	0.2538
		Reduction (Balanced)	0.1777	0.2391
		Reduction (Fairness Focused)	0.1787	<u>0.2367</u>
		Calibrated Equalized Odds	0.2094	0.5947
	XGBoost	Baseline	**0.1891**	0.3155
		Reweighing	0.1963	**0.1802**
		Disparate Impact Remover	**0.1891**	0.3155
		Reduction (Utility Focused)	<u>0.1945</u>	0.2460
		Reduction (Balanced)	0.1979	0.2301
		Reduction (Fairness Focused)	0.1993	<u>0.2261</u>
		Calibrated Equalized Odds	0.2251	0.5821
Adult Income dataset (v2)	Random Forest	Baseline	**0.1903**	0.5948
		Reweighing	0.2215	**0.2585**
		Disparate Impact Remover	**0.1903**	0.5948
		Reduction (Utility Focused)	0.2026	0.4249
		Reduction (Balanced)	0.2135	0.3889
		Reduction (Fairness Focused)	0.2240	<u>0.3764</u>
		Calibrated Equalized Odds	<u>0.2015</u>	0.7752
	XGBoost	Baseline	**0.2161**	0.6815
		Reweighing	0.2615	**0.1511**
		Disparate Impact Remover	**0.2161**	0.6815
		Reduction (Utility Focused)	0.2334	0.4081
		Reduction (Balanced)	0.2547	0.3607
		Reduction (Fairness Focused)	0.2748	<u>0.3308</u>
		Calibrated Equalized Odds	<u>0.2256</u>	0.8160

Calibrated Equalized Odds (red) is the farthest from 0 and is performing worse than the Baseline. Furthermore, the values have high variance ranging from 0.2 to 1.0.

On the other hand, Figure 4 (b) shows the eCDF plot the Balanced Accuracy with the ideal value 1. We observe that the mitigation algorithms have similar curves almost overlapping each other. The only exception is Calibrated Equalized Odds (red) with an eCDF curve furthest from the ideal value while having a higher variance in values. For all other bias mitigation algorithms, the Balanced Accuracy scores are closer to 0.8 across almost all shifts. Thus, from the two eCDF plots we can conclude that Reweighing is performing the best for this dataset while improving on fairness as measured by Equalized Odds with limited change in Balanced Accuracy. Further, the Calibrated Equalized Odds mitigation algorithm is the most vulnerable, experiencing higher variance in Equalized Odds and Balanced Accuracy scores when compared with others.

For an empirical analysis, we evaluated the Deviation Metric for Equalized Odds and Balanced Accuracy scores for the case study. Table 4 includes the corresponding DM values and expands the current case study to Marital-status bias in Adult Income dataset (v2), across both ML models: Random Forest and XGBoost. We find that the choice of the ML model doesn't affect the relative order of the top bias mitigation algorithms for the Adult Income dataset. For Gender bias in Adult Income dataset (v1), we find that Reweighing achieves the best scores followed by Reduction (Fairness Focused) as measured for Equalized Odds. However, for Balanced Accuracy, the best algorithm is Disparate Impact Remover (similar to Baseline) followed by Reduction (Utility Focused). Calibrated Equalized Odds performed worse than other algorithms including the Baseline, as was also observed from the eCDF plot. While measuring Marital-Status bias in Adult Income dataset (v2), the best algorithms are still the same. Calibrated Equalized Odds secures the second position as measured by Balanced Accuracy but performs the worst for Equalized Odds. We conclude that the choice of the most appropriate algorithm for this dataset depends on the importance of a particular metric (Balanced Accuracy or Equalized Odds) and the bias being evaluated. Deviation Metric can play a prominent role in enabling the user to make this decision by providing single-value points of comparison between multiple algorithms as shown in Table 4.

3.2.2 Case Study 2: Race Bias in Mortality dataset (v1). For the second case study, we explore the Race bias in Mortality dataset (v1) where the bias mitigation algorithms are trained with Random

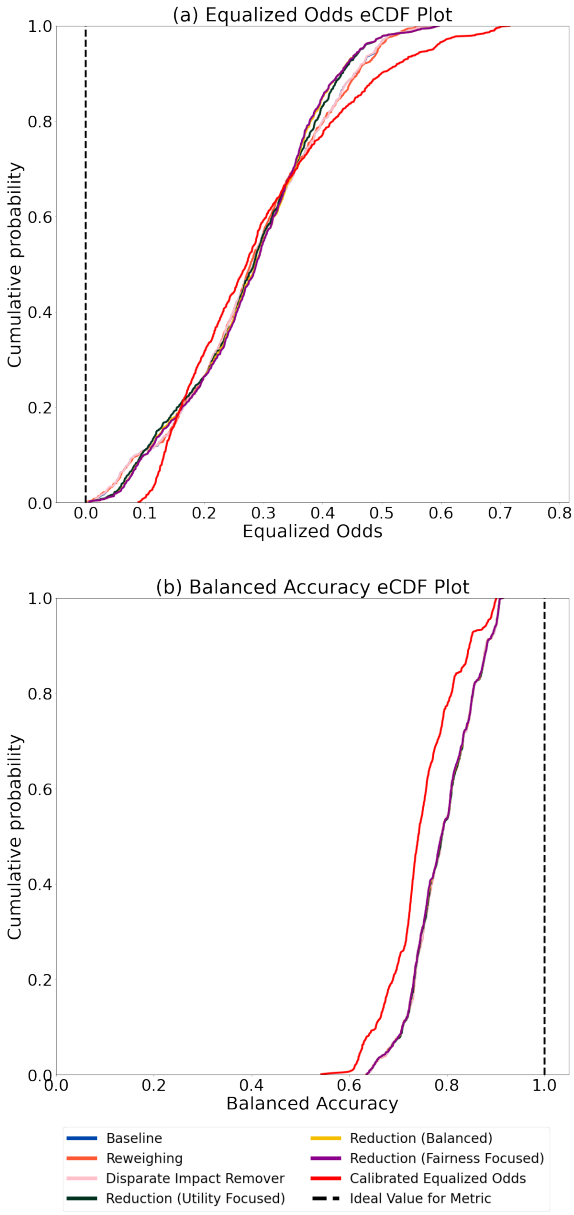

Figure 5: Empirical Cumulative Distribution Function (eCDFs) for (a) Equalized Odds and (b) Balanced Accuracy for Random Forest models trained with mitigation algorithms on the Mortality dataset (v1) addressing Race bias.

Forest models. The Baseline model is compared with the various bias mitigation algorithms on the synthetic scenarios generated using HealthGAN. The Equalized Odds and Balanced Accuracy scores for all 810 scenarios are plotted as an eCDF curve in Figure 5.

Figure 5 (a) shows the scores for Equalized odds. The eCDF curves for all bias mitigation algorithms, including the Baseline, follow a similar trend with high variation in the range of values from 0 to 0.7. This shows that under distribution shifts, almost all algorithms become vulnerable and have high biases, even higher than 0.5. From the plot, we observe that Calibrated Equalized Odds (red) shows a slight deviation from the other algorithms. Its lowest fairness score is closer to 0.1 as compared to 0 for others. Furthermore, the highest value also exceeds the other algorithms. However, when we look for the cumulative probabilities between 0.2 to 0.6 across the y-axis, Calibrated Equalized Odds curve is closer to the ideal value of 0 than others. In other words, it has lower Equalized Odd scores than other algorithms. This is especially where a metric such as Deviation Metric shines as it can capture all these variations and outputs a single value which we can be used for comparing algorithms. We describe this further in Table 5.

Based on Figure 5 (b), we find that except for Calibrated Equalized Odds (red), all algorithms almost overlap with each other including the Baseline. However, in contrast to the first case study, all algorithms have a larger range of Balanced Accuracy values ranging from 0.5 to 0.8. This highlights that training under distribution shifts for this dataset can sometimes lead to poorer Balanced Accuracy models. Additionally, Calibrated Equalized Odds suffers the most, having Balanced Accuracy scores always further away from the ideal value 1 in comparison with the other algorithms underscoring its poor performance.

We evaluate the Deviation Metric to easily compare the various algorithms based on Equalized Odds and Balanced Accuracy metrics, with the values described in Table 5. This is accompanied by the DM scores for the other two Mortality datasets (v2 and v3) for both ML models: Random Forest and XGBoost. In Mortality dataset (v1), we find that Balanced Accuracy scores for Random Forest are lower than XGBoost but it is reversed for Equalized Odds, creating a utility-fairness trade-off. However, irrespective of the model, we find that Reweighing, Disparate Impact Remover, and Reduction perform comparably on this dataset. For Mortality dataset (v2), the Baseline itself is performing the best as measured by Balanced Accuracy. However, for Equalized Odds, Reweighing is performing quite well with a DM score very close to 0. Mortality dataset (v3) has the most consistent scores across both models. For Equalized Odds, Reweighing is the best, followed by Reduction (Fairness Focused). In contrast, Disparate Impact Remover is performing the best, being closely followed by Reduction (Utility Focused) for Balanced Accuracy. From the various results, we can conclude that different mitigation algorithms work better for each given dataset and the utility-fairness trade-off. Again, DM played a vital role in identifying which algorithm is useful. For example, Figure 5 (a) eCDF curve was captured by the Deviation Metric for Equalized Odds in Table 5 and made it easy to realize that even when Calibrated Equalized Odds had lower Equalized Odds scores in certain scenarios, overall, the performance was not better than any of the other mitigation algorithms considered.

3.3 Reporting

Investigating each dataset, bias mitigation algorithm, and metric can be overwhelming and challenging. To accommodate and analyze such vast information, we developed the Fairness Report. The reporting tool is a comprehensive web-based application designed in R-Shiny to visualize the results using eCDF plots and DM scores. The user can access the performance of mitigation algorithms and

Table 5: Deviation Metric for Equalized Odds and Balanced Accuracy scores measured for Random Forest and XGBoost models trained on the Mortality dataset. The best mitigation algorithm is highlighted in bold while the second best is underlined for each pair of dataset and model combination.

Dataset	Machine Learning model	Mitigation	Deviation Metric for Balanced Accuracy	Deviation Metric for Equalized Odds
Mortality dataset (v1)	Random Forest	Baseline	**0.2079**	0.2807
		Reweighing	**0.2079**	0.2804
		Disparate Impact Remover	**0.2079**	0.2807
		Reduction (Utility Focused)	0.2082	**0.2768**
		Reduction (Balanced)	0.2090	0.2781
		Reduction (Fairness Focused)	0.2092	0.2782
		Calibrated Equalized Odds	0.2523	0.2948
	XGBoost	Baseline	**0.3504**	**0.0476**
		Reweighing	**0.3504**	0.0481
		Disparate Impact Remover	**0.3504**	**0.0476**
		Reduction (Utility Focused)	0.3511	0.0656
		Reduction (Balanced)	0.3515	0.0714
		Reduction (Fairness Focused)	0.3516	0.0723
		Calibrated Equalized Odds	0.3663	0.1140
Mortality dataset (v2)	Random Forest	Baseline	0.3006	0.1872
		Reweighing	**0.3005**	**0.1780**
		Disparate Impact Remover	0.3085	0.1849
		Reduction (Utility Focused)	0.3008	0.1847
		Reduction (Balanced)	0.3009	0.1846
		Reduction (Fairness Focused)	0.3009	0.1848
		Calibrated Equalized Odds	0.3199	0.2322
	XGBoost	Baseline	**0.3410**	0.1475
		Reweighing	0.3432	**0.0386**
		Disparate Impact Remover	0.3412	0.1476
		Reduction (Utility Focused)	0.3430	0.1548
		Reduction (Balanced)	0.3440	0.1615
		Reduction (Fairness Focused)	0.3445	0.1640
		Calibrated Equalized Odds	0.3555	0.2835
Mortality dataset (v3)	Random Forest	Baseline	**0.3792**	0.2857
		Reweighing	0.3862	**0.0447**
		Disparate Impact Remover	**0.3792**	0.2857
		Reduction (Utility Focused)	0.3818	0.2694
		Reduction (Balanced)	0.3829	0.2629
		Reduction (Fairness Focused)	0.3860	0.2584
		Calibrated Equalized Odds	0.3936	0.4537
	XGBoost	Baseline	**0.3739**	0.3645
		Reweighing	0.3831	**0.0373**
		Disparate Impact Remover	**0.3739**	0.3645
		Reduction (Utility Focused)	0.3767	0.3216
		Reduction (Balanced)	0.3792	0.3022
		Reduction (Fairness Focused)	0.3818	0.2950
		Calibrated Equalized Odds	0.3915	0.5433

identify specific distribution shifts as fairness vulnerabilities. Figure 6 describes a screenshot of the app comprised of three parts: (a) Sidebar: Includes options for selecting dataset, mitigation algorithm, and metrics, (b) Tabs: Provides different visualizations from summary to scenario analysis and (c) Content: Includes the visualization and scores based on the selected Sidebar and Tab options. Note that the results shown in Figure 6 are for XGBoost models.

The visualizations and analysis are presented to the user via the application split into four sections as described below:

- **Home:** The first tab summarizes and compares the Deviation Metric scores for all selected metrics for all bias mitigation algorithms. The relative order for the bias mitigation algorithms based on the DM scores is presented to quickly compare them based on any set of pre-defined metrics.

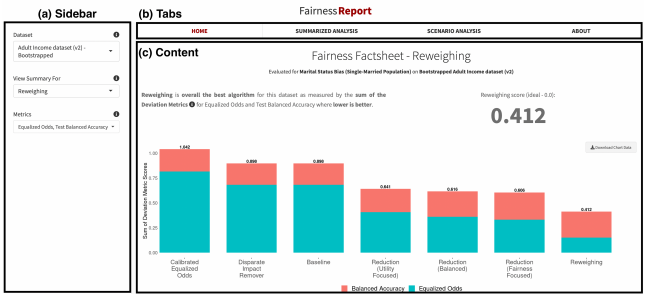

Figure 6: An interactive web application, Fairness Report, that visualizes bias mitigation algorithm performance in comparison with others using a combination of empirical values and plots.

- **Summarized Analysis:** The second tab compares the selected bias mitigation algorithm with the Baseline across all scenarios. The eCDF plot similar to Figure 4 is shown with the curves for the Baseline and the algorithm. This is accompanied by the heatmap identifying each scenario where the bias mitigation algorithm performed worse than Baseline, visualizing all vulnerable distribution shifts.
- **Scenario Analysis:** The third tab expands in-depth on the Summary Analysis tab and enables the user to select a certain range of scenarios based on protected attributes and outcome proportions. For comparison with the Baseline, the eCDF curve is plotted. This is accompanied by a line plot comparing the average and 95% Confidence Interval (CI) scores for each selected scenario with the Baseline.
- **About:** The fourth and last tab includes the details about the datasets, bias mitigation algorithms, and metrics included in the application along with external links to useful resources.

The Fairness Report makes it easy to identify fairness vulnerabilities for any selected bias mitigation algorithm. For example, the previously discussed heatmap in Figure 3 is taken from the Fairness Report when visualizing the Summarized Analysis tab for the Reduction (Fairness Focused) algorithm.

4 CONCLUSION

Bias mitigation algorithms are prone to fairness vulnerabilities caused by distribution shifts. While many bias mitigation algorithms exist, their applicability under distribution shifts is often not systematically evaluated. Rigorous evaluation is essential to ensure trust in algorithms' applications under settings where shifts are common. To address this issue, we proposed Fairness Auditor, a flexible stress-testing pipeline to rigorously evaluate the performance of bias mitigation algorithms using synthetic datasets.

In this paper, we highlight the capability of the Fairness Auditor by presenting results highlighting its ability to (a) identify fairness vulnerabilities and (b) compare algorithms using Deviation Metrics and the Fairness Report. We found that different bias mitigation algorithms may be useful, depending upon the metric important to the user. The process of comparison is facilitated by the Deviation Metric introduced in the paper as a means for capturing single-value scores across various synthetic scenarios. Additionally, visual and empirical results described by the Fairness Report together enable a comprehensive demonstration of the algorithm's capabilities, identifying scenarios where the bias mitigation algorithm works and where it is vulnerable.

Rigorous Stress-Testing: The goal of the Fairness Auditor is evaluation of any bias mitigation algorithm by conducting a thorough, in-depth analysis using many train and test distribution shifts. By introducing both label and demographic shifts in a given dataset, the scenarios form a test bed for evaluating the strength of the bias mitigation algorithm against compound shifts and identifying potential fairness vulnerabilities. Such an evaluation is not only necessary but key to building trust in bias mitigation methods before application. This is even more crucial in high-impact domains like healthcare, where an algorithm's applicability must be well-known as many decisions can be life-altering.

Synthetic Data Generation: Lack of good quality datasets often hinders a robust and comprehensive analysis of any algorithm. The Fairness Auditor addresses this limitation by generating synthetic scenarios using IPF from a given dataset. This implies that many datasets can be created from one. Using HealthGAN, we demonstrated that the Fairness Auditor can be extended to existing synthetic data generators. This also shows that privacy-preserving generators can be used to release synthetic data for robust fairness evaluation without compromising privacy.

Reporting: With the help of the Fairness Report, any existing/future bias mitigation algorithm can be compared with others on additional datasets with shifts. Such an analysis provides insight into the algorithm's vulnerabilities both visually and empirically, ensuring a robust comparison while identifying potential weaknesses. Additionally, the option for summarized or in-depth results ensures that the users know the exact shifts where the algorithm struggles and would aid them in developing more rigorous algorithms under shifts, building trust in AI. This requires the identification of fairness metrics and mitigation algorithms designed for these tasks and thus, has been left as future work.

The Fairness Auditor is designed to be comprehensive with the flexibility to include any dataset, bias mitigation algorithm, and metrics. This includes the Deviation Metric that enables the summary of a suite of scores calculated for any metric across many scenarios. The current work lays the foundation with classification and as a future direction, can be extended to auditing bias mitigation algorithms in other Machine Learning tasks such as regression and clustering. As a future work, the auditor can also be extended to evaluate the fairness of algorithms when deployed using scenarios representing potential future deployment populations to understand model fairness and utility. As the current process of auditing using a pre-defined set of scenarios can be expensive, another future direction is the development of adversarial methods to identify scenarios where mitigation algorithms produce inaccurate or unfair results.

ABSTRACT

Growing concerns about the fairness of algorithmic decision-making systems have prompted a proliferation of mathematical formulations aimed at remedying algorithmic bias. Yet, integrating mathematical fairness alone into algorithms is insufficient to ensure their acceptance, trust, and support by humans. It is also essential to understand what humans perceive as fair. In this study, we, therefore, conduct an empirical user study into crowdworkers' algorithmic fairness perceptions, focusing on algorithmic hiring. We build on perspectives from organizational justice theory, which categorizes fairness into distributive, procedural, and interactional components. By doing so, we find that algorithmic fairness perceptions are higher when crowdworkers are provided not only with information about the algorithmic outcome but also about the decision-making process. Remarkably, we observe this effect even when the decision-making process can be considered unfair, when gender, a sensitive attribute, is used as a main feature. By showing realistic trade-offs between fairness criteria, we moreover find a preference for equalizing false negatives over equalizing selection rates amongst groups. Our findings highlight the importance of considering all components of algorithmic fairness, rather than solely treating it as an outcome distribution problem. Importantly, our study contributes to the literature on the connection between mathematical– and perceived algorithmic fairness, and highlights the potential benefits of leveraging organizational justice theory to enhance the evaluation of perceived algorithmic fairness.

1 INTRODUCTION

Artificial Intelligence systems are increasingly being used to inform and make important decisions about human lives across a wide range of high-impact domains, such as criminal law, medicine, finance, and employment [42]. While algorithmic decision-making has the potential to offer numerous promising advantages to society, such as increased efficiency and accuracy, it can also produce discriminatory or unfair outcomes [23, 32], as evidenced by several infamous cases such as COMPAS, the criminal risk assessment algorithm that was accused of being racially biased against black defendants [2], and Amazon's recruitment tool, which turned out to discriminate against female candidates [13]. Ensuring algorithmic fairness has therefore become a major area of interest within the field of artificial intelligence. This has led to the design of a whole landscape of fairness criteria and approaches to embed these into algorithms, as well as to the development of multiple bias mitigation algorithms, open-source libraries, and auditing toolkits to measure, visualize, and improve different fairness aspects [4, 6, 30, 39, 45].

However, there are still large gaps between fairness researchers and machine learning practitioners [36]. As it is impossible to mathematically satisfy all the proposed statistical fairness criteria at once since they are mutually incompatible [3, 9, 24], a universal consensus on how to ensure algorithmic fairness is lacking [44]. More knowledge about what criteria or metrics to use in what context is hence needed, which underscores the importance of approaching algorithmic fairness not only from a technical viewpoint. We need to understand what humans perceive as fair, to ensure that algorithmic decision-making systems are accepted, trusted, and supported by humans, since fairness is not purely an algorithmic concept, but a human construct [5, 7, 36, 42].

The literature on human perceptions of algorithmic fairness, however, frequently offers mixed or inconsistent results, highlighting the need for a more coherent approach to algorithmic fairness [12, 42]. Therefore, multiple studies have started to draw inspiration from organizational justice, which is concerned with fairness perceptions of decisions made about employees in organizational settings [14, 18, 19, 22, 27, 32]. Organizational justice literature divides fairness perceptions into three distinct but correlated components: distributive fairness, procedural fairness, and interactional fairness [17]. This categorization can therefore provide a solid foundation on how to systematically investigate algorithmic fairness perceptions.

However, most of the research into algorithmic fairness perceptions focuses merely on one of these three fairness components. In this work, we aim to investigate *the effect of integrating these components on algorithmic fairness perceptions.* Additionally, we investigate the link between mathematical algorithmic fairness and human perceptions of distributive fairness, by examining *whether participants have a preference for either demographic parity or equality of opportunity.* We focus on algorithmic hiring, a context that is easily comprehensible for a lay public. While this area has seen increased interest in the integration of AI-enabled software, it that has also witnessed raising concerns about the potential of AI to perpetuate or exacerbate existing biases [29, 35, 40]. As a result, it is classified as a high-risk area in the EU AI act [11]. Moreover, there is no universal agreement on how fairness should be formalized in algorithmic hiring: for instance, certain recruitment algorithms proactively aim to increase diversity when ranking job candidates, while others do not [16]. As research has demonstrated that fairness perceptions during a hiring process play a critical role in job satisfaction, performance, and the relationship between employers and employees, obtaining insights into the perceived fairness of algorithmic hiring is of particular importance [25].

Toward that end, we conduct an experiment with 225 predominantly White, native English Prolific crowdworkers from the UK, in which we examine fairness perceptions of several hypothetical recruitment algorithms. We study the following two research questions:

- **RQ1**: How do human fairness perceptions of a recruitment algorithm differ when only given information about the distributive fairness of the algorithm, compared to when given information about both the procedural fairness and the distributive fairness of the algorithm?

By grouping our participants based on the amount of information they receive about the recruitment algorithms, according to the fairness components described in organizational justice theory, we find that participants who only receive information about the distributive fairness of the algorithms have the lowest fairness perceptions. When participants receive information about both procedural and distributive algorithmic fairness, they perceive the algorithms as fairer: interestingly, we observe this effect both when the sensitive attribute gender is included as a main feature in the algorithms and when it is not.

- **RQ2**: How do human fairness perceptions of a recruitment algorithm differ depending on whether it adheres to demographic parity or equality of opportunity?

By showing participants graphs that report the trade-offs between selection rate differences and false negative rate differences between two gender groups, we find a general preference for equality of opportunity over demographic parity. By qualitatively analyzing the rationales behind participants' fairness ratings, these findings are affirmed: a larger proportion of participants states to focus on qualification and false negatives, rather than selection rates. However, most participants specifically report taking into account the trade-offs between both these fairness criteria.

In sum, our study provides valuable insights into the relationship between algorithmic fairness and human perceptions of justice. Our experimental data and code can be found on our GitHub Repository: https://github.com/GuusjeJuijn/fairness-perceptions.

2 RELATED WORK

We start by taking a mathematical perspective on algorithmic fairness, by providing a concise overview of the most common criteria for algorithmic fairness and their associated trade-offs (§2.1). Subsequently, we adopt a human perspective, by describing the empirical literature on human algorithmic fairness perceptions and discussing the components of perceived fairness from organizational justice in an algorithmic context (§2.2).

2.1 Mathematical algorithmic fairness

Algorithmic fairness is a profoundly complex and many-faceted concept, which is reflected by the large landscape of criteria that try to grasp its meaning: with over 21 established mathematical formulas for fairness in binary classification problems, researchers have not yet come to a universal consensus on how to mathematically define what it means for a decision to be fair [8]. This section summarizes the fairness criteria that are most widely adopted and relevant to our study.

2.1.1 Group fairness. Group fairness criteria focus on treating persons that belong to a protected group, defined by a sensitive attribute such as gender or race, the same as persons that belong to any other group. To capture the different formulas belonging to this class, Barocas et al. [3] propose a taxonomy of statistical non-discrimination criteria consisting of three categories: independence, separation, and sufficiency. By depicting the sensitive attribute as S, the predicted outcome (the decision) as $\hat{Y}$, and the (true) outcome as Y, these three categories can be represented as follows:

$$Independence = \hat{Y} \perp S$$

$$Separation = \hat{Y} \perp S|Y$$

$$Sufficiency = Y \perp S|\hat{Y}$$

Within independence, the most common fairness criterion is demographic parity, or disparate impact. A classifier satisfies this criterion when the percentage of favorable outcomes is equal for both the protected and unprotected group [31]. To adhere to demographic parity, the true outcome Y does not have to be known: for instance, in a hiring setting, a recruitment algorithm satisfies demographic parity between men and women when hiring an equal number of male and female candidates, regardless of their qualifications.

More complex definitions fall under separation and sufficiency. If the predicted outcome is conditionally independent of the sensitive

attribute, given the true outcome, a classifier satisfies separation [3]. Two fairness criteria falling under this category are equality of opportunity, which requires the false negative rate to be equal for both groups, and predictive equality, which requires the false positive rate to be equal for both groups [9, 21].

Lastly, if the true outcome is conditionally independent of the sensitive attribute, given the predicted outcome, a classifier satisfies sufficiency. Sufficiency hence requires equal true outcomes over people that are given similar predictions. An example of a fairness criterion satisfying sufficiency, is calibration or test fairness [44].

2.1.2 Trade-offs between fairness definitions. Following the proliferation of research into mathematical criteria to define algorithmic fairness, researchers have started to investigate the mathematical relationships between these criteria. This has exposed an important issue: satisfying all fairness criteria simultaneously is impossible, as, under mild assumptions, any two out of the three aforementioned categories of group fairness are mutually exclusive [3, 9, 24]. Practitioners are therefore faced with the challenge of selecting among different fairness criteria and their associated trade-offs. However, which choice to make is a highly context-specific and difficult task, given the subtle differences between the different criteria, as well as other factors such as the availability of sensitive features, the level of understanding of the actual outcome label, and legal or organizational restrictions [36]. Multiple scholars, therefore, state that more emphasis on the social, human side of fairness is needed: in order to develop fair AI, it is essential to understand what humans perceive as fair and to acknowledge that fairness is not merely a technical construct [15, 36, 42].

2.2 Perceived algorithmic fairness

A growing body of literature applies organizational justice theory to the topic of perceived algorithmic fairness [5, 14, 18, 19, 22, 27, 32]. Organizational justice, like algorithmic decision-making, centers around the fairness of decisions made about others in a hierarchical environment. This similarity makes organizational justice a suitable source of inspiration for studying perceived algorithmic fairness [5]. Here, we discuss some of the related work on algorithmic fairness that focuses on one of the different components of perceived fairness described in organizational justice theory.

2.2.1 Distributive algorithmic fairness. Distributive fairness refers to the fairness of outcome distributions. It is based on norms for outcome allocation, such as equality (outcomes should be distributed equally amongst everyone) and equity (opportunities should be distributed equally based on everyone's circumstances) [10, 32, 42]. Robert et al. [37] note that distributive fairness is the most commonly discussed category within AI fairness literature. This finding could be attributed to the fact that many statistical fairness criteria emphasize distributive fairness, by focusing on how outcomes are divided across groups or individuals [32]. Dolata et al. [15] refer to this conclusion as the *distributiveness assumption*: the assumption that all fairness concerns can be represented as an outcome distribution problem. Most of the empirical work on the perceived fairness of algorithm outcomes focuses on basic fairness concepts, such as equality and equity [42]. However, only a handful of studies on distributive algorithmic fairness focus on the perceived fairness of particular mathematical fairness criteria specifically [22, 41].

Srivastava et al. [41] conduct an experiment to identify the mathematical fairness criterion that best captures crowdworkers' perceptions of fairness. By letting participants choose between a succession of model pairs, showing the predictions and true outcomes of a medical risk and criminal risk prediction algorithm, they find that participants prefer demographic parity over more complicated definitions, such as error parity and equal false positive rates. This finding suggests that humans exhibit a preference for fairness definitions that are more simplistic in nature.

However, Harrison et al. [22] draw different conclusions. They perform a between-subjects experiment in a bail decision-making context, in which they let participants judge the fairness of two models with pairwise fairness trade-offs. They identify two interesting fairness preferences: first, subjects favor equalizing the false positive rate over equalizing the accuracy across groups. Second, subjects also favor equalizing the false positive rate over equalizing the percentage of favorable outcomes (i.e., having demographic parity) across groups.

This latter result is in contrast with that of Srivastava et al., raising questions about the effect of different visualizations and ways of presenting information on participants' fairness perceptions.

2.2.2 Procedural algorithmic fairness. Unlike distributive fairness, procedural fairness focuses on the fairness of the decision-making process rather than the outcome. Morse et al. [32] investigate the procedural fairness of five popular mathematical fairness criteria along the six components of procedural fairness originally described by Leventhal [28]: consistency, bias suppression, representativeness, correctability, accuracy, and ethicality. By relating the fairness criteria to these different components, they provide directions for choosing the right criterion per situation and provide a fundament for better understanding and assessing the procedural fairness of these fairness metrics: they, for example, reason that equality of opportunity and equalized odds are criteria with a high level of procedural fairness [32].

Grgic-Hlaca et al. [18] take a different approach to investigate procedural algorithmic fairness: they seek to identify feature properties that influence the perceived fairness of using certain features as input for an algorithmic decision-making model. By investigating participants' assessments of different feature properties, they find that participants consider a feature's perceived relevance and reliability most important. As these feature properties are unrelated to discrimination, Grgíc-Hlaca et al. conclude that procedural unfairness concerns reach far beyond discrimination only and that therefore, other feature properties should also be taken into account when assessing algorithmic fairness.

Other authors explore the perceived procedural fairness of including certain features in an algorithm. Pierson [34], for example, finds that men are more likely to include gender as an attribute in an education recommendation algorithm, compared to women. Grgić-Hlača et al. [20] moreover find that men perceive the inclusion of race as a feature as more fair compared to women.

2.2.3 Interactional algorithmic fairness. Lastly, interactional fairness refers to providing sufficient information and giving truthful

explanations about decision procedures. It is concerned with presenting people with adequate information about the process of how a decision is reached and is therefore closely related to procedural fairness[1] [5, 10]. In an organizational justice setting, an example of interactional fairness is providing employees explanations for layoff decisions: it has been shown that if employees receive honest, thorough, and accurate explanations when being fired, they perceive these decisions as significantly fairer [27].

Multiple studies investigate the effect of explanations for decisions on perceived algorithmic fairness. For example, by performing a user study in a criminal risk setting, Dodge et al. [14] find that feature importance-based explanations and demographic-based explanations increase participants' algorithmic fairness perceptions. In an online user study in a medical decision-making context, Angerschmid et al. [1] also find a positive effect of feature importance-based explanations on perceived algorithmic fairness. These insights will be leveraged in **RQ1** of our study.

3 METHODOLOGY

Our methodology is two-folded. We first created machine learning models that adhered to different fairness criteria (§3.1). We then conducted an online user study in which participants judged the fairness of these models (§3.2).

3.1 Model development

We first trained machine learning models on the Utrecht Fairness Recruitment dataset[2]. As this data set was specifically designed to mimic realistic recruiting data and to demonstrate fairness issues, and did not contain any missing values or ambiguous features, we considered it an appropriate data set for the purposes of our user study. The data set contained information about the recruitment decisions of four hypothetical companies. We split the data from one company into a training set (750 instances) and a testing set (250 instances). Using Scikit-learn [33], we trained three logistic regression models, using default parameters, to predict whether an individual in the data set was hired by the company or not. We trained one original, raw model, one model mitigated for demographic parity, and one model mitigated for equality of opportunity. Bias mitigation was applied using the ThresholdOptimizer algorithm[3] from Microsoft FairLearn [6]. This postprocessing algorithm, introduced by Hardt et al. [21], adjusts a learned classifier by applying group-specific thresholds, to satisfy a specified fairness constraint.

Postprocessing for demographic parity and equality of opportunity specifically was done for several reasons. First of all, multiple studies suggest that both of these criteria are appropriate for algorithmic hiring, the context we focus on in our empirical study [16, 26, 32, 35]. Mitigating for demographic parity, moreover, allowed for further investigation of the results of Srivastava et al. [41], who found that lay people tend to have a preference for this criterion in different contexts. Besides, as demographic parity is often used in practice and relatively easy to understand, we considered this to be a suitable criterion for this study [38]. Since, according to Morse et al. [32], equality of opportunity scores high on procedural fairness, we considered this a second suitable criterion. The accuracies and fairness metrics of all three classifiers are reported in Table 1. Although the mitigated models did not perfectly meet the proposed criteria, postprocessing substantially decreased the differences in either selection rates or false negative rates between groups.

3.2 Empirical study

To assess our research questions, we performed an online experiment on the crowdsourcing platform Prolific Academic using Qualtrics survey software. The survey was distributed at the end of January 2023. Here, we outline our study design, survey structure, and participant demographics.

3.2.1 Study Design. Participants' fairness perceptions of several hypothetical recruitment algorithms were assessed using a direct measure based on Harrison et al. [22], asking *"Do you think this algorithm is fair?"*. To ensure that every participant had a similar definition in mind, we provided them with a fairness definition by Mehrabi et al. [31]: *"Fairness is the absence of any prejudice or favoritism towards an individual or a group based on their intrinsic or acquired traits"*. Participants were asked to provide a judgment on a 7-point Likert scale, ranging from 1 ("not at all fair") to 7 ("completely fair"). Additionally, at the end of the survey, participants were asked to elaborate on the motivations behind their ratings through an open-ended query, asking *"In the previous questions, which factors did you consider most important in determining whether an algorithm was fair or unfair?"*. This was done to qualitatively investigate the rationales behind the respondents' fairness perceptions.

Each participant was presented with five different graphs representing algorithms, of which the selection rates and false negative rates were based on the logistic regression models described in §3.1. In these graphs, the selection rates were defined as the proportion of hired candidates, while the false negative rates were defined as the proportion of qualified candidates who were not hired. We explicitly opted to describe the figures in this way, as we anticipated that the terms 'selection rate' and 'false negative rate' would not be easily comprehensible to participants without machine learning knowledge.

One of these five algorithms represented the original, unmitigated model. Two of these algorithms represented demographic parity: one perfectly following the criterion and one representing the mitigated model. Two of these algorithms represented equality of opportunity: again, one perfectly following the criterion and one representing the mitigated model.

Participants were divided into three groups. The amount of information participants received about these algorithms differed per group, based on the fairness components described in organizational justice theory. We considered procedural and interactional fairness together, due to the strong connection and overlap between these two components.

Group 1: distributive fairness. The first group only received information about the distributive fairness of the algorithms. This was visualized as a graph representing the algorithm outcomes,

[1] In our empirical study, we, therefore, choose to consider procedural and interactional fairness together.

Table 1: Fairness metrics of the original model, the demographic parity-mitigated model and the equality of opportunity-mitigated model

Model	Gender	Accuracy	Selection Rate	False Negative Rate
Original	Female	0.918	0.123	0.333
	Male	0.847	0.468	0.158
	Difference	*0.071*	*0.335*	*0.175*
Demographic parity-mitigated	Female	0.839	0.197	0.133
	Male	0.742	0.250	0.509
	Difference	*0.151*	*0.035*	*0.376*
Equality of opportunity-mitigated	Female	0.926	0.164	0.133
	Male	0.847	0.468	0.158
	Difference	*0.079*	*0.304*	*0.025*

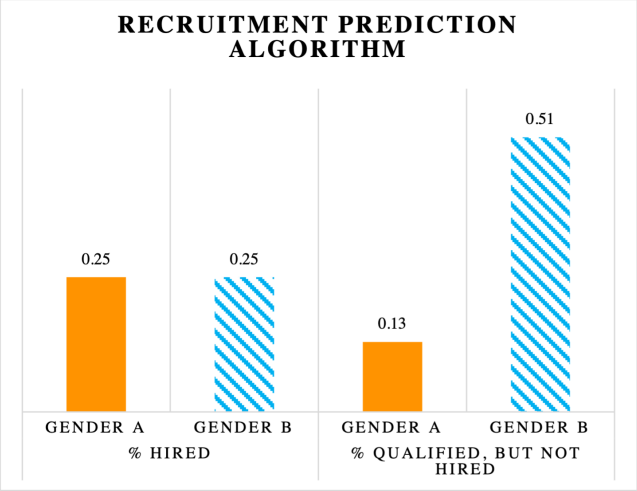

Figure 1: Example outcome graph, representing distributive fairness, showed to each participant. On the left, the selection rates are shown. On the right, the false negative rates are shown. This algorithm adheres to demographic parity but not to equality of opportunity.

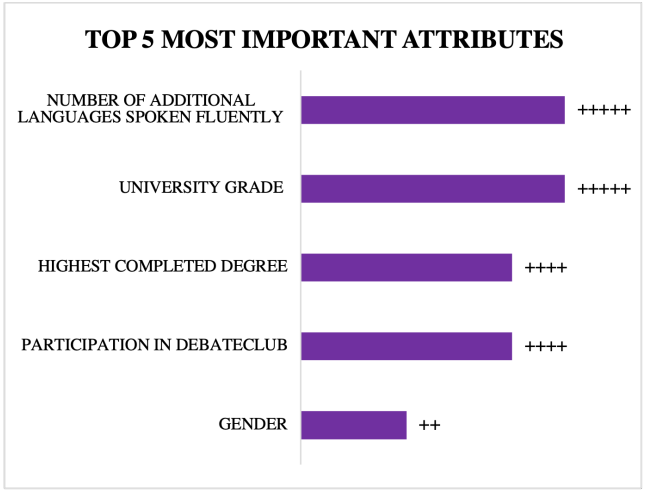

Figure 2: Feature importance graph shown to group 2, representing procedural fairness. The graph shown to group 3 was the same, except for the sensitive attribute 'gender' being changed for the non-sensitive attribute 'exact study'.

showing a pairwise trade-off between the selection rates and false negative rates between two gender groups. Instead of only showing one aspect of algorithmic fairness, by, for example, only showing the difference in false negative rates between groups, we chose to represent a more realistic real-world scenario by showing the trade-offs between different fairness criteria. By doing so, we drew inspiration from the work of Harrison et al. [22]. We explicitly chose to rename the two gender groups into *Gender A* and *Gender B*, to limit the effect of implicit biases regarding gender roles. An example of a graph representing distributive fairness is shown in Figure 1.[4]

[4]We first piloted these graphs amongst colleagues, to make sure they were clear enough to interpret.

Group 2: distributive and procedural fairness, with sensitive attribute. The second group not only received information about the distributive fairness of the algorithms, but also about the procedural fairness of the algorithms. Like Grgic-Hlaca et al. [18], we considered the features used by the algorithm as an important aspect of procedural fairness. Therefore, we visualized procedural fairness as a feature importance explanation. Like Dodge et al. [14], we presented the feature coefficients of the logistic regression models as strings of '+'s representing the relative importance of each feature. To limit the amount of information, we only showed the top five most influential features. For each of the algorithms, the feature importance graph stayed the same, as postprocessing does not change the model coefficients. Figure 2 displays the feature importance graph shown to the participants of group 2.

Group 3: distributive and procedural fairness, without sensitive attribute. The information provided to group 3 was almost identical to that of group 2, except for a small change in the feature importance graph. In this group, we changed the attribute *'gender'* into a less sensitive attribute, with a similarly high feature coefficient, *'exact study'*. We included this group in our study to make sure that potential differences in fairness perceptions between the groups could not only be attributed to the use of the sensitive feature *gender* as an attribute.

3.2.2 Survey Structure. After signing a consent form, participants were shown an introductory text. The purpose of this text was to introduce the topic of algorithmic fairness, clarify the task, present the context, and demonstrate a sample graph to ensure that the participants could properly interpret the visual representations. Each participant was then randomly assigned to one of the three groups. The participants were divided evenly across the groups to ensure that each group had an equal number of participants. Within each group, every participant was asked to rate the fairness of five different recruitment algorithms: one representing the original, unmitigated model, two adhering to demographic parity, and two adhering to equality of opportunity. These algorithms were presented in a randomized order to limit order effects. After these five questions, participants were asked to write down which factors they considered most important in their fairness analysis. The survey ended with demographic questions and a message thanking the participants for their time and giving them a completion code to register their submission in Prolific. Figure 3 shows an overview of the experimental flow.

3.2.3 Participants. Participants were pre-screened on having obtained at least a high school diploma, having English as a first language, and residing in the UK. We rewarded them with £10,84 per hour, conforming to the minimum wage in the UK. On average, the survey took 4.2 minutes to complete. By manually checking the response times, data from participants that took less than 2 minutes to complete the survey were deleted to ensure the quality of answers. In total, data from 225 participants were used. Table 2 summarizes our participants' demographics[5].

Table 2: Participants' demographics

		% (n=225)
Gender	Female	50%
	Male	50%
	Other	<1%
Age	18–30	33%
	30–45	35%
	45–60	22%
	60+	10%
Race/ethnicity	White	92%
	Asian	4%
	Mixed	3%
	Black	1%
Education	High school diploma	54%
	Technical/community college	40%
	Undergraduate degree	5%
	Graduate degree	<1%
	Doctorate degree (PhD/other)	<1%

4 RESULTS

4.1 Quantitative Analysis

4.1.1 ***RQ1***. First, we considered the effect of the type of information given about the algorithms on participants' fairness perceptions. For each of the three groups, we computed the average fairness perceptions of the original algorithm, the algorithms representing demographic parity, and the algorithms representing equality of opportunity. As shown in Figure 4, participants who received information about both the distributive and procedural fairness of the algorithms (groups 2 and 3) consistently perceived the algorithms as fairer compared to participants who only received information about the distributive fairness of the algorithms (group 1). We observed this effect in both groups 2 and 3, although fairness perceptions were generally higher in group 3, in which the sensitive attribute gender was not included as a main attribute in the feature importance graph.

Table 3 reports the results of a Kruskal-Wallis H test (a non-parametric variant of the ANOVA test to compare multiple groups), followed by a multiple comparisons post-hoc Dunn test, to test for significant differences between the three groups. The tests were performed separately for the different algorithms (the original algorithm, the algorithms adhering to demographic parity, and the algorithms adhering to equality of opportunity). Results indicated significant differences between groups 1 and 2, and groups 1 and 3, for all algorithms. Differences between groups 2 and 3 were not significant.

4.1.2 ***RQ2***. Next, we investigated whether participants preferred either demographic parity or equality of opportunity. For each of the three groups, we computed the average fairness perceptions of the algorithms representing demographic parity and the average fairness perceptions of the algorithms representing equality of opportunity. Figure 5 shows that across all three groups, participants tended to have a preference for the algorithms representing equality of opportunity. A Wilcoxon-Signed Rank test (a non-parametric variant of the paired t-test) indicated that in groups 2 and 3, the average perceived fairness scores for the algorithms representing equality of opportunity were significantly higher than the average perceived fairness scores for the algorithms representing demographic parity *($W = 601.5$, $p = 0.013$* and *$W = 636.5$, $p = 0.016$* respectively). However, in group 1, these differences were not statistically significant *($W = 777.0$, $p = 0.541$)*.

4.1.3 ***Gender differences***. Additionally, we examined potential differences in average scores among male and female participants. Of all three groups, for each algorithm, we compared the average scores between men and women, using a Mann-Whitney U-test (a non-parametric variant of the independent t-test). However, the results of these tests did not reveal any significant differences.

[5]Age and race were automatically collected by Prolific. Our survey additionally asked for gender and the highest level of education obtained.

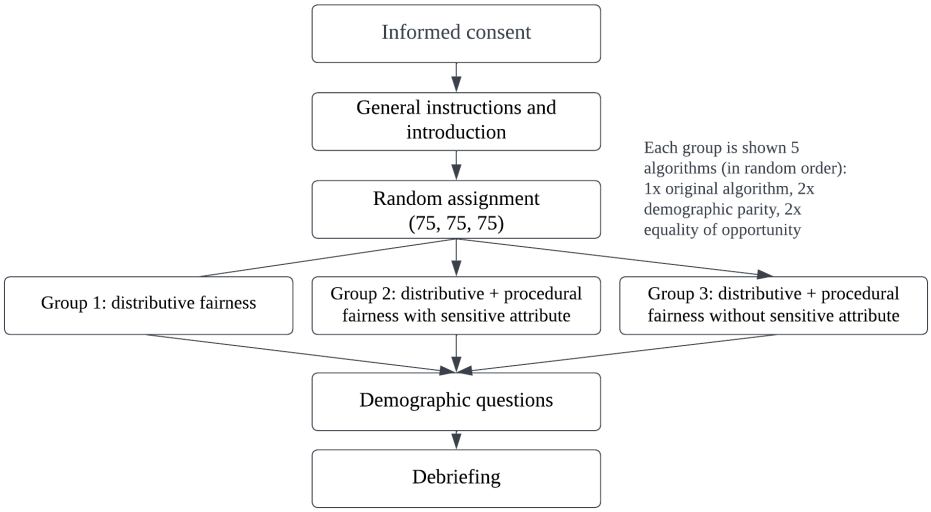

Figure 3: Experimental Flow

Table 3: Results of Kruskal-Wallis H test and post-hoc Dunn test to test for significant differences between the three groups. P-values are in italics if results are significant at α=0.05. Results of the Kruskal-Wallis H test indicate that the average scores, for all algorithms, differ significantly across groups. Pairwise comparisons by Dunn's test show that differences between groups 1 and 2, and 1 and 3, are significant at α=0.05. Differences between groups 2 and 3 are not significant.

Algorithm	Kruskal-Wallis H test		Dunn's Multiple Comparisons test		
			Groups 1-2	Groups 1-3	Groups 2-3
	H	p	p	p	p
Original	10.691	*0.005*	*0.009*	*0.003*	0.715
Demographic Parity	8.452	*0.014*	*0.044*	*0.005*	0.419
Equality of Opportunity	18.127	*<0.001*	*0.001*	*<0.001*	0.468

4.2 Qualitative Analysis

To gain additional insights into the findings of our quantitative analysis, we qualitatively analyzed participants' rationales behind their fairness ratings by openly coding their responses to the open-ended question of which factors they considered most important in determining the fairness of the algorithms. Although each participant provided an explanation, we encountered a variety of response lengths: responses varied in length between 1 word and 59 words, with a mean of 12 words and a median of 9 words. By first identifying first-order codes out of these responses and grouping these into second-order codes, we systematically classified the responses. Figure 6 gives an overview of these categories and provides, per category, an indicative quote. Two annotators independently reviewed the responses. In 80% of the cases, they initially agreed. The remaining 20% of responses were assigned a final classification after a discussion between the annotators. For 9% of the responses, no clear category was identified (e.g.: *"If it looked fair or not", "All combined"*). In 4 responses, multiple categories were mentioned. In these cases, our approach was to classify the response based on the category mentioned first.

We now discuss some of the responses falling under the two second-order codes we identified: distributive fairness and procedural fairness.

4.2.1 Distributive fairness. While we encountered a variety of answers, the biggest proportion of explanations (n=164, 73%) could be attributed to the outcome of the algorithms, relating to the concept of distributive fairness. This was as expected, as only two out of three groups received a feature importance graph, and all three groups received information about distributive fairness. However, interestingly, we observed that across all three groups, the majority of participants focused on distributive fairness rather than procedural fairness (82% of all answers in group 1, 61% of all answers in group 2, and 76% of all answers in group 3).

More specifically, across all three groups, we found that most participants (n=68) emphasized the importance of considering the trade-offs between the different fairness criteria shown in the graphs. For example, P45 (group 1), stated: *"I mainly looked at the proportions between genders of those qualified but not hired in comparison to the genders when hired"*. The second most frequently mentioned category pertained to the concept of equal opportunity:

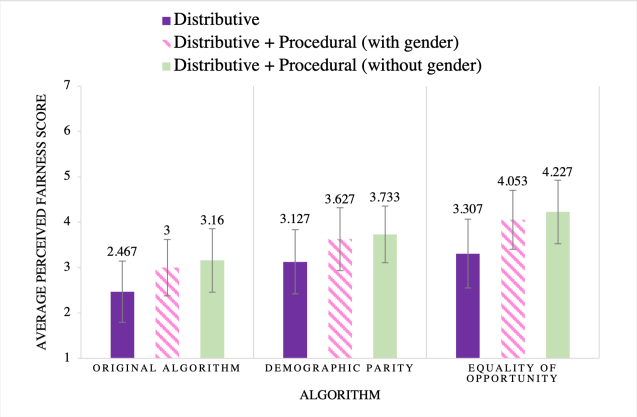

Figure 4: Average perceived fairness scores, on a 7-point Likert scale, of each of the three groups. Error bars indicate standard deviations. Bar graphs show that the group that only received information about the distributive fairness of the algorithms rated each of the three algorithms lower than the groups that also received information about the procedural fairness of the algorithms. In the group in which gender was not a main attribute, fairness perceptions were highest.

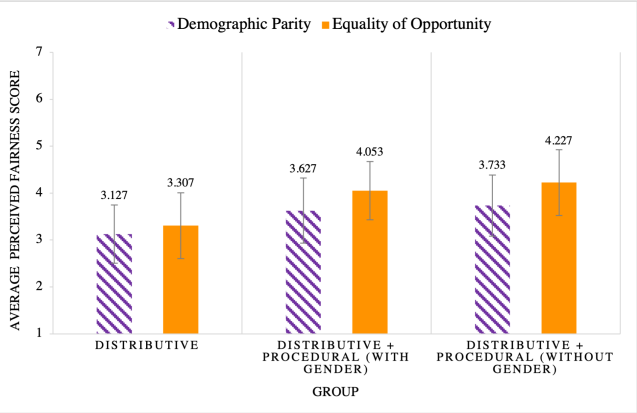

Figure 5: Average perceived fairness scores, on a 7-point Likert scale, of the algorithms adhering to demographic parity and equality of opportunity. Error bars indicate standard deviations. Bar graphs show that across all three groups, algorithms adhering to equality of opportunity were rated higher compared to algorithms adhering to demographic parity.

a notable proportion of participants (n=53) mainly focused on false negative rates and the qualifications of candidates. This finding suggests a preference for fairness criteria that consider the actual outcome. For example, P18 (group 1) answered: *"The percentage that was qualified but not hired was the most important factor for me"*. Nevertheless, there was also a considerable number of participants (n=43) that primarily considered the selection rates of both groups, e.g.: *"Whether the hired % of candidates were as equal as possible"* (P38, group 2). However, across all three groups, this category, associated with demographic parity, was mentioned less frequently than the category relating to equal opportunity.

4.2.2 Procedural fairness. 18% of answers (n=41) could be attributed to the decision-making process, and therefore, to the concept of procedural fairness (7% of all answers in group 1, 27% of all answers in group 2, and 21% of all answers in group 3).

The majority of these responses (n=34) were related to the features used by the algorithms and their relative importance. For example, in group 2, in which gender was included as a main attribute in the feature importance graph, we encountered 11 answers that explicitly criticized its usage, e.g.: *"I marked them all low as I don't see why gender would be an important factor "* (P68, group 2). Other participants mainly focused on the importance or combination of the different attributes, e.g., *"The 5 main attributes were the main thing I considered"* (P52, group 2).

Apart from the procedural fairness of using certain features, some participants did not provide reasons specific to the information shown in the graphs but criticized the use of algorithms for hiring in general (n=7). For example, P70 (group 3), wrote: *"I don't believe this kind of selection is fair in any circumstances"*, and P31 (group 1) stated: *"I don't find the process fair as I believe the candidate should have a formal interview rather than just basing the hire on grades and qualifications"*.

5 DISCUSSION

Previous studies on algorithmic fairness perceptions have primarily focused on either distributive fairness, procedural fairness, or interactional fairness in isolation. However, our results highlight *the need to consider the interplay between these different fairness components* in research into fair AI.

By considering the importance of different features used by a model as a key aspect of procedural fairness, our main finding is that **participants who receive information about both the distributive and procedural fairness of an algorithm, perceive it as fairer, than participants who only receive information about the distributive fairness of an algorithm**. Surprisingly, even when gender, a sensitive attribute, is included as a primary attribute in the algorithms, we still observe this effect, despite a substantial number of participants citing it as unfair in the open-ended question.

Our findings underscore the potential consequences of adopting the *distributiveness assumption* as described by Dolata et al. [15], as we show that solely representing algorithmic fairness as an outcome distribution issue can lead to lower perceptions of fairness. Our results suggest that providing more information about the workings of an algorithm can enhance fairness perceptions. This is consistent with the results of Dodge et al. [14] and Angerschmid et al. [1], who found that feature importance-based explanations have a positive impact on algorithmic fairness perceptions.

Furthermore, our work provides empirical insights into how mathematical fairness criteria are related to human algorithmic fairness perceptions. By measuring and comparing participants' fairness perceptions of recruitment algorithms adhering to two

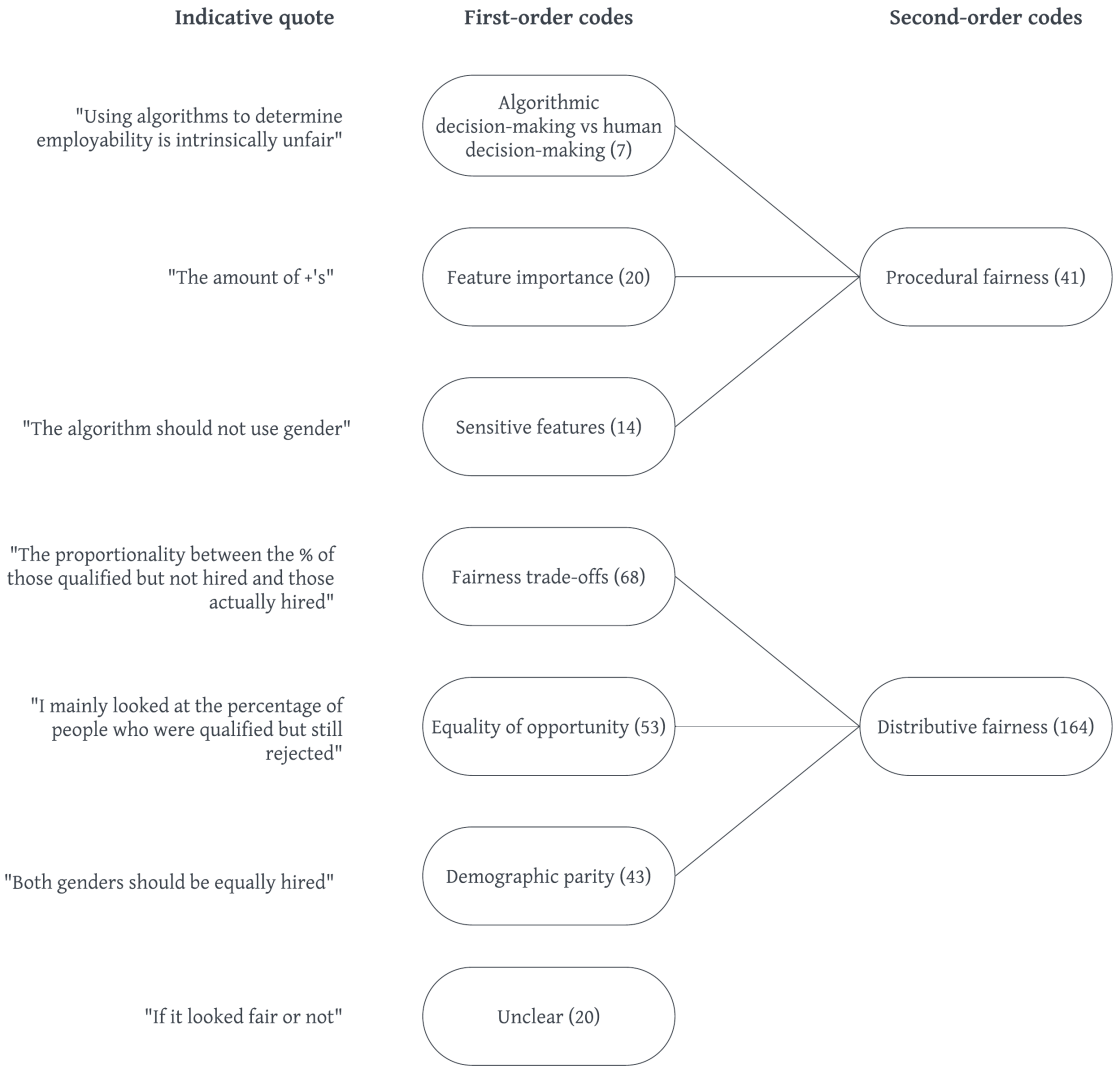

Figure 6: Indicative quotes, first-order codes, and second-order codes for the open-ended question: *"Which factors did you consider most important in determining whether a model was fair or unfair?"*

different algorithmic fairness criteria, we find **a significant preference for equality of opportunity over demographic parity**, when given information about both the distributive and procedural fairness of the algorithms. These findings are affirmed in our qualitative analysis, in which we note that a larger proportion of participants assigns greater importance to false negative rates when forming their fairness judgments, as opposed to (equal) selection rates among genders.

Our results are in contrast with the preference for demographic parity found by Srivastava et al. [41]. As they focus on a medical risk prediction and criminal risk prediction setting, rather than hiring, these varying contexts could be a possible reason behind these contrasting findings. For instance, decision-making in medical and criminal risk settings may involve higher stakes compared to hiring. Moreover, these settings may not capture the imagination as much as hiring does, possibly leading to different fairness judgements. It is, however, also plausible that these contrasting results can be explained by the varying methods of visualizing fairness issues. Where Srivastava et al. [41] represent their algorithms by showing the individual outcomes of ten decision subjects, we report the trade-offs between two fairness criteria. Moreover, while all participants in the study of Srivastava et al. [41] are solely provided with information about the algorithmic outcomes, relating to the concept of distributive fairness, two-thirds of our participants also receive information about the procedural fairness of the algorithms.

Another potential explanation for our findings could be associated with the participants' levels of comprehension of the fairness criteria. In a study into lay people's understanding of mathematical fairness criteria, interestingly, Saha et al. [38] find that participants' comprehension of equality of opportunity is lower compared to their comprehension of demographic parity. Additionally, they observe that participants who score higher on comprehension tend to have lower fairness perceptions. In line with this reasoning, a possible explanation for our findings is that our participants had a better understanding of the algorithms adhering to demographic parity compared to the algorithms adhering to equality of opportunity. This could have resulted in assigning a lower score to the algorithms adhering to demographic parity.

Limitations. Our study has several limitations. First, we conducted our study with crowdworkers. Although we pre-selected them on having obtained at least a high-school diploma, we can not completely rule out the possibility of some participants not understanding or being able to correctly interpret the trade-offs being shown. We tried to keep our visualizations as straightforward as possible by showing bar graphs but acknowledge the possible difficulty of the task. As our results were consistent amongst groups, we however believe our results correctly reflect the intuitions of our participants.

A second limitation pertains to our approach to describing false negative algorithmic predictions in terms of qualifications. We used synthetic data in our experiments. However, in real-world hiring scenarios, determining whether candidates are 'qualified' is a subjective decision, susceptible to different types of biases. It is important to acknowledge that a real-world hiring scenario encompasses a much greater level of complexity, in which qualifications may never be assessed with complete certainty.

A third limitation relates to the features used by our models. As our data set did not indicate what kind of companies it considered, some participants mentioned they did not fully understand the particular selection of the top five most important attributes. Moreover, since we used postprocessing bias mitigation, the feature importance graph stayed the same across all algorithms, which could possibly have caused some confusion. We did this, however, to ensure the validity of studying the differences between groups. Future research could investigate the effect of different levels of feature importance on participants' fairness perceptions.

A final limitation relates to our participants' demographics. While we had an even distribution of male and female participants, the vast majority of our participants were White. Future research should aim to expand the representation of racial groups, to mitigate the risk of developing a one-sided and potentially biased understanding of perceived algorithmic fairness.

Future Directions. Our results emphasize that understanding algorithmic fairness perceptions requires careful consideration of both visualization and contextual factors. Suggestions for future work, therefore, include:

- Exploring the effect of presenting various visualizations, and offering additional context about the decision-making process, on participants' algorithmic fairness evaluations. Van Berkel et al. [43], for example, take a useful start in this direction, by evaluating the effect of scatterplot and text-based visualizations of algorithmic outcomes on fairness perceptions.
- Assessing participants' algorithmic fairness perceptions using implicit measures, rather than explicitly asking whether they think an algorithm is fair. Implementing such a design could potentially reduce the influence of cognitive biases and response biases, such as social desirability bias.
- Investigating participants' preferred mathematical fairness criteria in multiple contexts, besides algorithmic hiring. For instance, a future study could categorize various contexts based on the risk-oriented approach of the AI act, which categorizes AI systems into 4 levels: unacceptable, high, minimal, or low risk [11]. Such a study could then examine whether participants' preferences for certain fairness criteria in different contexts vary based on these different levels of risk.
- Studying whether participants' fairness perceptions are affected by receiving additional information about an algorithm, by conducting a within-subjects study, as opposed to a between-subjects study. For example, one approach could involve presenting participants with information about the distributive fairness of an algorithm, followed by information about its procedural fairness. By asking for their fairness perceptions at these two points in time, it could be investigated whether providing information about procedural fairness *alters* fairness perceptions.

6 CONCLUSION

In this study, we approach the topic of perceived algorithmic fairness through the lens of organizational justice theory, using algorithmic hiring as a case study. Our key finding is that providing information about the procedural fairness of an algorithm increases fairness perceptions, even when the process can be considered unfair. We moreover find a preference for equality of opportunity over demographic parity, when given information about the distributive and procedural fairness of an algorithm. Our results highlight the interplay between the different components of fairness in organizational justice theory, and the relationship between mathematical algorithmic fairness and perceived algorithmic fairness. By performing an empirical study amongst crowdworkers, we add to the growing body of literature on public perceptions of algorithmic fairness and provide important directions for future research.

ABSTRACT

Text-to-Image (T2I) generation is enabling new applications that support creators, designers, and general end users of productivity software by generating illustrative content with high photorealism starting from a given descriptive text as a prompt. Such models are however trained on massive amounts of web data, which surfaces the peril of potential harmful biases that may leak in the generation process itself. In this paper, we take a multi-dimensional approach to studying and quantifying common social biases as reflected in the generated images, by focusing on how *occupations*, *personality traits*, and *everyday situations* are depicted across representations of (perceived) *gender*, *age*, *race*, and *geographical location*. Through an extensive set of both automated and human evaluation experiments we present findings for two popular T2I models: DALLE-v2 and Stable Diffusion. Our results reveal that there exist severe occupational biases of neutral prompts majorly excluding groups of people from results for both models. Such biases can get mitigated by increasing the amount of specification in the prompt itself, although the prompting mitigation will not address discrepancies in image quality or other usages of the model or its representations in other scenarios. Further, we observe personality traits being associated with only a limited set of people at the intersection of race, gender, and age. Finally, an analysis of geographical location representations on everyday situations (e.g., park, food, weddings) shows that for most situations, images generated through default location-neutral prompts are closer and more similar to images generated for locations of United States and Germany.

1 INTRODUCTION

Recent progress in learning large Text-to-Image (T2I) generation models from <image, caption> pairs has created new opportunities for improving user productivity in areas like design, document processing, image search, and entertainment. Several models have been proposed, with impressive photorealism properties: DALLE-v2 [22], Stable Diffusion [23], and Imagen [24]. Despite architectural variations amongst them, all such models have one aspect in common: they are trained on massive amounts of data crawled from the Internet. For proprietary models, the exact datasets used for training are currently not available to the research community (e.g., DALLE-v2 and Imagen). In other cases (e.g., Stable Diffusion) the training data originates from open-source initiatives such as LAION-400 and -5B [25, 26]. What does it mean however to release, consume, and use a model that is trained on large, non-curated, and partially non-public web data? Previous work has shown that datasets filtered from the web and search engines can suffer from bias, lack of representation for minority groups and cultures, and harmful content [4, 8, 11, 12, 17, 18, 20]. Such biases may then make their way to AI-generated content and be resurfaced again, creating therefore a confirmatory process that can propagate known issues in ways that erase or undo previous mitigation efforts.

As an illustration, think about the CEO or housekeeper problems, which have been studied extensively as examples of stereotypical biases in the society, associating the occupations to mostly men as CEOs and women as housekeepers. For all such examples, there exist three different views: i) the real-world distribution across different dimensions (e.g., gender, race, age) based on labor statistics, ii) the distribution as shown in search engine results, and more recently iii) the distribution as shown in image generation results. As a glimpse to our results, Figure 1 shows the representation of

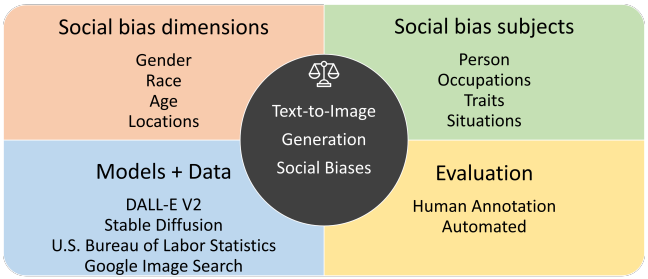

Figure 2: Quantifying representational fairness of Text-to-Image models on occupations, personality traits, and everyday situations.

women for five occupation examples. In all these cases, we observe that image generation models create a major setback on representational fairness when compared to data from the U.S. Bureau of Labor Statistics (BLS) and even Google Image Search (GIS). Occupations like CEO and computer programmer have almost 0% representation on women for images generated by DALLE-v2, and other occupations like nurse and housekeeper have almost 100% representation on women for images generated by Stable Diffusion.

In this work, we set to systematically quantify the extent of representational biases in large vision and language generation models (Figure 2). Results shown in this paper are intended to inform technology and policy makers about major trends in representational fairness issues observed in recently developed models. Our method studies two models (DALLE-v2 and Stable Diffusion v1) across four social bias dimensions (*gender*, *race*, *age*, and *geographical location*). To observe bias in generated content, we use prompts that describe *occupations* (e.g., doctor, housekeeper) *personality traits* (e.g., an energetic person), *everyday situations* (e.g., concert, dinner), and simply the "person" prompt. For occupations and personality traits prompts, we study representation across the different dimensions through both automated and crowdsourced human evaluation. First, we look at representation on default, neutral prompts that do not specify gender, age, or race. Then, we expand the prompts with these dimensions (e.g., a male housekeeper, a black engineer) to see how much of the bias could be mitigated through prompt expansion and whether there exist other discrepancies besides representations, such as discrepancies in image quality. Note that, both aspects of representation fairness are important. Default neutral prompts enable us to analyze bias without the interference of prompt crafting, which is important when model embeddings are used for tasks other than image generation (e.g., classification, question answering). Expanded prompts help estimating the effectiveness of mitigation techniques for generation or search, which is a commonly used technique for results diversification in web search [7, 28].

For prompts related to everyday situations, we use both default and location-specific prompts describing situations in categories such as: events, food, institutions, clothing, places, community. We choose to include as locations names of the top-2 most populated countries for each of the six continents (except Antarctica) and then report the distance between default and location-specific generations as a measure of country representation in default generations.

Results from this study show that while both models under analysis exhibit major biases, these biases are not always the same in nature and representation ratios. For example, while DALLE-v2 tends to generate more white, younger (age 18-40) men, Stable Diffusion v1 generates more white women and is more balanced on age representation. Similarly, while both models reinforce and exacerbate stereotypical occupational and personality traits biases, DALLE-v2 seems to suffer more from extreme cases where the distribution contains almost no representation from a given gender or race. However, results on both models also show that prompt expansion strategies can be effective for diversification, with a handful of examples where they do not help, and more examples of occupations where prompt expansion leads to discrepancies in image quality between gendered prompts. Finally, across everyday situations and countries, we see that countries like Nigeria, Ethiopia, India (for Stable Diffusion only), Papua New Guinea, Columbia are the farthest from default generations, and countries like USA, Australia, and Germany are the closest.

The rest of the paper is organized as follows. Section 2 situates this study in the context of previous work. Section 3 details the experimental method with respect to image generation and data annotation with automated and crowdsourced labels. Section 4 presents results for all aspects mentioned in Figure 2, and Section 5 discusses takeaways and future directions.

2 RELATED WORK

Social Bias in Image Search. While search engines have improved the speed and convenience of accessing information, studies have uncovered gender and racial biases in the results. Previous work [13] analyzed the representation of gender in image search results for occupational queries, comparing the results to U.S. BLS 2015 data. Additionally, the study evaluated the ways in which men and women were depicted in the images. The findings showed that the images displayed in the results slightly magnified gender stereotypes, exhibit a slight under-representation of women, such that an occupation with 50% women in BLS would be expected to have about 45% women in the results on average, and portrayed the less represented gender in a less professional manner. A follow up study [19] expanded upon these results to determine if underrepresented races were also depicted poorly in image search results. Their findings indicated that women were still underrepresented in image search in 2020, just as they were in 2015. Additionally, individuals of color were also shown to be underrepresented. Several more recent studies have shown similar results while studying different search engines and dimensions of bias [8, 27] including geographical location [17]. This work instead studies biases of image generation methods from text and shows that in many ways, these models are a step back on improving representational fairness and exhibit more severe biases than even image search.

Text-to-Image Generative Models. Several text-to-image models trained from large <image, caption> pairs corpora [25, 26] have been recently introduced and deployed in applications. DALLE-v2 [22], can generate high-quality images based on textual descriptions. This is achieved by employing CLIP embeddings [21], which bridge the gap between the textual and visual domains. The generation process involves a combination of up-sampling and convolutional

Table 1: Summary of study results.

Bias Subjects	Gender	Race	Age
Person	DALLE-v2 (Figure 5) has a higher representation of male individuals (70%) while SD displays a gender bias towards female individuals (66% of images depict females).	The generated images from both models demonstrate (Figure 6) a higher frequency of individuals of the white race, with a minimum of 70% of images for this group.	SD (Figure 7) has a more diverse representation of ages. DALLE-v2 tends to depict younger individuals most frequently. Specifically, 76% of images generated by DALLE-v2 depict adults aged 18-40.
Occupations	• DALLE-v2 (Figure 9) accentuates gender under-representation of women in several occupations when compared to BLS data, including technical writer, optician, bartender, and bus driver, while over-representing them in customer service representative, primary school teacher, and telemarketer. • Similarly, SD accentuates gender under-representation women in occupations like technical writer, bartender, telemarketer, and custodian but over-represents them in PR person, pilot, police officer, and author. • Only eight and seven of the 43 evaluated occupations in DALLE-v2 and SD's output, respectively, have proportions of female individuals within +5% of the corresponding labor statistics.	Several race groups were found to be under-represented or over-represented by significant margins in both datasets. Additionally, a significant proportion of occupations had zero representation (Figure 21) of black workers (DALLE-v2 – 72%, SD - 37%), with some race groups being under-represented or over-represented by at least 20%.	• For DALLE-v2, images corresponding to administrative assistant, customer service representative, receptionist, electrician, and nurse occupations were dominated by individuals aged 18-40, with a minimum representation of 96%. In contrast, the 40-60 age group dominated truck driver and CEO occupations, with a minimum representation of 78%. The over 60 age group was prominent in clergy member and tax collector occupations. • For Stable Diffusion, bartender, computer programmer, telemarketer, and electrician occupations were dominated by individuals aged 18-40, with a minimum representation of 98%. CEO, custodian, and clergy member occupations were dominated by individuals aged 40-60, with a minimum representation of 60%. The over 60 age group was prominent in the occupation of bus driver.
Expanded Prompts	Gendered prompts may not fully mitigate gender bias in image generation, as our study found that even with specific prompts for male or female occupations, 5% of the DALLE-v2 images were of the opposite gender. Additionally, the expansion strategy introduces new biases (Figure 10).	Using race prompts to mitigate bias in image generation can be ineffective, as demonstrated by the DALLE-v2 generated images for "black mail carrier" and "black crane operator" that were of white individuals, and for "East Asian garbage collector" that were mostly of individuals from Southeast Asia.	Using age prompts to mitigate bias may also have limitations. Specifically, in DALLE-v2, prompts for junior "receptionist" and "child-care worker" generated 4% of images depicting seniors. SD seems to ignore gender, race, and age specific prompts more frequently than DALLE-v2.
Image Quality	In general, except for a few outliers, gender-skewed representations appear to exhibit greater similarity with real-world images. This means that image quality is higher when gendered prompts use the gender that is most represented in neutral prompts, and lower otherwise. This result shows that even though expanded prompts may increase output diversity, there may still exist discrepancies in image quality (Figure 11 and Figure 10b).		
Traits	Traits typically associated with competence, such as "intelligent," "strong-minded," and "rational," are primarily attributed to men (Table 3). Conversely, women have the strongest association with images depicting warm traits like "affectionate," "warm" and "sensitive" (Table 3).	The white race is more commonly associated with positive traits such as "competent," "active," "rational," and "sympathetic" (appendix Figure24). However, when it comes to traits related to "ambition," "vigorous," and "striving," the representation of white race is comparatively lower (appendix Figure 25).	Prompts depicting caring and altruistic behaviors lead to more generations that appear to be from individuals over 60 years old. Prompts describing rationality and tolerance are most associated with individuals aged between 40 and 60 years. In contrast, personality traits prompts describing laziness, ambition, and a tendency towards perfectionism, are most associated to individuals between 18 and 40 years.
Everyday Situations	Both models have the least representation of Nigeria, Ethiopia, and Papua New Guinea in generations of everyday situations (Figures 36, 37, 38, and 39). Germany has the highest representation by DALLE-v2 and the United States is the most represented by Stable Diffusion.		

layers. However, the denoising process within the pixel space can be computationally intensive, requiring a significant amount of memory as it involves manipulating individual pixels. In contrast, Stable Diffusion [23] suggests running the denoising process in the latent space, allowing for high-quality image generation on low-cost GPUs. In this work, we study both models as representatives of generation approaches that operate in the pixel and latent space.

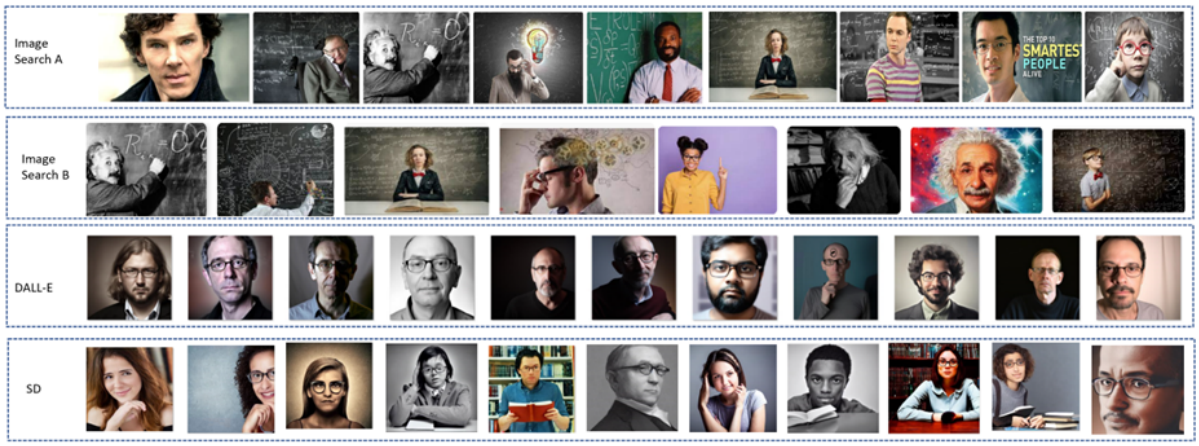

Figure 3: Images generated by Image Search Engines and DALLE-v2 for the prompt "Intelligent Person".

Social bias in Text-to-Image Generative Models. Various initial studies have tried to quantify the bias in recent text-to-image generation models [3, 5, 29]. Cho et al. [5] evaluate the gender and racial biases of text-to-image models, based on the skew of gender and skin tone distributions of images created using neutral occupation prompts. To identify gender and skin tone in the generated images, they use both automated and human inspection. According to their findings, Stable Diffusion has a greater propensity than minDALL-E to produce images of a certain gender or skin tone from neutral prompts. In addition to gender and race, our work also examines biases in images associated with age and geographical location as they are reflected not only in occupational queries but also on queries that specify personality traits and everyday situations. For occupational queries, our work also joins the results with data from the U.S. Bureau of Labor Statistics as a real-world reference point, albeit limited to only representation in the United States.

Similarly, Bianchi et al. [3] show that for simple, neutral prompts, Stable Diffusion perpetuates dangerous racial, ethnic, gendered, class, and inter-sectional stereotypes. They also observe stereotype amplification. Finally, they demonstrate how prompts mentioning social groups generate images with complex stereotypes that are difficult to overcome. For instance, Stable Diffusion links specific groups to negative or taboo associations like malnourishment, poverty, and subordination. Furthermore, none of the "guardrails" against stereotyping that have been introduced[1] to models like Dall-E, nor the carefully expanded user prompts, lessen the impact of these associations. Zhang et al. [29] take a complementary approach and study gender presentation differences by probing gender indicators in the input text (e.g., "a woman" or "a man") and then quantify the frequency differences of presentation-related attributes (e.g., "a shirt" and "a dress") through human and automated evaluation. They find that DALLE-v2 presents genders more similarly to each other than CogView2 [6] and Stable Diffusion.

Our study goes beyond previous research by examining two models (DALLE-v2 and Stable Diffusion v1) across four different topics such as people, occupations, traits, and everyday life, taking into account four social bias dimensions - gender, race, age, and geography, using both human and automated evaluation methods (Figure 2). In addition, we characterize the impact of prompt crafting for occupational queries, which has not been carefully quantified thus far beyond example-based evidence. Table 2 shows how our study advances the state-of-the-art in evaluating representational fairness for T2I generation.

3 METHODOLOGY

3.1 Social Bias Dimensions

As the images are computer-generated and do not involve actual individuals, our emphasis is on annotating discrete perceived attributes for the people depicted in the images. In real-world scenarios and for real individuals, such attributes are often continuous and, in some cases, socially constructed.

Gender: In this study we use a simplistic and binary specification of gender in prompts and analysis, which refers to the categorization of gender into two distinct and mutually exclusive categories of male

Figure 4: Images generated by Image Search Engines, DALLE-v2, and SD for the prompt "Office in Ethiopia". In comparison to the results from the Image Search, both models depict Ethiopia as being in a state of poor economic conditions.

and female. While this specification does not capture important non-binary definitions of gender, it enables us to look at the very least at how known traditional biases on male vs. female distributions are exposed in image generation.

Race: Race and ethnicity are two distinct terms used to describe people's identities. Race is a social construct based on physical characteristics, such as skin color, hair texture, and facial features, while ethnicity refers to a person's cultural background, including traditions, language, and history. While related, race and ethnicity are not interchangeable and have different meanings. In this study, we use the seven race classification defined by the FairFace study [16]: White, Black, Indian, East Asian, Southeast Asian, Middle East, and Latino. Again, even though this work and previous work uses a categorical definition of race for analytical purposes, often this is a continuous and intersectional concept.

Age: We have defined four age groups that will help us examine the characteristics, behaviors, and experiences of people at different stages of their lives, seen through the lens of text-to-image models. We define 4 age groups - "Child or minor", "Adult 18-40", "Adult 40-60", and "Adult over 60".

3.2 Social Bias Subjects

We assess the T2I models by presenting them with four different types of prompts, namely, *person*, *occupation*, *traits*, and *everyday situations*. As part of the prompt engineering exercise, we experimented with various prompts such as "a picture of a [prompt]", "a portrait of a [prompt]", "a photo of a [prompt]", and "a [prompt]". We discovered that DALLE-v2 generated higher quality images when using the "a portrait of a [prompt]", while SD V1 was more effective with the "a photo of a [prompt]". Therefore, we incorporated these prompt prefixes into all of our queries. Our criteria for quality in this case included the model's ability to generate actual human faces (rather than other non-related content or drawings) that are salient in the image (rather than covered, blurred, or far away in the generated view).

To measure the effectiveness of expanded prompts as a mitigation strategy, we gathered images for occupation prompts with explicit gender (e.g., a female doctor, a male nurse), race (e.g., a white teacher, a black author), and age (e.g., a junior biologist, a senior drafter).

Person: To assess the presence of representation bias in the images generated for people, we employed the prompt "person".

Occupations: The objective of this study was to determine the degree to which the distribution of gender, race, and age of people appearing in images generated by models for various occupation corresponds to their actual representation in those occupations. As a reference for actual representation we used estimates from the US Bureau of Labor and Statistics (BLS) from year 2022[2]. Note that even if the distribution of generated images is similar to the BLS distribution, this does not necessarily mean that the model has a fair representation, given that real-world distributions are also biased. Rather, it is only an indication that the model does not propagate bias even further. In addition, this is only a reference to representation in the United states and does not depict the same representation for other locations in the world. The full list of occupations is available in the appendix (Table 6). We have used the abbreviation CP for Computer Programmer, PST for Primary School Teacher, and CSR for Customer Service Representative. We had to make minor changes to the original list proposed by previous work [18] based on BLS 2022 data availability per occupation.

Personality traits: We leverage here a list of trait adjectives proposed by Abele et al. [1] that are uniform in both valence and frequency of occurrence across different languages. Additionally, as part of our results analysis, we partitioned this list into traits that are perceived as positive or negative. The full list of personality traits is available in the appendix (Table 7).

Everyday situations: To generate prompts for everyday situations, we employ both generic and location-specific descriptions of situations across various categories, including events, food, institutions, clothing, places, and community. We opted to include the names of the two most populous countries from each of the six continents (excluding Antarctica) as location-specific prompts - The United States of America, China, India, Nigeria, Ethiopia, Russia, Germany, Mexico, Brazil, Colombia, Australia, and Papua New Guinea. For everyday situations then, the prompt template would be "a [situation] in [country]", which depicts situations such as "a library in Brazil" or "breakfast in Ethiopia". We also considered using country-based adjectives such as "Ethiopian", "American" etc., but we noticed that such prompts lead to images that are heavily dominated by the presence of flags for the specified countries.

[2]https://www.bls.gov/cps/cpsaat11.htm

3.3 Model and Data

We utilized OpenAI's DALLE-v2 API and Stable Diffusion (SD) V1 repository[3] to produce images. In our study, we included the first 50 images featuring humans (as detected by Azure Cognitive Services - Analyze Image API[4] and FairFace [16]) for each of the prompts associated with person, occupations, and traits. However, we increased the number to 250 images for prompts linked to everyday circumstances and occupations that involve explicit gender, race, and age, as we employed automated evaluation techniques for these prompts. We show sample images generated for the prompt "an intelligent person" in Figure 3, "an engineer" in appendix, Figure 16, and "an office in Ethiopia" in Figure 4.

3.4 Evaluation

3.4.1 Human Evaluation.

We used Amazon Mechanical Turk[5] to annotate the race, gender, and age groups. We assigned three workers for each image and ensured an average wage of $12 per hour. If two or three annotators[6] agreed on their judgements, we took the label as ground-truth. If all three workers produced different responses, we categorized the label as "unclear" and excluded the image from our study. The appendix Figure 40 depicts the questions presented to annotators through the Mechanical Turk interface. For each image, the annotators were asked to indicate whether they see cartoons, humans, or no humans in the image. They were also asked to provide information about the gender, race, and age of the people in the image. To assist annotators in comprehending the task, we provided 37 examples along with ground truth annotations from the FairFace [16] data set covering various combinations of race, age, and gender.

3.4.2 Automated Evaluation.

Azure Cognitive Services - Analyze Image API. Our study only includes images that feature humans. In order to identify images with humans, we utilize Microsoft Cognitive Services Computer Vision API v1, specifically the Analyze Image operation. This operation extracts a rich set of visual features based on the image content. We specifically focus on the "tags" and "faces" features. We check whether the "faces" feature is non-empty, or whether the "tags" contain words that reference human beings, including but not limited to, "man", "woman", "girl", and "child".

FairFace [16] dataset comprises 108,501 images, with an emphasis on balanced race composition. Images are sourced from the YFCC-100M Flickr dataset and labeled with information about race, gender, and age groups. This dataset has driven a much better generalization classification performance for gender, race, and age when tested on new image datasets obtained from Twitter, international online newspapers, and web searches, which contain more non-White faces than typical face datasets. The study defines seven race groups: White, Black, Indian, East Asian, Southeast Asian, Middle Eastern, and Latino. We employ the same race categorization and use the corresponding pre-trained model[7] which is based on a ResNet [9] architecture with ADAM [15] optimization, and a learning rate of 0.0001. To detect faces, the work utilized dlib1's CNN-based face detector [14] and ran the attribute classifier on each face.

Evaluation of Everyday Situations. To assess the level of representation of various countries in the images created for prompts related to everyday situations, we calculate the average CLIP [21] embedding across the images generated for both default and location-specific prompts, and then compute the distance between them. The resulting distance is presented visually in the form of a heat map later in the evaluation. The lower the distance, the closer the country representation is expected to be from the default representation.

4 RESULTS

A brief summary of the results presented in this section is also summarized in Table 1.

4.1 What does a person look like in T2I generation?

To address this question, we analyzed the distribution of gender (Figure 5), race (Figure 6), and age (Figure 7) across 50 images generated with the prompt "person". The results of both human and automated evaluations indicate that DALLE-v2 exhibits a gender bias, with a higher representation of male individuals (70%). In contrast, SD displays a gender bias towards female individuals, with 66% of the generated images depicting females.

Both models display a racial bias towards individuals of the white race, with at least 70% of the generated images depicting white individuals. Notably, DALLE-v2 fails to represent individuals of East Asian, Southeast Asian, or Middle Eastern descent, while SD does not portray individuals who are of Latino or Middle Eastern origin. While SD exhibits a more varied representation of ages, DALLE-v2 tends to depict individuals in the younger age group, with 76% of the images depicting adults aged 18-40.

4.2 Representational bias for occupations

4.2.1 Neutral Occupations.

To ensure accurate labeling of gender, race, and age in images, we employed a majority vote approach across three annotators. Images with ambiguous labels, i.e., those without majority agreement, were labeled as "unclear". Additionally, we excluded prompts that fell into the following categories:

- Prompts whose generated images contained too few individuals. Examples include "a garbage collector" or "a truck driver", which tended to generate images of garbage containers or trucks rather than individuals.
- Prompts that consistently resulted in images for which the face of the generated individual was obstructed by equipment, such as cameras blocking the faces of photographers.
- Prompts that consistently resulted in caricatures that did not clearly depict race and age, such as those generated for the prompt "a tax collector".

After applying the filtering process, a total of 44 occupations were identified for further analysis. The full list of occupations is available in appendix, Table 6.

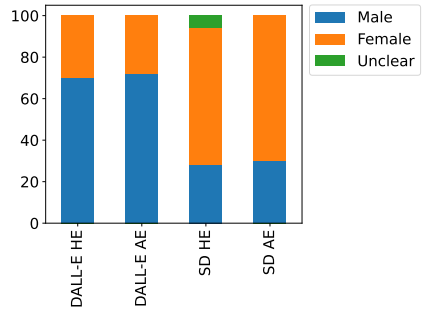

Figure 5: Gender dist. for "person"

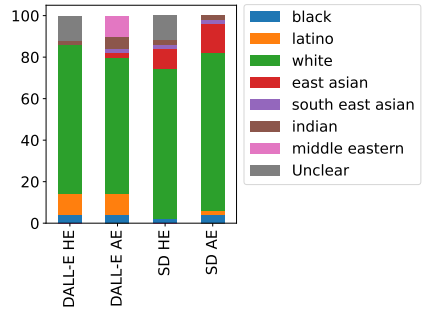

Figure 6: Race dist. for "person"

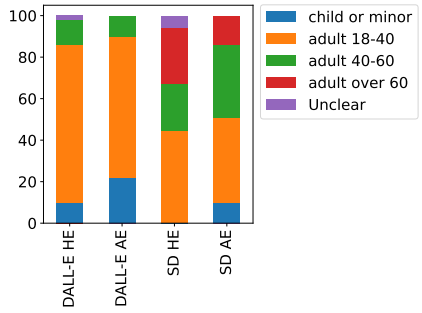

Figure 7: Age dist. for "person"

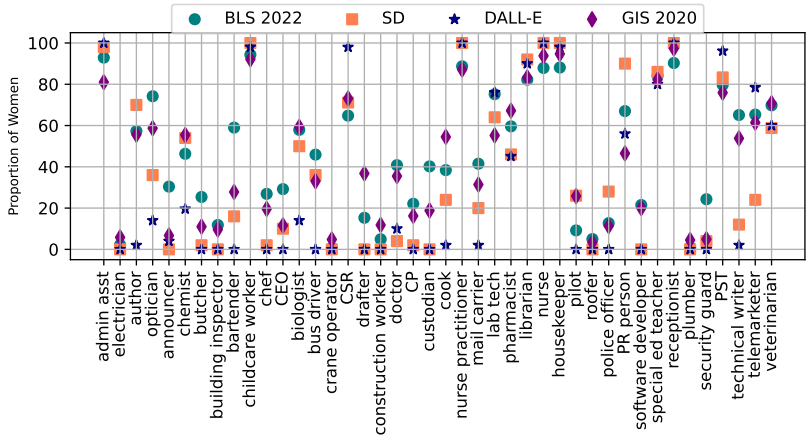

Figure 8: Proportion of Women as reported by BLS 2022, images generated by DALLE-v2 and SD, and GIS 2020.

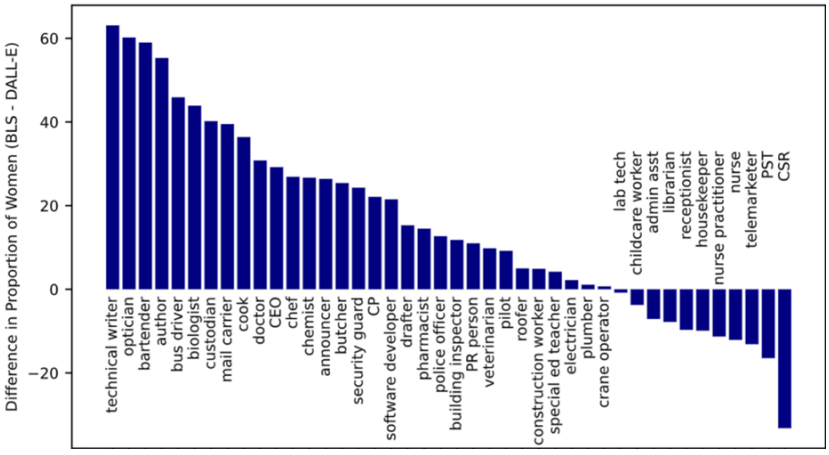

Figure 9: Difference in the Proportion of Women (BLS representation - DALLE-v2 representation). The higher the difference, the more the occupation deviates from BLS representation when depicted by DALLE-v2.

As a means of establishing a baseline, in these results we utilize labor statistics (from BLS 2022) and conduct a comparative analysis of the gender, race, and age distributions observed in the images generated by occupation prompts. We also compare these distributions with the Image Search results as reported by [19] in 2020.

The results described in the following sections on neutral prompts are based on human evaluation.

Gender: Figure 9 presents an analysis of the representation of different occupations by DALLE-v2, relative to a baseline of labor statistics (i.e., the difference between BLS representation and model representation). The findings reveal that certain occupations, including technical writer, optician, bartender, and bus driver, exhibit a significant reinforcement of under-representation of women in DALLE-v2's output. Conversely, for other occupations such as customer service representative, primary school teacher, and telemarketer over-representation is reinforced when compared to BLS. Only eight out of the 43 occupations analyzed demonstrate proportions of female individuals in DALLE-v2's output that fall within a range of ± 5% of the corresponding proportions in labor statistics.

In the appendix Figure 19, an investigation into the representation of various occupations by SD is presented, using a baseline of labor statistics. The analysis exposes a significant reinforcement of under-representation of women in the output of SD for certain occupations, including technical writer, bartender, telemarketer, and custodian. Conversely, SD's output reinforces over-representation for women in other occupations such as PR person, pilot, police officer, and author. A mere seven out of the 43 occupations exhibit proportions of female individuals in SD's output that fall within a range of ± 5% of the corresponding proportions in labor statistics.

Figure 8 shows the proportion of women as reported by labor statistics 2022, GIS 2020, DALLE-v2, and SD. With the exception of PR person, pilot, police officer, author, chemist, and telemarketer, the alignment of over/under representation of occupations by the two models is directional. The correlation between DALLE-v2 (appendix, Figure 17) and SD (appendix, Figure 18) and the labor statistics concerning the proportion of women in various occupations is 0.84 and 0.87, respectively.

Race: We conducted a comparison between the proportion of white and black races in DALLE-v2 occupations and BLS statistics. Our analysis revealed that for certain occupations, such as childcare worker, announcer, nurse, and housekeeper, white race was underrepresented by more than 50% when compared to the BLS baseline. The occupations of Pilot and Primary School Teacher were the only two where the proportion of white workers matched that of the BLS data. Additionally, our analysis of SD data showed that for certain occupations, including construction worker, childcare worker, and housekeeper, the white race group was under-represented by more than 50%. Nurse was the only occupation whose representation proportion matched that of the BLS data.

Furthermore, our analysis revealed that in 72% of the occupations, for DALLE-v2 the proportion of images that represented black individuals was zero. In contrast, our analysis of SD data showed that 37% of occupations had zero representation from the black race group, with childcare worker being over-represented by 48% and telemarketer being under-represented by 21%.

Age: The DALLE-v2 human evaluated data provides insights into the age distribution of various occupations. Specifically, administrative assistant, customer service representative, receptionist, electrician, and nurse are occupations that are largely dominated by individuals within the 18-40 age group, with a minimum representation of 96%. Conversely, the 40-60 age group dominates occupations such as truck driver and CEO, with a minimum representation of 78%. Finally, the over 60 age group is prominent in occupations such as clergy member and tax collector.

For Stable Diffusion, occupations such as bartender, computer programmer, telemarketer, and electrician are dominated by individuals within the 18-40 age group, with a minimum representation of 98%. CEO, custodian, and clergy member are occupations that are dominated by individuals within the 40-60 age group, with a minimum representation of 60%. Finally, the over 60 age group is prominent in the occupation of bus driver.

4.2.2 Expanded prompts.

We assessed the efficacy of prompt expansion as a strategy to mitigate bias in image generation. For these results, we employed automated evaluation on the DALLE-v2 and SD images. Section 4.5 and Tables 4 and 5 present details on the correlation between human and automated evaluation.

Our findings indicate that even with specific gender prompts, such as "male childcare worker" or "male primary school teacher," 5% of the DALLE-v2 generated images were female. Similarly, when using gender prompts for female-dominated occupations such as "female security guard" or "female custodian," at least 5% of the generated images were male. Additionally, the expansion strategy introduces new biases (Figure 10). This suggests that gender prompts alone may not be sufficient to fully mitigate gender bias in image generation. We also found that race prompts did not always succeed in mitigating bias. For example, at least 9% of the images for "black mail carrier" and "black crane operator" were of white individuals. Using age prompts as a mitigation strategy was also found to have limitations. For instance, 4% of the generated images for prompts such as "a junior receptionist" and "a junior childcare worker" were of seniors.

Similarly, images generated by SD demonstrate similar patterns. Gender-specific prompts like "a female police officer," "a female roofer," "a female cook," and "a drafter" contain 24%, 19%, 10%, and 10% male images, respectively. In the same way, prompts such as "a male administrative assistant," "a male receptionist," "a male housekeeper," and "a male paralegal" generate 60%, 53%, 25%, and 18% female images. We also observed that race prompts did not always successfully reduce bias. For instance, for the prompt "a Middle Eastern special ed teacher," 17% and 21% of the images were of white and Indian individuals, respectively. Similarly, age-related prompts such as "a junior crane operator," "a junior electrician," and "a junior plumber" generated images of individuals over 60, at least 10% of the time. Overall, SD seems to ignore gender, race, and age specific prompts more frequently than DALLE-v2.

The study suggests that using prompts for gender, race, or age may not always be sufficient to mitigate biases in image generation. Furthermore, in the next section we also show that even when expanded prompts are effective, they can also lead to discrepancy and drops in image quality.

4.2.3 Image Quality Evaluation.

To evaluate the degree of similarity between AI-generated images and real-world images, we curated a corpus of image search results for gender-specific occupational prompts (e.g. "male doctor," "female doctor") using the Bing Image Search API. We subsequently employed the Fréchet Inception Distance (FID) [10] to compute the

differences between two image datasets. The FID metric is computed by extracting features from each image using an Inception V3 model trained on ImageNet. The appendix Figures 22 and 23 depict the FID scores for the models, stratified by gender. Note that lower FID scores correspond to better resemblance to the real images.

Except for a few outliers, gender-skewed representations exhibit more similarity with real-world images. Specifically, for DALLE-v2, occupations (appendix, Figure 22) such as CEO, crane operator, roofer, and bus driver, which are male-dominated, display better FID scores when compared to female-dominated occupations, such as nurse, childcare worker, primary school teacher, and administrative assistants, which have better FID scores when compared to their male counterparts. To illustrate quality discrepancies, we examine the images for the prompt - "female announcer" in Figures 11 and 10b more closely. The examples show that DALLE-v2 images exhibit less diversity and are predominantly dominated by individuals of East Asian descent. Lack of output diversity may in fact be one of the main factors that drives worse image quality scores for DALLE-v2.

4.3 Representational bias for personality traits

As a result of the SD model generating non-human images for over 50% for certain personality traits prompts, we limit our study to DALLE-v2. All the results are based on human evaluation. Our observations indicate that traits typically associated with competence, such as "intelligent," "strong-minded," and "rational," are primarily attributed to men (Table 3). Conversely, women have the strongest association with images depicting warm traits like "affectionate," "warm," and "sensitive" (Table 3). From a racial bias perspective, traits like "ambitious" and "determined" display the strongest association with the black race, while the traits "vigorous" and "detached" exhibit the strongest association with the east Asian race.

Furthermore, we categorized the traits into positive and negative groups and further investigated their association with different racial groups represented in the images. The positive traits are represented in the appendix Figure 24, while the negative traits are shown in the appendix Figure 25. Our findings indicate that the white race is more commonly associated with positive traits such as "competent," "active," "rational," and "sympathetic." However, when it comes to traits related to "ambition," "vigorous," and "striving," the representation of white race is comparatively lower. In addition, we found that the white race is strongly linked with negative traits such as "dominant" and "egoistic," while being less represented in images for the "detached" and "hardheaded" traits.

Different age groups are represented by distinct sets of traits. Prompts depicting caring and altruistic behaviors lead to more generations that appear to be from individuals over 60 years old. Prompts describing rationality and tolerance are most associated with individuals aged between 40 and 60 years. In contrast, personality traits prompts describing laziness, ambition, and perfectionism, are most associated to individuals between 18 and 40 years.

4.4 Representational bias for everyday situations

In this study, we conducted an analysis of everyday situations using CLIP embeddings, categorizing them into six distinct categories:

Table 3: Traits with 100% male representation and traits with female representation ≥ that of male.

top male traits		top female traits
boastful	striving	sensitive
energetic	industrious	affectionate
egoistic	intelligent	harmonious
dogmatic	gullible	supportive
decisive	moral	warm
rational	reliable	
strong-minded	self-critical	

events, food, institutions, clothing, places, and community. Our analysis encompassed a total of 12 geographic locations, representing the two most populated countries for each of the six continents. As an example, Figure 13 and Figure 14 display the distance between default and location-specific generations in the *events* category, which serves as a metric for assessing country representation in default generations. Specifically, each cell in the figure corresponds to a distinct country. The lower the distance, the closer the representation of the country is to the default one. The analysis revealed that Nigeria, Ethiopia, and Papua New Guinea have the lowest representation across the events in both models. Conversely, Australia, Germany, and the United States were most represented.

Figures 36, 37, 38, and 39 illustrate the distribution of countries that are least and most represented across all situation prompts. Our analysis reveals that Nigeria, Ethiopia, and Papua New Guinea are the least represented countries by both models. Notably, Germany is the most represented country in DALLE-v2, while the United States is the most represented in the SD. In conclusion, our analysis suggests that DALLE-v2 images are generally more representative of all countries included in our study.

4.5 Human vs. Automated Evaluation

We present the correlation results for the evaluation of occupations and traits between human and automated assessment methods. The data for these assessments were collected across various demographic dimensions, including gender, race, and age, and are presented in Tables 4 and 5. The correlation coefficient was found to be greater than 0.9 for all groups except for white individuals in the occupation category. Despite this, we were not able to meaningfully compute correlation scores for groups that were significantly under-represented in generations from both models. These include age groups younger than 18 and older than 60, as well as all other race groups different from black and white. Therefore, it is not conclusive how well the automated evaluation would work for these groups, if we were to have generated images for them.

4.6 Limitations

While this work provides an overview to major representational biases of image generation models across different dimensions and topics, further work is needed to quantify other forms of biases in depth. In particular, through this work we were not able to provide insights on how T2I models represent non-binary gender definitions or other under represented communities such as individuals

(a) "a portrait of an announcer". Bias towards male individuals. Try the prompt expansion mitigation strategy? FID = 201

(b) "a portrait of a female announcer". Prompt expansion addresses gender bias but introduces racial bias. FID = 237

(c) "a portrait of a male announcer". Shows improved racial representation compared to female prompt. FID = 164

Figure 10: DALLE-v2: An illustration of the prompt expansion mitigation strategy resulting in the emergence of new biases. A lower FID indicates better-quality images.

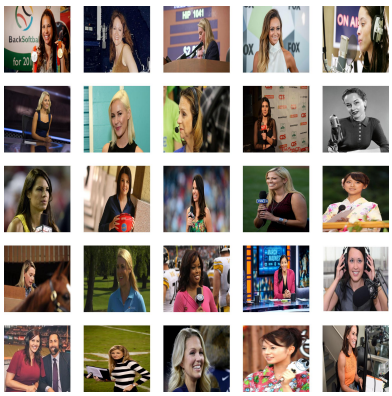

Figure 11: Image Search results for "female announcer".

Table 4: Human vs. Automated eval. for neutral occupations.

Dimensions	Correlation (DALLE-v2)	Correlation (SD)
Gender	1	0.99
Race – white	0.87	0.89
Race – black	0.99	0.98
Age – Adult 18-40	0.95	0.91
Age – Adult 40-60	0.95	0.91

with disabilities, smaller countries, and religious groups. Based on example-based evidence, we observe that such groups are generally poorly represented in neutral prompts. However, deeper analysis is needed to investigate whether prompt expansion can mitigate representation and at what cost. As we observed with expanded gendered prompts for occupations, prompt expansion may not always be a solution to other forms of biases that lead to either image quality discrepancies or more complex associations that require a

Table 5: DALLE-v2 : Human vs. Automated eval. for traits.

Dimensions	Correlation
Gender	0.99
Race – white	0.93
Race – black	0.98
Age – Adult 18-40	0.91
Age – Adult 40-60	0.9

qualitative evaluation. For example, previous work [3] showed that images generated with prompts that specify countries also represent some countries in a poor economic status, as we also illustrate in Figure 4. Similarly, there exists a risk that generations for non-binary gender definitions or religious groups could be associated with common and harmful stereotypes about such groups. Studying these associations is important for setting the right expectations on how far prompt expansion strategies bring us for mitigating representational fairness concerns.

This work also evaluated two models: DALLE-V2 and Stable Diffusion v1. Further work is needed to evaluate proprietary models (e.g., Imagen) and new models (e.g., Stable Diffusion v2) continuing to be released and deployed in real-world applications.

5 CONCLUSION

This study measured the biases in two different T2I models - DALL-E V2 and Stable Diffusion v1 - using both human and automated evaluation methods. We focused on four social bias dimensions: gender, race, age, and geographical location. To identify biases in the models' generated content, we used various prompts, such as descriptions of occupations, personality traits, everyday situations, and the general "person" prompt. Results showed that both models exhibited significant biases across all dimensions and even exacerbated them when compared to recent labor statistics (BLS). Prompt

Figure 14: Heat map representing SD images for the events category.

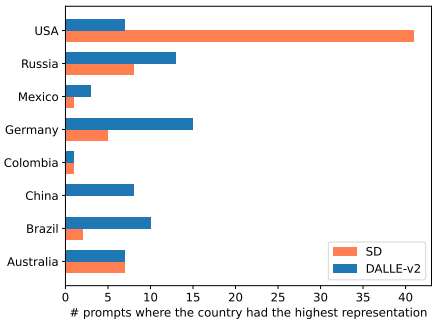

Figure 15: The most represented countries across situation prompts for DALLE-v2.

expansion strategies could effectively diversify the generated content, but this could also lead to variations in image quality. Finally, we observed that some countries were under represented in images depicting everyday situations while others were over represented. Moving forward, we plan to explore more mitigation strategies to address these biases. We envision the presented results and method of study to be informational to the process of evaluating and building new generative models with an increased focus on responsible development and representational fairness.

ACKNOWLEDGMENTS

We thank Chad Atalla, Ece Kamar, and Xavier Fernandes for insightful discussions and feedback. This study would not have been possible without the contribution of crowdsourcing workers on labeling perceived demographic attributes for generated images.

Table 6: All occupation prompts used for the study. The list largely corresponds to the list of occupations used in previous work on image search bias [18].

Occupation prompts	
electrician	cook
building inspector	author
crane operator	announcer
drafter	doctor
construction worker	optician
custodian	biologist
roofer	chemist
software developer	pharmacist
plumber	PR person
butcher	veterinarian
chef	lab tech
computer programmer	telemarketer
security guard	special ed teacher
chief executive officer	librarian
bartender	primary school teacher
pilot	customer service representative
police officer	housekeeper
bus driver	childcare worker
technical writer	administrative assistant
mail carrier	nurse practitioner
receptionist	nurse

Table 7: All personality traits prompts used for the study. The list corresponds to the list of traits adjectives proposed in previous work [2].

Personality traits prompts		
able	egoistic	perfectionist
active	emotional	persistent
affectionate	energetic	polite
altruistic	expressive	rational
ambitious	fair	reliable
assertive	friendly	reserved
boastful	gullible	self-confident
capable	hardhearted	self-critical
caring	harmonious	self-reliant
communicative	helpful	self-sacrificing
competent	honest	sensitive
competitive	independent	sociable
conceited	industrious	striving
conscientious	insecure	strong-minded
considerate	intelligent	supportive
creative	lazy	sympathetic
decisive	moral	tolerant
detached	obstinate	trustworthy
determined	open	understanding
dogmatic	open-minded	vigorous
dominant	outgoing	warm

A APPENDIX

Figure 16: Images generated by Image Search Engines, DALLE-v2, and SD for the prompt "Engineer".

Table 8: Correlation between BLS 2022 and DALLE-v2/SD for occupation prompts.

Dimension	BLS 2022 vs. DALLE-v2	BLS 2022 vs. SD
Gender	0.84	0.87
Race – white	0.18	0.20
Race – black	0.30	0.51

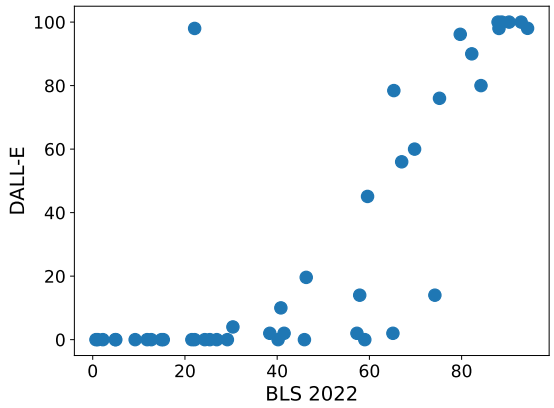

Figure 17: Proportion of Women in Occupation BLS 2022 vs. DALLE-v2.

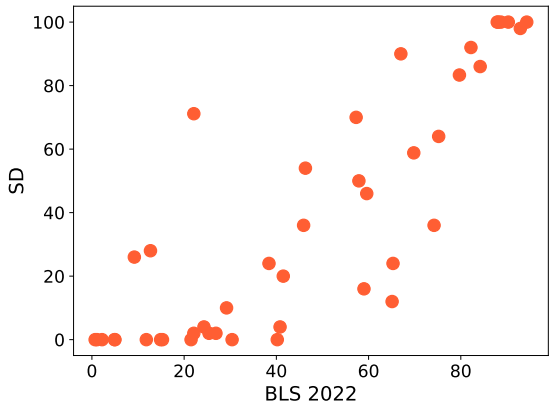

Figure 18: Proportion of Women in Occupation BLS 2022 vs. SD.

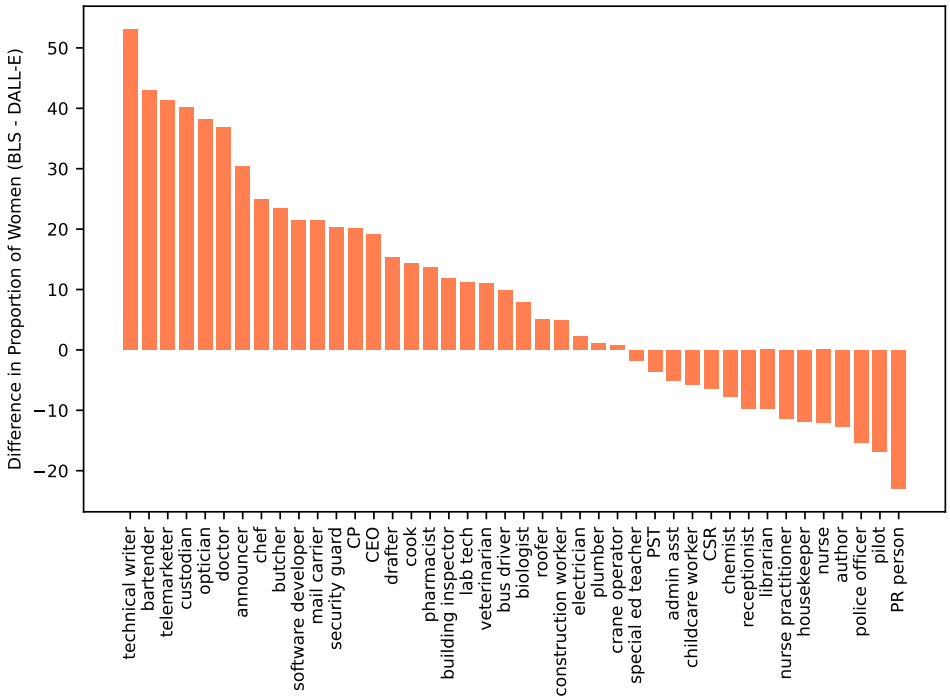

Figure 19: Difference in the Proportion of Women (BLS representation - SD representation). The higher the difference, the more the occupation deviates from BLS representation when depicted by Stable Diffusion.

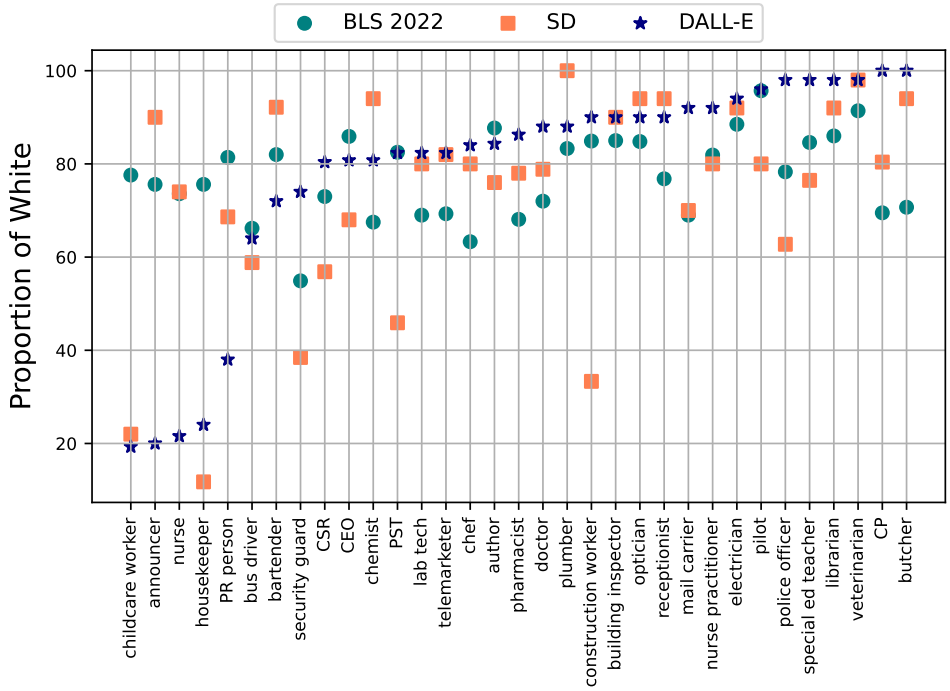

Figure 20: Proportion of White as reported by BLS 2022,images generated by DALLE-v2 and SD, and GIS 2020.

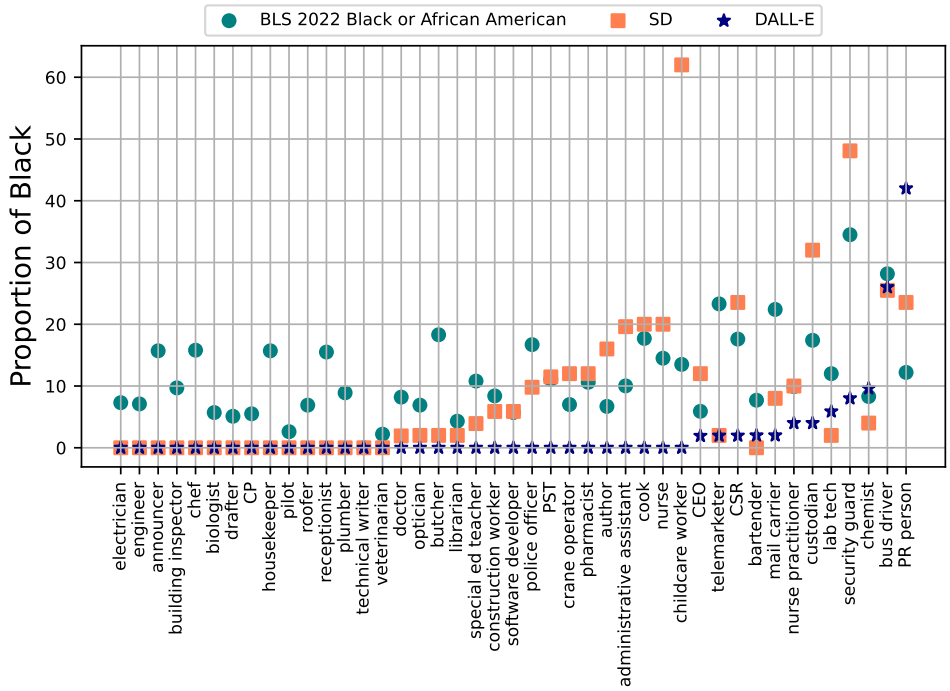

Figure 21: Proportion of Black as reported by BLS 2022, images generated by DALLE-v2 and SD, and GIS 2020.

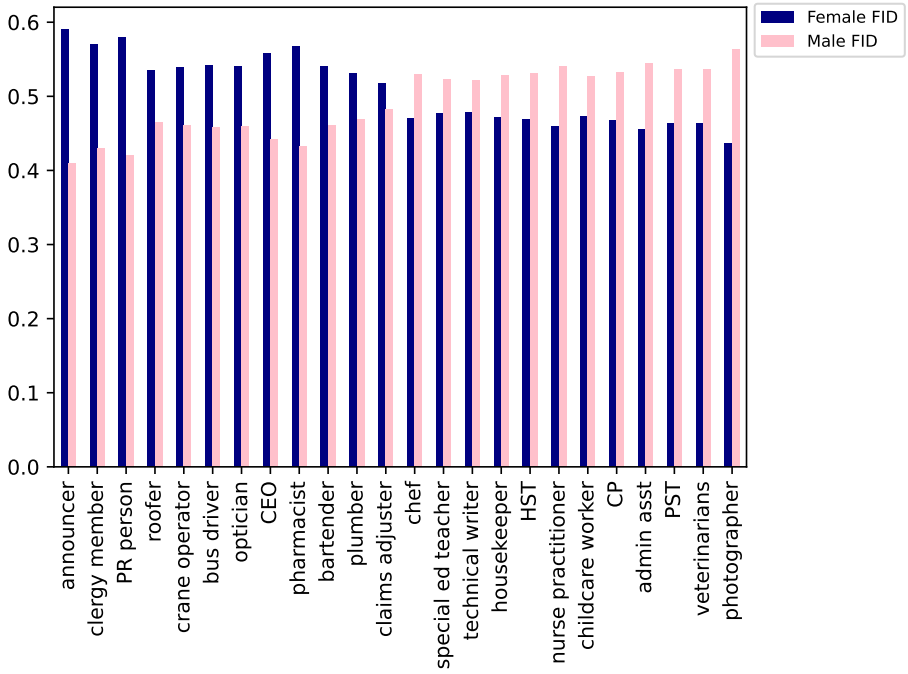

Figure 22: FID scores for gendered occupational prompts using DALLE-v2. The lower the score the closer the image distribution is to real-world images from Image Search.

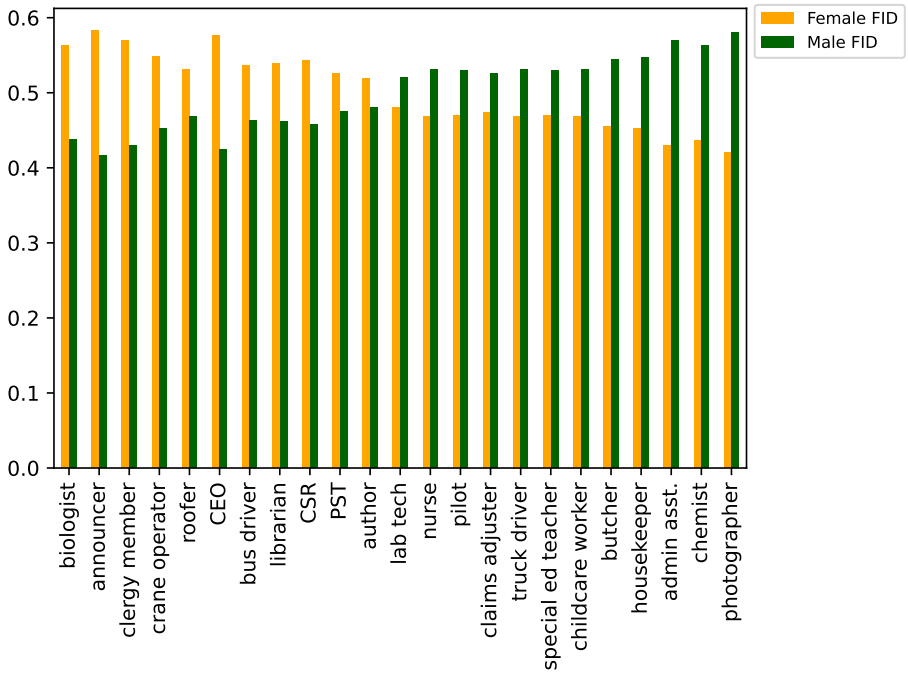

Figure 23: FID scores for gendered occupational prompts using SD. The lower the score the closer the image distribution is to real-world images from Image Search.

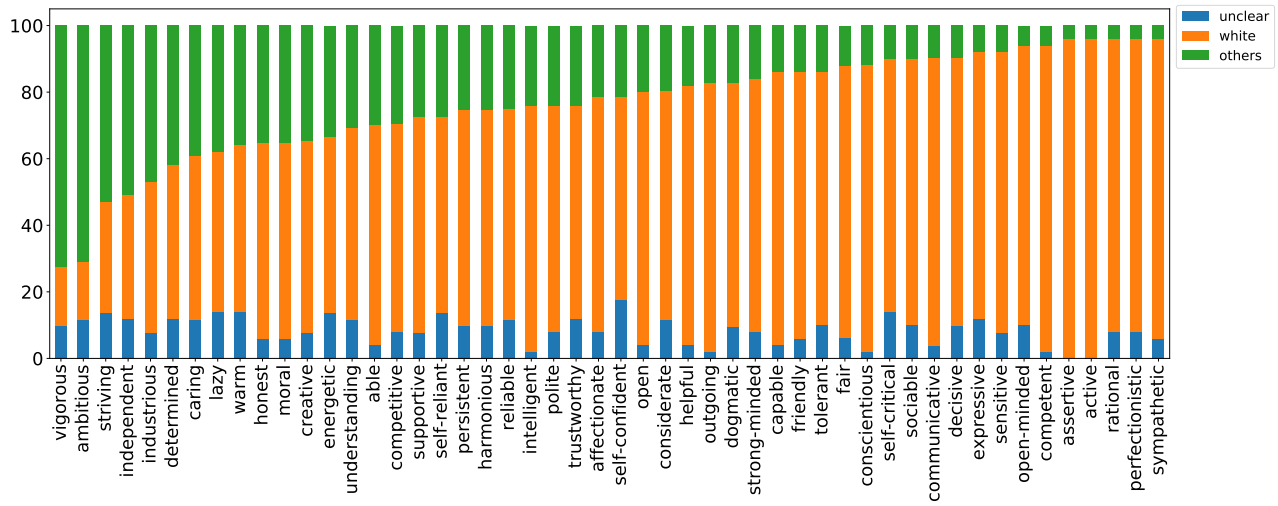

Figure 24: Distribution of race for positive traits.

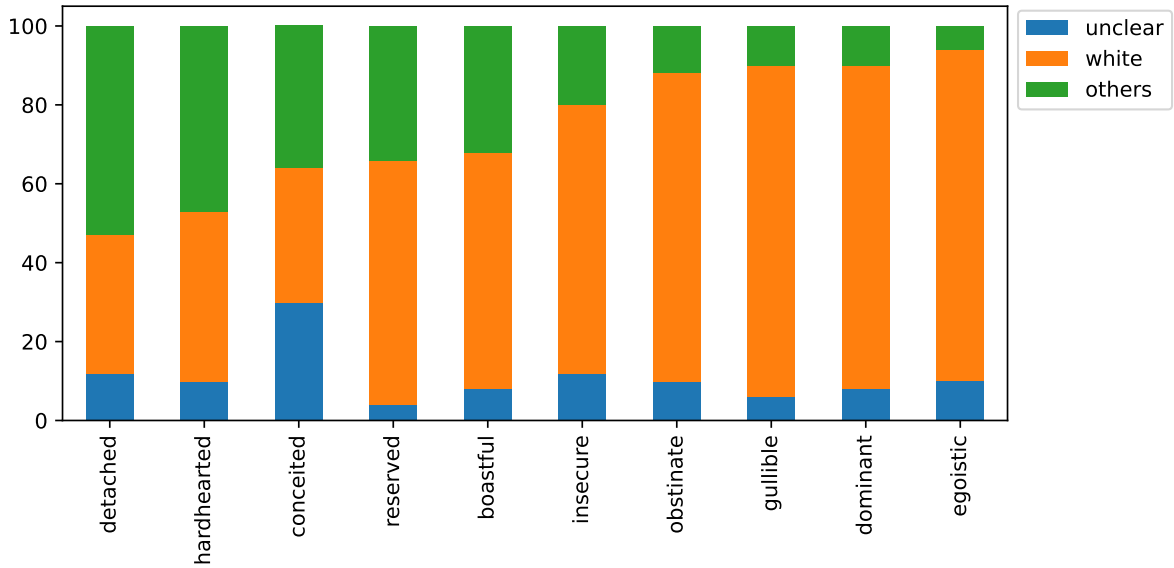

Figure 25: Distribution of race for negative traits.

ABSTRACT

We propose a novel taxonomy for bias evaluation of discriminative foundation models, such as Contrastive Language-Pretraining (CLIP), that are used for labeling tasks. We then systematically evaluate existing methods for mitigating bias in these models with respect to our taxonomy. Specifically, we evaluate OpenAI's CLIP and OpenCLIP models for key applications, such as zero-shot classification, image retrieval and image captioning. We categorize desired behaviors based around three axes: (i) if the task concerns humans; (ii) how subjective the task is (i.e., how likely it is that people from a diverse range of backgrounds would agree on a labeling); and (iii) the intended purpose of the task and if fairness is better served by impartiality (i.e., making decisions independent of the protected attributes) or representation (i.e., making decisions to maximize diversity). Finally, we provide quantitative fairness evaluations for both binary-valued and multi-valued protected attributes over ten diverse datasets. We find that fair PCA, a post-processing method for fair representations, works very well for debiasing in most of the aforementioned tasks while incurring only minor loss of performance. However, different debiasing approaches vary in their effectiveness depending on the task. Hence, one should choose the debiasing approach depending on the specific use case.

1 INTRODUCTION

Popular generative foundation models regularly make the news, both because of the rapid rate of progress in the field and the potential harms including copyright violation and the hallucination of incorrect and possibly libelous data. However, in many ways the dangers of discriminative models can be more insidious. Discriminative[1] models such as CLIP [45] allow for the zero-shot classification of data, i.e., without access to labeled training data they can assign images to a set of previously unseen labels. As zero-shot solutions do not require conventional data sources, models can be optimistically deployed without systematically evaluating if they are accurate, fair, or even if the task they are deployed on makes sense (e.g., identify hard workers from resume photographs). Because discriminative models may be used to make decisions about individuals, their behavior can have a direct impact on a person's life (e.g., through controlling access to education, employment or medical care) in a way that generative models that create text or images do not. This work looks at the potential harms associated with classifying, retrieving and captioning image data using discriminative multi-modal foundation models, and ask a key question:

What constitutes the desired behavior for discriminative foundation models in downstream tasks?

Our goal is challenging due to a combination of two factors: first, the rise and commoditization of zero-shot machine learning; and second, the plethora of inconsistent fairness definitions [52].

Intrinsically, zero-shot hinges on the idea that a single ML system should perform well on diverse unseen datasets without specialist training [34], while algorithmic fairness has consolidated on the idea that specific fairness definitions are more appropriate for specific tasks [52]. The intersection of these ideas creates a tension.

Indeed, how can we check the fairness of a general-purpose system if we cannot agree on a general definition of fairness? To address this question, we propose a coarse taxonomy of tasks and describe the ideal behavior of a foundation model on such tasks. We base our taxonomy around three concepts:

(1) *Human centricity:* Do the labels concern humans?
(2) *Label consistency:* Is there likely to be an agreement on how data should be labeled both within a culture and across a wide range of cultures?

[1] Our use of the words "generative" and "discriminative" follows the machine learning literature (e.g., [6]). A generative model is one that can generate synthetic data, such as images or text, and a discriminative model is one that can distinguish between types of data, for example, by classifying images as cats or dogs. This use of "discriminative" does not imply that the model is biased towards or against particular protected groups.

Table 1: The range of desiderata and their corresponding measures. *The motivation underlying our desiderata is straightforward: where consistent labelings exist, we expect foundation models to reproduce them, and in human-centric tasks we should reproduce them equally well for all groups. Where labels are subjective (i.e., likely to be labeled inconsistently by different groups), reproducing labels is less of a concern, and instead we prioritize groups to be represented equally. The question then is what does 'equally' mean? For much of the fairness literature, 'equally' refers to the idea that decisions should be made independently of protected attributes such as race or gender (potentially conditioned on the true label). This leads to notions such as equal opportunity [27] (see "independence measures" in the top left part of the table) or demographic parity [29] ("independence measures" in the bottom left part of the table). However, this is not the only relevant notion of equal representation. In some cases, we may wish to sample uniformly from the* support of the distribution *rather than the distribution, and this leads to analogous notions provided under "diversity measures" in the table. By $Y, \hat{Y}, Z$ we denote a datapoint's ground-truth label, predicted label, and protected attribute, respectively; P denotes a generic probability distribution over these three variables.*

	HUMAN-CENTRIC	NON-HUMAN-CENTRIC
Objective task	Labels should be reproduced consistently for all groups **Independence measures:** High performance per group on standard metrics and $P(\hat{Y}=1\|Z=z_1,Y=1)=P(\hat{Y}=1\|Z=z_2,Y=1)\ \forall z_1,z_2$ Figures 2 and 6 **Diversity measures:** High performance per group on standard metrics and $P(\hat{Y}=1\wedge Z=z_1\wedge Y=1)=P(\hat{Y}=1\wedge Z=z_2\wedge Y=1)\ \forall z_1,z_2$ Table 3	Labels should be reproduced consistently High performance on standard metrics Tables 2, 4, and 18
Subjective task	Labels should represent all groups equally **Independence measures:** $P(\hat{Y}=1\|Z=z_1)=P(\hat{Y}=1\|Z=z_2)\ \forall z_1,z_2$ Figures 1, 3, 4, 5, 7, 8, 9, 10, 11, 12, 13 14, 15 and 16. Tables 9, 10, 11, 12, 13, 15, and 17. **Diversity measures:** $P(\hat{Y}=1\wedge Z=z_1)=P(\hat{Y}=1\wedge Z=z_2)\ \forall z_1,z_2$ Tables 5, 6, 7, 8, 14, 16	*Out of scope*

(3) *Purpose of the task:* Can the task be perceived to be assigning labels to individuals, or to be recovering diverse samples that characterize the spread of data?

Based on the answers to these questions, we propose metrics that encode the values implicit in these decisions (see Table 1).

Importantly, we find that different answers to these questions naturally lead to different metrics. Consequently, we observe that many of the existing works in fairness for foundation models, which propose new methods evaluated with respect to particular metrics, are enforcing unexamined value judgments about what the ideal behavior should be. Moreover, as part of the taxonomy depends not only on the type of task but also on the purpose, it is impossible to satisfy all metrics simultaneously.

Using our taxonomy, we provide a systematic evaluation of OpenAI's CLIP [45] and OpenCLIP [28] models, for binary (gender) and multi-valued (race) attributes.[2] Additionally, we evaluate a range of existing bias mitigation methods for these models. We argue that existing fairness methods are designed to encourage either independence or diversity, and show empirically that they prioritize one or the other. As such, the choice of a particular fairness method should be driven by the intended use case, and a decision as to which harms are relevant (Section 4).

Outline of the paper. In Section 2, we first review the CLIP model and some of its fairness issues highlighted in the existing literature and describe the different debiasing methods we evaluate. In Section 3, we explain the details of different evaluation tasks. In Section 4, we introduce different fairness metrics for which we show the results in Section 5. In Section 6 we conclude the paper.

2 FOUNDATION MODELS, CLIP, AND FAIRNESS OF CLIP

In the past few years, *large* models trained on huge amounts of data, primarily crawled from the internet, have become popular (e.g., BERT [20], CLIP [45], GPT-3 [10], DALL-E [46], Stable Diffusion [47]). Many of these models have gained attention even in the general public and extensive news coverage, which typically also addresses the risks and shortcomings of these models (e.g., [39, 42]). These large models are now commonly referred to as foundation models, a name coined by researchers from Stanford to "underscore their critically central yet incomplete character" [8]. They exist in various flavors that cover a wide range of data modalities (e.g., language, vision or multi-modal), training objectives (e.g., predicting

[2] As an artifact of the available datasets, we make use of annotations that indicate *perceived* gender and race. Labels are assigned coarsely by a third party into binary bins for gender and into seven racial groups (see [30] for details). They do not reflect how people in the dataset identify.

a word deleted from a piece of text or aligning images and their captions in a joint embedding space) and application areas (e.g., data generation tasks such as image synthesis or data analysis tasks such as image classification, retrieval or captioning). What foundation models have in common is that they were trained on broad data, where the quantity of data was prioritized over its quality, and that they can be adapted to a wide range of downstream tasks, often with no or only minimal supervision. The former property makes foundation models prone to concerning behavior, ranging from algorithmic bias [45] over toxicity and offensive content [15] to privacy concerns [12]. The latter property increases the risk that any concerning behavior could spread much wider than with a traditional model trained to solve a specific task.

In this section, we briefly describe the required background of the CLIP model as an illustration of a typical discriminative foundation model and relevant fairness concerns. We discuss additional related work in Appendix A.

2.1 Contrastive Language Image Pretraining (CLIP)

OpenAI's CLIP [45] is a discriminative foundation model for computer vision trained on 400 million image-text pairs to align corresponding image and text examples within a joint embedding space. To that end, CLIP uses a contrastive loss which tries to push the representations of the corresponding image and text examples together and the representations of the non-corresponding examples far apart. This joint multi-modal embedding space can then be used for several downstream tasks such as image retrieval, image captioning or zero-shot classification. CLIP achieves remarkable zero-shot classification performance in several tasks, which in some cases rivals that of the classical supervised competitors. In certain scenarios, the downstream applications could result in direct harm to individuals, e.g., classifying images into professionals vs non-professionals, retrieving a set of doctors from a dataset or captioning images for assisting blind people, which give rise to several fairness concerns. While OpenAI's CLIP is proprietary, we also present results (Section 5.5 and Appendix F) for its open source implementation OpenCLIP [28]. OpenCLIP has the same objective function and architecture as the original OpenAI CLIP, but it was trained on the publicly available LAION-400M dataset [48].

2.2 Existing fairness evaluations of CLIP

Recent works highlighted some biases present in the CLIP model. The original CLIP paper [45] demonstrated gender and race biases in certain zero-shot tasks including classifying facial images into crime-related vs. non-crime-related categories or into human vs. non-human animal categories. These fairness evaluations were limited in scope to a small number of tasks and datasets.

Wang et al. [55], Berg et al. [4] and Dehouche [18] demonstrated that CLIP embeddings have a gender or race bias in certain tasks. In their study, Wang et al. [55] highlighted gender bias in CLIP embeddings when used for image retrieval tasks. In their experiments, they first created gender-neutral test queries by replacing the gendered words with neutral alternatives in the captions of the MSCOCO 1K test set. Subsequently, they utilized the CLIP embeddings to retrieve images based on these neutral queries. Their findings reveal that, on average, 6.4 out of top 10 results were images of men. However, it is important to consider a few factors while considering their results. i) They did not provide additional metrics that account for differences in the base rate of men and women. ii) They did not evaluate the fairness of CLIP embeddings using well-known fairness measures, such as demographic parity or equality of opportunity. iii) Their approach involved aggregating the signed biases of all queries. This aggregation method can potentially lead to the cancellation of systematic biases across different queries, thereby reducing the apparent bias of the system. For instance, if a search for 'home-maker' predominantly returns women and a search for 'technician' predominantly returns men, aggregating the two together suggests greater gender neutrality than when considering any one on its own.

Berg et al. [4] have also raised concerns in gender-related fairness issues of the CLIP embeddings. Their findings indicate that the CLIP model exhibits a representation bias with respect to gender in image retrieval tasks, particularly for queries such as clever, lazy, hardworking, kind, or unkind. However, it is worth noting that their analysis is limited to the face-focused FairFace and UTKFace datasets. Additionally, their evaluation of zero-shot classification was limited to the classification categories presented in the original CLIP paper [45]. Another aspect that their analysis is missing is the evaluation on well-established fairness metrics such as demographic parity and equal opportunity. Instead, they primarily focus on ranking metrics like Skew [25] and KL-divergence.

Dehouche [18] studied the fairness of CLIP by performing zero-shot classification to classify 10000 synthetically generated portrait photos into male vs. female, white person vs. person of color, attractive vs. unattractive, friendly vs. unfriendly, rich vs. poor, and intelligent vs. unintelligent. They found a strong correlation between classification as female and attractive, between male and rich, and between white person and attractive. They applied the strategy of Bolukbasi et al. [7] for debiasing word embeddings, by removing gender bias, and found that this strategy reduced the correlation between classification as female and attractive or between male and rich. Compared to Dehouche [18], we perform a more extensive fairness evaluation, considering not only zero-shot classification but also image retrieval and image captioning, and we compare several bias mitigation methods.

2.3 Bias mitigation methods for CLIP

In this section, we discuss two existing bias mitigation methods explicitly proposed for CLIP and the modifications we make to run them. To our knowledge, this is an exhaustive list — it contains every method claiming to improve the fairness of CLIP at the time of the submission of our paper. We also discuss a recently introduced version of fair PCA [32], which is a general approach to make representations fair and which we investigate in our experiments. In Appendix A we discuss concurrent works for debiasing CLIP.

2.3.1 CLIP-clip (referred to as MI in the results). Wang et al. [55] proposed a simple post-processing approach to make CLIP representation fair w.r.t. gender. Given a dataset with gender annotations, they calculate the mutual information between CLIP embedding on the training split of the dataset and its corresponding values of

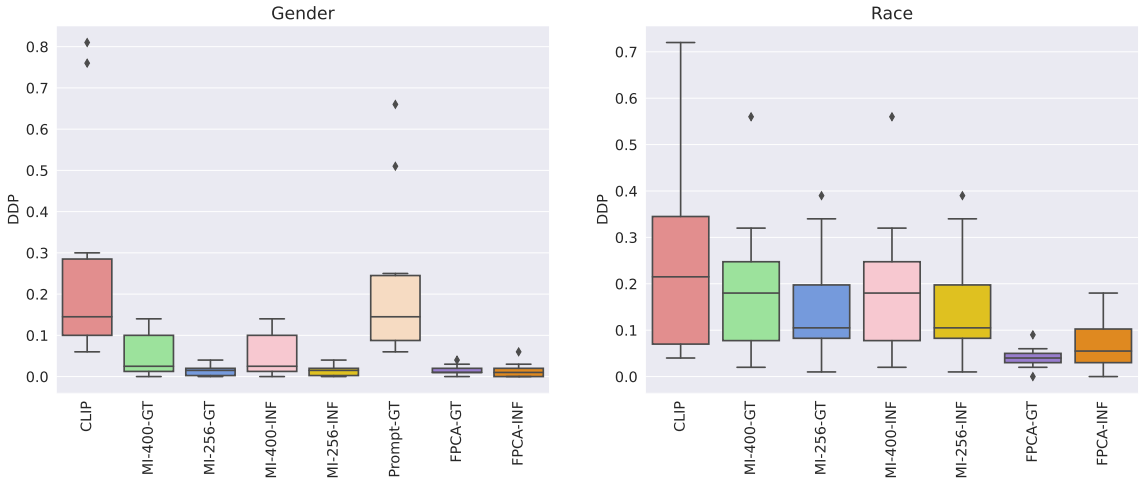

Figure 1: [Classification - DDP - Subjective - FairFace] We plot DDP, given in Eq. (1) for gender (left) and race (right), summarizing the distribution over multiple zero-shot classification tasks (provided in Appendix C) using FairFace dataset. *"GT" and "INF" refers to whether the value of the protected attributes used to train the corresponding method were ground truth or inferred using CLIP. These figures shows that fair PCA based methods are more effective in reducing demographic disparity for different groups of the protected attributes. Additionally, mutual information based methods are more effective when more dimensions are reduced.*

the gender attribute. Then, they greedily select a prescribed number of dimensions with the highest mutual information to cut, and retain the rest of the m dimension in the CLIP representations. The smaller the value of m, the more debiased the CLIP representations, as shown in Figures 1, 2, 4 and 5. However, the performance using the reduced CLIP embeddings worsens on several non-gender related tasks, as shown in Tables 2, 3, 4, 13 and 18. This demonstrates the well-known accuracy-fairness trade-off.

Wang et al. [55] did not show results using non-binary (e.g. race) attributes. We extend their method to the multi-valued attributes and show results using the race attribute (see Figures 1 and 4).

2.3.2 Prompt learning (referred to as Prompt in the results). Berg et al. [4] proposed a method to reduce bias the CLIP model by incorporating learnable text prompts into sensitive queries. To achieve this, they select a set of queries such as 'a photo of a good/evil/smart person' and utilize a dataset of images annotated with the protected group information. For each query, they add learnable text prompts. Subsequently, they calculate the text and image embeddings using the CLIP's text and image encoders. Next, they compute the similarity logits by taking the dot product between each pair of image-text embeddings. These similarity logits are then fed into an adversarial classifier, which aims to predict the protected attribute. The training objective aims to learn the text prompts in a manner that prevents the adversarial network from accurately predicting the protected attribute. The ultimate goal is to reduce the correlation between the similarity logits and the protected attributes. Additionally, they use an image-text contrastive (itc) loss to maintain the performance of the embeddings. They maintain the balance between the two loss values using a hyperparameter λ.

Berg et al. [4] utilized FairFace dataset for the debiasing loss and Flickr30K dataset for the itc loss, focusing on the gender attribute. Consequently, we evaluate their method only for the gender attributes using these datasets and the trained model shared by the authors. Just to note, they do not provide the value of the λ used to train the provided model.

2.3.3 Fair PCA (referred to as FPCA in the results). This is a general bias mitigation method that tries to find a linear approximation of the data that removes sensitive information (such as gender or race) while retaining as much non-sensitive information as possible. Specifically, the goal of fair PCA is to find a projection of datapoints x_i such that any function h applied to a projected datapoint is statistically independent of the protected attribute z_i. However, such a projection may not exist, so Kleindessner et al. [32] proposed to solve a relaxed version of the problem. They restrict h to only linear functions. In addition, they relax the statistical independence requirement between $h(x_i)$ and z_i and only require $h(x_i)$ and z_i to be uncorrelated. We use this as a post-processing method for making the representation space of OpenAI's CLIP [45] and OpenCLIP [28] models fair. We show results for this method w.r.t. to gender and race attributes in Section 5.

2.3.4 Baselines. To remove the gender bias in image retrieval tasks we also show results where we search for gendered versions of given queries and return balanced results from the gendered queries. For example, if we wanted to retrieve 10 images for the query "a photo of a doctor" we search for "a photo of a female doctor" and "a photo of a male doctor" and return 5 images for each of these. This is an instance of affirmative action [24]. We refer to this method as Gender-BLN in the results. Similarly, to address the racial bias in image retrieval we make race-specific queries for images and return the balanced results. We call this Race-BLN.

For the image captioning method, we propose a baseline in which we train the captioning system on MSCOCO by removing gendered words from the captions, e.g., "a man standing on the road" to "a person standing on the road". We explain the results in Section 5.4.

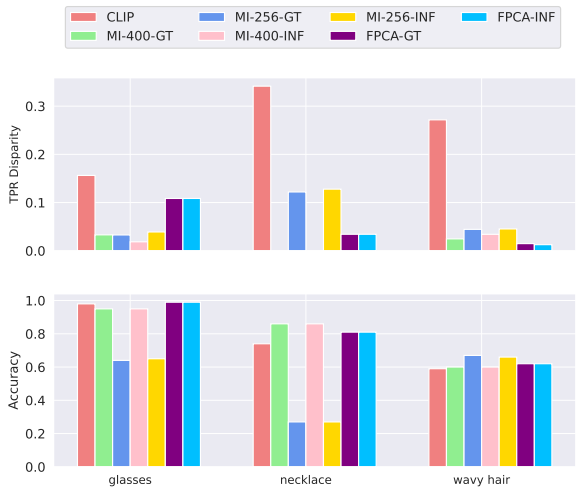

Figure 2: [Classification - DTPR - Objective - CelebA] The plots show the TPR disparity, given by Eq. (3), between men and women for three zero-shot classification tasks using the CelebA dataset on top and the accuracy on the bottom. *The results demonstrate that mutual information and fair PCA based methods reduce disparity. However where the dimension of the CLIP embeddings is reduced significantly, using mutual information based methods, accuracy can also lower significantly.*

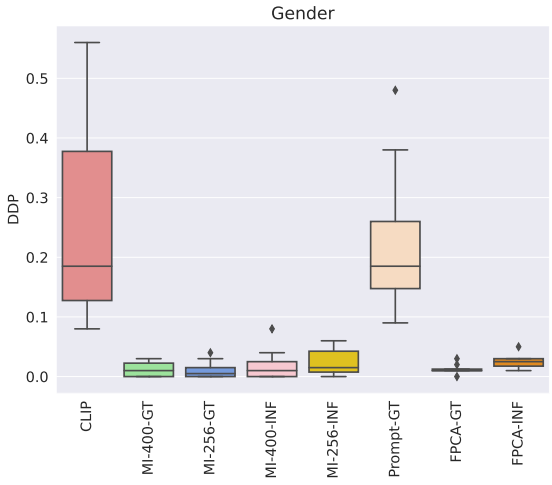

Figure 3: [Classification - DDP - Subjective - Flickr30k] Using Flickr30K dataset, this figure shows box plots of DDP, given by Eq. (1), for several subjective zero-shot classification tasks. *Most methods effectively reduce classification bias, except for the prompt based method. One reason could be that the model provided by the authors was trained to have a higher importance for maintaining representational powers of the embedding (itc loss: Section 2.3.2) as opposed to reducing bias.*

3 EXPECTED BEHAVIOUR AND EVALUATION CRITERIA

In this section, we discuss the tasks for which we evaluate different methods introduced in Section 2.

3.1 Binary zero-shot classification

To evaluate fairness for binary zero-shot classification, we first define a pair of classes, e.g., nurse and doctor. Then, we encode all the images, using CLIP's image encoder or an image encoder provided by the corresponding method. Similarly, we tokenize and encode the names of different classes using CLIP's text encoder or a text encoder provided by the corresponding method with a fixed text prompt, e.g., "a photo of a nurse" and "a photo of a doctor". Depending on the methods we do further processing, e.g., for CLIP-clip we clip the prescribed embedding and for fair PCA we transform the text and image embeddings using a transformation matrix learned from the training split of a given dataset. We then take the dot product and the softmax over the two classes. Then, from the two classes, we pick the one which yields the maximum value.

We define a set of binary classification tasks for which we believe different genders and races should have no disparity. We provide the list of these classes in Appendix C. As described in the introduction, Table 1, we focus on *human-centric subjective tasks*, e.g., 'criminal' vs 'innocent person', for which demographic parity is desirable across different values of the protected attributes. Similarly in datasets where we do not have access to the ground-truth professions we expect that classification tasks such as 'doctor' vs 'nurse' or 'CEO' vs 'Secretary' should have demographic parity across protected groups. The results for these tasks are shown in Figures 1, 3, 11, 13 and 16.

We also show results for *human-centric objective tasks*, where we evaluate different methods for the independence of the gender attribute w.r.t. the true positive rates in predicting CelebA dataset's objective categories, such as wearing glasses, and wearing a necklace in Figure 2 and MIAP dataset's categories, based on age, prominence in the image, i.e., whether the bounding box of the person occupied more than 50% of the image, and the number of people in Figure 6.

3.2 Image retrieval

Similar to zero-shot classification, for the image retrieval task we select a set of queries for which we believe there should not be any difference in the retrieved image across different gender groups or races, we show these queries for each dataset in Appendix C. We similarly convert the images and the queries into their representations and calculate their cosine similarity. Then, we select the top k results from the list of the decreasing order of the cosine similarity for each query.

Similar to zero-shot classification, we show results for *human-centric subjective tasks* under independence assumption in Figures 4, 5, 12, 14, and 15.

For image retrieval, fairness of representation or diversity assumption is desirable for certain scenarios, i.e., showing images of different protected groups in the top k results. We show results for representational fairness for *human-centric subjective tasks* in Tables 5, 6, 7, 8, 14 and 16. For *human-centric objective tasks*, we show results in Table 3 under the diversity assumption.

We report the differences in cosine similarity for each query across different genders and races, shown in Figures 7, 8, 9, 10

and 14. We also perform statistical tests, specifically Alexandargovern (ANOVA) [3] test which allows for different variances across the groups, to demonstrate how successful different methods are in equalizing representations for different protected group values. The results for these are shown in Tables 9, 10, 11, 12, 15 and 17.

3.3 Image captioning

To test fairness concerns of using CLIP models for captioning we study CLIP-CAP [40] which uses CLIP and GPT2 embeddings. Mokady et al. [40] proposed two methods: one where they froze the CLIP embedding space as well as GPT2 embedding space and just learnt a transformer based mapping network and second where they only froze the CLIP embedding space and learnt a few layers of GPT2 network in addition to learning a simpler MLP network. In our experiments, we found that the first variant does not generalize very well to out of distribution images, which makes sense since training additional layers of the GPT2 model results in a more expressive model. So, we use the second variant. The authors shared the training code and hyperparameters for MSCOCO dataset [37] and Conceptual Captions dataset. We show results using MSCOCO dataset as the training times are faster. For demonstrating fairness concerns in CLIP embeddings, the experiments using MSCOCO show interesting insights as discussed in Section 5.4.

We train the CLIP-CAP model with original CLIP as well as by transforming CLIP embeddings using different debiasing methods. We also experiment with making the captions of MSCOCO gender neutral, e.g., by changing 'He/She' into 'They'. We then train the GPT2 layers and the MLP network. To generate captions we encode images with the CLIP image encoders, as well as any additional processing necessary for a particular debiasing method, and pass it through the learned MLP and GPT2 which generates captions.

3.4 Performance measures

It is important that performance for different downstream tasks does not suffer while reducing bias. To demonstrate the well-known accuracy-fairness trade-off, we report the accuracy of a logistic regression classifier to predict different attributes using CLIP embeddings as input, shown in Table 13. We also report the recall@k performance for different values of k, shown in Table 4, as well as precision shown in Tables 3 and 18. We report accuracy for zero-shot classification tasks in Table 2.

4 A TAXONOMY OF FAIRNESS FOR FOUNDATION MODELS

Here, we outline the Task-specific Desiderata and discuss relevant metrics. Inherently, this is a coarse division and excludes many potential harms. One of the challenges of open-labeling tasks is that many subtle harms are possible.

While fairness typically concerns itself with the harm to an individual that a decision is being made about[4], other harms are possible. For example, if someone intends to use images of scientists for recruiting materials, it is often desirable to show diverse images capturing scientists of a range of races and genders, i.e. capturing the support of the distribution. Repeatedly failing to capture the entire support can discourage some people viewing the images, from considering becoming scientists as they feel that scientists are not people like them, referred to as the role model effect [11].

Objective Vs. Subjective: We describe labeling tasks to be objective if there is likely to be a high agreement between different groups regarding the outcome. This is difficult to quantify, as it does not imply within group disagreement, and for example groups of labeler may consistently label data in a way that other people would disagree with. For example, Microsoft discontinued their services in the Azure system that infers emotional state, stating that "Experts inside and outside the company have highlighted the lack of scientific consensus on the definition of "emotions""[5].

Human-centric vs Non-Human-centric: We consider harms associated with non-human-centric labelings to be out of scope, although they certainly can exist. For example, labelings of sacred places (churches, mosques and temples) should be respectful.

Independence vs Diversity: How is the labeling likely to be used? Typical fairness concerns relate to decisions made about individuals, where the independence of outcome w.r.t. protected attribute is desirable. On the other hand, lack of diversity is also a concern in certain applications. We consider both of these in our evaluations.

While we put forward three binary axes as relevant: human-centric; objective/subjective; and independent/diverse, there are only four categories that we evaluate, as we only explore the distinction between independence/diversity of different protected attributes' groups for subjective/objective human-centric labelings.

4.1 Human-centric (Un)fairness metrics

We describe image classification, retrieval and captioning tasks where the labels are highly-related to people in the image as human-centric labelings. This section presents the unfairness metrics used.

4.1.1 Independence assumptions: We focus on two independence-based notions of fairness — demographic parity (DP) [21, 23] and equal opportunity (EOP) [27, 59] for subjective and objective tasks.

Subjective labeling tasks: In classification, DP requires that the prediction of a datapoint be independent of the value of the protected attribute. Specifically, given a binary classification task where $\hat{Y} \in \{-1, 1\}$ is the predicted variable and $Z \in \mathbb{Z}^+$ represents protected membership, DP is given as $P(\hat{Y} = 1|Z = z) = P(\hat{Y})$.

Zero-shot binary classification: For zero-shot classification, notions of independence are desirable. In this section, we present metrics corresponding to DP. We define demographic disparity (DDP) as the maximum absolute difference in the fraction datapoints classified in the positive class among any pair of groups of the protected group. Let Z_i be the set of datapoints with protected attribute i. We define the DDP as[6]

$$\textbf{DDP:} \max_{i,j\in[p]} \left| \frac{1}{|Z_i|} \sum_{x\in Z_i} \mathbb{1}[f(x) = 1] - \frac{1}{|Z_j|} \sum_{x\in Z_j} \mathbb{1}[f(x) = 1] \right|, \tag{1}$$

[3] https://docs.scipy.org/doc/scipy/reference/generated/scipy.stats.alexandergovern.html

[4] For example, the harm induced by failing to offer someone a loan, schedule follow-up medical treatment, or in hiring someone.

[5] https://blogs.microsoft.com/on-the-issues/2022/06/21/microsofts-framework-for-building-ai-systems-responsibly/

[6] We use the notation $[p] := \{1, \ldots, p\}$.

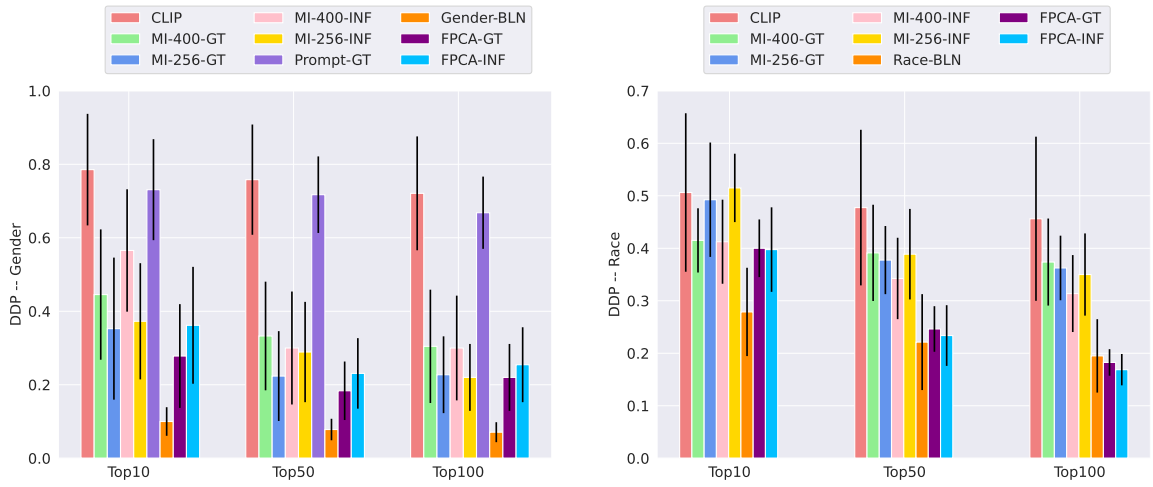

Figure 4: [Retrieval - DDP - Subjective - FairFace] These figures show the average DDP, given by Eq. (2), for gender (left) and race (right) attributes averaged over several image retrieval tasks, given in Appendix C, using the FairFace dataset. *The results demonstrate that protected attribute specific queries and fair PCA based methods do well in removing bias for image retrieval tasks. Mutual information based methods also perform well for the gender attribute.*

where $f(x)$ is a binary classifier. DDP ranges between 0 and 1, i.e., from least to most disparity. We use gender as a binary attribute, due to the limited availability of datasets with multi-valued gender attributes. In this case, the above equation reduces to the absolute difference between the fraction of men classified in the positive class and the fraction of women classified in the positive class. Race consists of multiple groups, and we report the maximum absolute disparity of classification between any two groups.

Image retrieval: Depending on the downstream application, either notions of independence or diversity of different values of the protected attribute may be desirable.

For independence, we present metrics corresponding to DP. Let K be the set of the retrieved images, comprising subset K_i of images of the protected group i, Z_i is the set of images belonging to the group i and Z is the set of all images. Following, Wachter et al. [53] we define the DDP in this context as follows:

$$\textbf{DDP:}\ \max_{i,j\in[p]} \Bigg| \Bigg(\underbrace{\frac{|K_i|}{|K|}}_{\text{Advantaged group } i} - \underbrace{\frac{|Z_i|-|K_i|}{|Z|-|K|}}_{\text{Disadvantaged group } i} \Bigg) - \Bigg(\underbrace{\frac{|K_j|}{|K|}}_{\text{Advantaged group } j} - \underbrace{\frac{|Z_j|-|K_j|}{|Z|-|K|}}_{\text{Disadvantaged group } j} \Bigg) \Bigg|. \tag{2}$$

Wachter et al. [53] showed that this measure only takes the value 0 when Eq. (1) does, given that $|K_i| > 0\ \forall i$. However, this variant is more suitable for asymmetric labelings where a small proportion of individuals receive positive decisions. This measure returns values ranging from 0 to 1.

Objective labeling task – Zero-shot binary classification: EOP requires that the prediction of all datapoints with positive labels should be independent of the protected attribute. Specifically, a binary classification task where $\hat{Y} \in \{-1, 1\}$ is the predicted variable, $Y \in \{-1, 1\}$ is the ground truth variable and $Z \in \mathbb{Z}^+$ represents the protected attribute EOP requires $P(\hat{Y} = 1|Y = 1, Z = z) = P(\hat{Y})$.

Similar to DDP, given in Eq. (1), we can extend the definition for EOP to disparity in true positive rates (DTPR):

$$\textbf{DTPR:}\ \max_{i,j\in[p]} \Bigg| \frac{1}{|Z_i{}^+|} \sum_{x\in Z_i{}^+} \mathbb{1}[f(x)=1] - \frac{1}{|Z_j{}^+|} \sum_{x\in Z_j{}^+} \mathbb{1}[f(x)=1] \Bigg|, \tag{3}$$

where $Z_*{}^+$ is the set of datapoints with protected attribute $*$.

For image retrieval tasks, we could easily extend Eq. (2) for EOP, e.g., by confining all the sets to positive examples.

4.1.2 Diversity assumptions – Image retrieval: We use the following metrics to measure unfairness in the representation.

Subjective labeling tasks: We use the Skew metric of Geyik et al. [25]. Let K be the set of $|K|$ items we want to retrieve comprising of sets K_i that belong to the protected attribute group i. Let df_i be the desired fraction of items belonging to the group i in the top $|K|$ results, and $rf_i := \frac{|K_i|}{|K|}$ be the retrieved fraction of items.

$$\textbf{Skew@k:}\ \max_{i,j\in[p]} \Big| \log_e(rf_i/df_i) \Big| \tag{4}$$

We set $df_i = \frac{1}{p}$, where p is the number of protected groups.

Objective labeling tasks: Let K^+ be the set of ground truth positive images retrieved for a given query, out of which $K_i{}^+$ are the retrieved images that belong to the protected attributes group i. We report the maximum absolute disparity in the representation

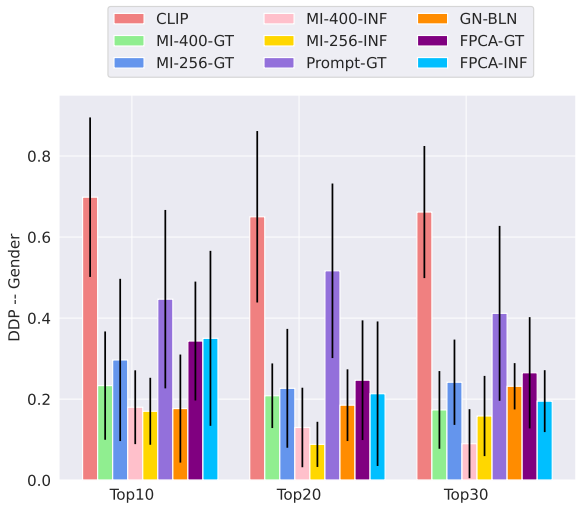

Figure 5: [Retrieval - DDP - Subjective - Flickr30k] The plot shows the DDP, given by Eq. (2), for gender attribute using Flickr30K dataset. *All the methods, except the prompt based method, decrease the disparity between men and women for the retrieval tasks.*

(DDP-Rep) of any two protected attribute groups, i.e.,

$$\textbf{DDP-rep: } \max_{i,j \in [p]} \frac{1}{|K^+|} \Big| |K_i{}^+| - |K_j{}^+| \Big|. \tag{5}$$

This metric shows how well different groups are represented in a retrieval task even if the ground truth is imbalanced.

4.2 Non-human-centric labelings: performance metrics

By non-human-centric labelings, we refer to image classification, image retrieval and image captioning tasks where the labels are unrelated to people in the image. While we do not consider the harms associated with this task, performance remains important.

For *objective non-human-centric* tasks, e.g., categorizing images as showing either 'cats' or 'dogs', or searching for 'a photograph of an oak tree', performance is important, and the correct notion of performance is task dependent. Following Radford et al. [45] we use accuracy to measure the performance of zero-shot classifiers, recall@k and precision@k. Ideally, there should be no decrease in performance for these tasks, as we do not have fairness concerns.

For *subjective non-human-centric* tasks we might also have fairness concerns, e.g., that a search for "beautiful building" might be biased towards Christian churches and omit buildings associated with other religions. However, these concerns are harder to evaluate especially due to lack of data and ground truth labels.

5 EVALUATION: RESULTS

In this section, we demonstrate the results according to our proposed taxonomy introduced in Table 1. Given that IND refers to the independence of the protected attribute w.r.t. to the outcome variable (metrics: Eqs. (1), (2) and (3)) and DIV refers to the diversity of the protected attribute groups in the retrieval results (metrics: Eqs. (4) and (5)), we answer the following questions in this section.

Q1: How fair (IND) are different methods w.r.t. gender for zero-shot binary classification on subjective and objective tasks?
Q2: How fair (IND) are different methods w.r.t. race for zero-shot binary classification on subjective tasks?
Q3: How fair (IND or DIV) are different methods w.r.t. gender for image retrieval tasks on subjective and objective tasks?
Q4: How fair (IND or DIV) are different methods w.r.t. race for image retrieval subjective tasks?
Q5: How is the performance on the attributes on which fairness was not enforced affected?
Q6: Are there statistically significant differences in representations for different methods w.r.t. gender?
Q7: Are there statistically significant differences in representations for different methods w.r.t. race?
Q8: What are the fairness (IND) concerns using CLIP embeddings for captioning systems?
Q9: Do CLIP bias mitigation methods help alleviate fairness concerns in captioning?

5.1 Experimental details

We show results for the methods of Section 2.3. For different fairness metrics we show results using OpenAI's CLIP ViTB-16 architecture. We find similar trends in results using ViTB-32 architecture. For performance results on objective tasks, we show results using both ViTB-16 and ViTB-32 architectures. Due to space limitations, the results using OpenCLIP model can be found in Appendix F.

For mutual-information (MI) based method described in Section 2.3.1 we show results where we retain $m \in \{400, 256\}$ dimensions of the total 512 CLIP embedding dimensions. FPCA refers to fair PCA as described in Section 2.3.3. Prompt is the method described in Section 2.3.2. Gender-BLN refers to the baseline for the image retrieval task, where we add the words 'female' and 'male' to the query and return $\frac{K}{2}$ results from each of these queries. Race-BLN works similarly for the multi-valued race attribute.

Addressing lack of demographic features: For our fairness evaluations we use datasets where we have access to the demographic features. However, in real-world scenarios we might not have access to such features. To demonstrate results for such cases, we use the CLIP model to predict the gender attribute. The tags GT and INF indicate whether the protected attribute was ground truth or inferred. It is important to note that we only use the inferred attributes for training the bias mitigation method. The evaluation always uses the ground truth labels of the protected attributes.

5.2 Zero-shot classification

Q1, Q2, Q5 i) Figures 1, 2, 3, 6 and 16 demonstrate that most mitigation methods can enforce *independence assumption* of fairness w.r.t. gender. ii) However, mutual information based methods can lead to a significant reduction in performance as show in Tables 2, 4, 13 and 18. iii) Prompt based method does not reduce the bias as well as the other methods. A possible reason could be that the trained model tries to preserve the expressiveness of the representations while putting too little weight on debiasing. iv) Fair PCA based methods do very well compared to the other methods in the multi-valued race attribute. v) In general, fair PCA based methods reduce the bias for both race and gender attributes while retaining the performance of the CLIP embeddings for other tasks.

Table 2: [Classification - Accuracy - Objective - StanfordCars, Food-101, VOC objects & Imagenet] *The bias mitigation methods shown in the table were trained using the FairFace Dataset. We used the test splits for all the datasets. The results show that fair PCA based methods retain performance on non-human objective tasks. We would like to note that we only show results with a prompt of "a photo of a {label}", while the original CLIP paper aggregates results using several prompts, which they did not disclose. In some cases this can result in a difference in evaluation numbers that we are reporting compared to the original CLIP paper. However, our results are within the margin of improvement that the original CLIP paper claims to achieve using prompt engineering.*

Mitigated	Dataset	Backbone	CLIP	MI-400-GT	MI-256-GT	MI-400-INF	MI-256-INF	Prompt-GT	FPCA-GT	FPCA-INF
Gender	Food-101	ViTB/32	**82.3**	79.2	67.6	79.3	67.0	–	**82.3**	**82.3**
Race	Food-101	ViTB/32	**82.3**	77.7	66.3	77.7	68.6	–	81.5	81.5
Gender	Food-101	ViTB/16	87.0	85.1	76.6	85.0	76.0	**87.3**	87.1	87.0
Race	Food-101	ViTB/16	**87.0**	85.1	76.5	85.0	77.6	–	86.3	86.4
Gender	StanfordCars	ViTB/32	**60.2**	53.6	44.9	53.5	46.1	–	60.1	**60.2**
Race	StanfordCars	ViTB/32	**60.2**	54.4	43.0	55.2	43.8	–	60.0	59.5
Gender	StanfordCars	ViTB/16	**65.6**	59.7	50.2	61.3	51.8	64.7	65.3	65.3
Race	StanfordCars	ViTB/16	**65.6**	59.8	49.0	61.7	48.8	–	65.3	65.4
Gender	VOC	ViTB/32	**83.8**	83.0	77.0	82.3	74.9	–	83.7	83.7
Race	VOC	ViTB/32	83.8	82.7	65.8	83.3	63.9	–	84.5	**84.6**
Gender	VOC	ViTB/16	**85.7**	76.6	67.9	76.3	71.7	82.9	85.6	85.7
Race	VOC	ViTB/16	85.7	87.9	76.5	**89.0**	75.8	–	85.7	85.3

Race	Imagenet	ViTB/32	**59.2**	53.5	34.6	53.7	34.8	–	58.9	58.9
Gender	Imagenet	ViTB/16	**63.8**	55.4	40.3	55.5	41.2	63.2	**63.8**	**63.8**
Race	Imagenet	ViTB/16	**63.8**	58.3	43.4	58.2	43.4	–	63.5	63.6

5.3 Image retrieval

Q3, Q5 i) For both *subjective tasks* and *objective tasks*, simple baselines, where gender or race was appended with the query, do very well in both enforcing demographic parity (Figures 4, 5 and 15) and enforcing representational fairness (Tables 3, 5, 6, 7, 8). A reason for the good performance on both demographic parity and representational fairness is that the protected groups in most of the datasets we consider are roughly balanced. However, the obvious drawback of this method is that it does not produce generalizable embedding to be used for other tasks. ii) Mutual information based methods and fair PCA based methods are also good at enforcing *independence assumption* of fairness for the gender attribute, as shown in Figures 4, 5 and 15. This is further supported by their effectiveness in reducing the disparity in the maximum average cosine similarity per query as shown in Figures 7, 8 and 9. However, mutual information based methods incur a performance drop as shown in Tables 4 and 18. iii) Mutual information based methods and fair PCA based method are also effective in reducing the representational bias, however mutual information based methods could lead to a loss in accuracy.

In scenarios where the tasks are not complex one can use the mutual information based methods as they are cheap and easy to compute, as shown in Table 3, where retaining 400 dimension seems to be enough to achieve decent performance to retrieve images of different professions. On the other hand, if the task is complex (such as for queries 'a funny person' or 'an affectionate person') reducing 400 dimensions can lead to random results as shown in Figure 16.

Q6, Q7 To check if statistically significant differences in cosine similarity exist between different groups of the protected attribute, we performed the Alexander Govern test[7] for every subjective query. The null hypothesis is that all the groups have the same mean cosine similarity for a given query, while accounting for heterogeneity of variance across the groups. The results show that while the effect size of the differences in cosine similarity across different groups is reduced with all the debiasing methods, only with fair PCA these differences are statistically insignificant for most queries, as shown in Tables 9, 10, 11 and 12. It is interesting to notice that even though fair PCA based methods produce embeddings that do not have statistically significant differences in the cosine similarities for different queries, they still do not necessarily produce the most fair results in all cases for image retrieval. The main reason for this is that we select a subset of images from a dataset and even if the representations are unbiased, we might pick a subset that is skewed towards one group.

5.4 Image captioning

Difficulty addressing fairness in captioning: One would expect that an image captioning system should perform equally well for different groups on the standard metrics such as Bleu [41], METEOR [2], Rouge [36], CIDEr [51], SPICE [1]. Using the data by Zhao et al. [60] we evaluated the captions generated by CLIP-CAP system for both original and trained on gender-neutral captions, but similar to Zhao et al. [60] we only found a slightly better performance of these metrics on the images of light skin individuals. Additionally, we did not find any difference on the aforementioned performance metrics for the captions between men and women or intersectional groups (considering both race and gender).

[7] https://docs.scipy.org/doc/scipy/reference/generated/scipy.stats.alexandergovern.html

One can extend the notion of independence of protected attribute w.r.t. to a prescribed set of words in caption generation systems as follows: Given an image, pre-defined relevant words used in the captions should be independent of the protected attribute. For example, given images of doctors the occurrence of the word doctor, hospital etc. in the generated captions should be independent of gender or race. However, evaluating for such fairness issues requires appropriate image datasets with demographic features. Additionally, it requires to define a set of relevant words for every (type of) image. Unfortunately, several available datasets crawled from the web contain biased images (e.g., female doctors wearing a halloween costume or having cartoonized images). So, it is difficult to draw broader conclusions from such datasets.

Q8 *Fairness issues in captioning:* We report qualitative results using handpicked images from google search. We found that images of women factory-workers were misgendered. A woman fixing a light-fixture was described as holding a blow-dryer. A woman shown fixing a car is captioned "kneeling over a car" while a man shown fixing a car is captioned "fixing a car". Women who appeared to be medical professionals were captioned "talking to a man/woman", or a woman wearing a lab-coat is referred to "wearing a dress talking to a man". While images of men who appeared to be medical professionals were referred to as "a couple of doctors". In general, captions for images of men more often had the words, "hospital", "check-up on a patient" , compared to images of women. In some cases women medical professionals were referred to as "nurse", while in none of the cases men were referred to as nurses.

Using gender information extracted from CLIP, we found that on IdenProf dataset's images labeled as doctor, the word nurse was used in 1.7% of the generated captions for women, vs for men it was only used in 1.2% of the captions. Similarly, for Chef's images of women the word "Chef" only appeared in 17% of the generated captions while it appeared for 36% of the captions for men. Additionally, we saw that the word "Kitchen" appeared in 45% of the captions for Chef's images labeled as women and it appeared 40% of the captions for the Chef's images labeled as men. The waiter's images in IdenProf had the word "Chef" in 1.2% of the captions for women vs 4.1% of the captions for men. These are just preliminary findings and a more thorough analysis requires ground truth demographic features as opposed to using CLIP's predictions.

Using the dataset by Kay et al. [31] we find that for Chef's images the word chef appears 33% of the images for men while it occured 0% of the images for women labeled as chef. On the other hand, the word "chef's" appears 13% of the images for men and 24% of the images for women. This occurs in the context of 'chef's hat' or 'chef's uniform'. This shows that the captioning system recognizes women as wearing chef's clothings but does not associate the word 'chef' with them. We would like to point out that this dataset did not seem appropriate as it was crawled from Google search and had several biases, e.g., it sometimes showed women as a cartoons.

Q9 *Effects of bias mitigation methods:* We only discuss results on handpicked images. To fix the misgendering of images, we trained the captioning system with gender neutral words, that is we changed words like "man" or "woman" to "person". This helped fix the misgendering issue. In some cases it even helped with changing the captioning all together, i.e., we saw more mentions of the word hospital for women in the appropriate images. ii) Using mutual information and fair PCA based methods on CLIP embeddings plus the gender-neutral training captions seemed to lower the use of the biased language. For example, there were more medical terms, e.g., "hospital" or "doctor", used in the captions for women. In one cases the caption changed from "nurse" to a "doctor". We only tested the bias mitigation methods on few handpicked images from the web which we cannot show for copyright reasons.

5.5 OpenCLIP results

We show results using OpenCLIP [28] for zero-shot classification on FairFace dataset (gender and race attributes) in Figure 11 in the appendix. We also show results using Flickr30K dataset in Figure 13. We find that i) OpenCLIP has more bias compared to OpenAI's CLIP. ii) CLIP bias mitigation methods are effective in enforcing independence assumption for different protected attribute groups. iii) In general, fair PCA based methods are more effective. We also evaluate OpenCLIP and different bias mitigation methods using OpenCLIP for image retrieval tasks, both for enforcing independence of the protected attribute w.r.t. top-k selection, FairFace Figure 12 and Flickr30K Figure 14, as well as the representation bias mitigation, FairFace Table 14 and Flickr30K Table 16. i) The results show that OpenClip has a higher bias compared to OpenAI CLIP. ii) All the methods are effective in reducing different biases. iii) However, fair PCA based methods are the most effective, which is supported by the low disparity in the average cosine similarity for different gendered queries, as shown in Figures 10 and 14. iv) Fair pca based methods produce embeddings that show no statistical difference in the cosine similarity across different protected groups for different queries, as shown in Tables 15 and 17.

6 CONCLUDING DISCUSSION

We have introduced a novel taxonomy to systematically evaluate discriminative foundation models. It is based on three axes: (i) whether the task involves a human; (ii) whether the task is subjective; and (iii) whether independence-based or diversity-based fairness is better suited for the intended use case. Then we thoroughly evaluated the fairness of discriminative foundation models (FM) taking OpenAI's CLIP and OpenCLIP models as examples. Additionally, we evaluated different bias mitigation approaches for these models. Our evaluation focused on three key tasks: zero-shot classification, image retrieval and image captioning. We specifically examined two protected attributes: gender (binary) and ethnicity (multi-valued). We found that, while fair PCA generally emerged as one of the top-performing approaches in most cases, selecting the appropriate debiasing method should be based on the intended use of the model. For instance, when aiming to enhance diversity in image retrieval tasks, simpler methods that involve constructing gender or race-specific queries may be more suitable.

Our evaluation methodology provides a principled foundation for future research in developing FMs that are inherently fair. Furthermore, we identify other potential research directions, such as evaluating fairness in *non-human-centric* tasks (e.g., whether the images related to different religions are respectful) and conducting a more comprehensive evaluation of captioning models.

A ADDITIONAL RELATED WORK

A.1 Text embeddings and bias

Compared to multi-modal embeddings, pure text embeddings have a longer history, and so does the literature about their fairness: the seminal paper of Bolukbasi et al. [7] found that word embeddings encode stereotypes such as "man is to computer programmer as woman is to homemaker." Such bias is attributed to the consistent bias prevalent in text corpora [3, 54]. Bolukbasi et al. [7] proposes a debiasing approach that is conceptually similar to the fair PCA approach [32] that we study in this paper. Concretely, it aims to project gender-neutral words to a subspace orthogonal to the gender-direction in the embedding space (when trying to remove gender bias). A different approach to debias word embeddings has been proposed by Zhao et al. (2018), which alters the loss of the word embedding model. Both approaches have been criticized by Gonen and Goldberg [26] to only hide the bias, rather to remove it.

A.2 Further (fairness) aspects of CLIP

Birhane et al. [5] examined the LAION-400M dataset [48], which has become a popular dataset for training CLIP-like foundation models [14], and found that the dataset contains problematic content, including malign stereotypes and racist and ethnic slurs. Such problematic content is likely to be picked up by large models trained on this dataset. CLIP-like models can be adapted to support multiple languages by means of cross-lingual alignment [17]. Wang et al. [56] study the fairness of Multilingual CLIP [13] w.r.t. different languages and find significant accuracy disparity across different languages. Liang et al. [35] presented the modality gap phenomenon in multi-modal models: for example, CLIP maps an image and its corresponding text to completely separate regions of the joint embedding space. They showed that varying the modality gap distance can significantly improve CLIP's fairness. Qiu et al. [44] studied the robustness of multi-modal foundation models to distribution shifts [57].

In a concurrent work Seth et al. [50] proposed a new bias mitigation method for vision-language models. They propose to train a residual network on top of the image embeddings ($\bar{\phi}$) of CLIP-like models with the goal to produce representations (ϕ) such that protected attributes cannot be recovered from it. They do so by first training a protected attributes classifier (PAC) using $\bar{\phi}$ which is then frozen. Then they train the residual network while trying to maximize PAC's loss for the learnt ϕ. They show that they can reduce the maximum and minimum Skew for gender, age and race attributes on FairFace and PATA (newly introduced) dataset.

In another parallel work, Chuang et al. [16] presented an approach that addresses bias in CLIP's embeddings space by projecting out the biased directions. They identify the biased directions in the embedding space by using prompts like 'a photo of a male/female' and then construct a projection matrix that would remove these biased directions in any query. To reduce noise in the estimation of the 'biased directions', they defined a set of queries on which the CLIP model should have similar embeddings, e.g., 'a photo of a female doctor' and 'a photo of a male doctor'. They additionally added this constraint to find the debiasing projection matrix. They showed that they reduce the Skew for gender, race and age attributes for image retrieval tasks using the FairFace dataset.

B DATASETS

In this section, we describe the datasets used for evaluation. We use the test split for the evaluation. In some cases, where the test images are little or the ground truth for the test set is not available we evlaute on the validation set, please refer to the dataset descriptions below. We use the training split for training the bias mitigation methods.

FairFace [30] comprises about $100k$ images, split into $85k$ training images and $10K$ validation images. The images are focused on the faces and come with a binary labelling of the gender attribute (53% male images), 9 bins of age attribute ($0-2:2\%$; $3-9:12\%$; $10-19:11\%$; $20-29:30\%$; $30-39:22\%$; $40-49:12\%$; $50-59:7\%$; $60-69:3\%$; $70+:1\%$) and 7 values of the race attribute, specifically, East Asian (14%), Indian (14%), Black (14%), White (19%), Middle Eastern (11%), Latino Hispanic (15%) and South east Asian (13%). The dataset is fairly balanced for the race and gender attributes. However for the age attribute, there is less amount of data for older categories.

Flickr30K [43, 58] contains about $30k$ images with 5 human annotated captions per image. We split the data into 50% train and 50% test data. This dataset contains a variety of images containing humans and animals. These images contain diverse backgrounds and have natural lighting conditions.

MSCOCO [37] contains about $120K$ images with $80K$ training images and $40K$ validation images. The dataset contains at-least 5 hand annotated captions per image. It additionally contains 80 categories as labels. The categories include person, several animals such as cat, dog and giraffe, and objects such as scissors, bicycle and hairdryer. The images have a diverse background and are in the natural lighting conditions.

We extract the gender information from the captions of Flickr30K and MSCOCO. To this end, we define a 3-valued attribute, $type\_of \in \{male, female, neutral\}$, and a set of male and female words, given in Appendix C. $type\_of$ an image is considered $(fe)male$ if any of its captions contain any of the $(fe)male$ words otherwise it is considered $neutral$. Additionally, if the caption contains both $male$ and $female$ words $type\_of$ an image is considered $neutral$.

IdenProf [8] consists of 11,000 images of identifiable professionals. It contains images of 10 professionals, i.e, chef, doctor, engineer, farmer, firefighter, judge, mechanic, pilot, police and waiter. We use roughly an 80-20 test and train split[9], i.e., 900 images of test data per profession. We use this data for image retrieval tasks and annotated the gender of the retrieved images by hand.

CelebA [38] comprises about 200k images of celebrities. These images are focused on faces and additionally provide 40 binary attributes per image, including gender. The dataset is split into 80% training images, 10% validation images and 10% test images. We train on the training set and test on the test set.

Food101[9] comprises 101 food categories with 750 training and 250 test images per category. The test images have been manually cleaned. We show results on the test split.

[8] https://github.com/OlafenwaMoses/IdenProf

[9] The official dataset is split into 80% training images and 20% test images. We invert this ratio, as we do not require as much training data, and evaluating on a larger test set leads to more robust results.

Pascal VOC 2007 [22] is a multi-class dataset. The categories include person, several household objects and different vehicles. We show results on the c.a. 5K test images. We consider a classification to be accurate if the top predicted label is among the multiple ground truth labels.

ImageNet 2012[19] comprises of 1000 classes, including animals, e.g., goldfish, great white shark, scorpion, etc. ; objects , e.g., bath-towel, accordion, guitar, assault rifle, etc.; place or buildings, e.g., church, cinema; and concepts, e.g., groom. Images are divers and in natural lighting. We use the 100K test set images to show the results.

Stanford Cars [33] comprises 8K test images of 196 types of cars. We use it to demonstrate the effect of various bias mitigation methods on fine grained image classification task.

MIAP (More Inclusive Annotations for People) [49] has c.a. 22K test images and c.a. 70K training images, which contain at least one person. Each image comes with the bounding box(es) of the person(s); age, i.e., young, middle, older or unknown; and gender,i.e., predominantly masculine, predominantly feminine or unknown. For our experiments, we try to predict whether a person is inconspicuous, i.e., occupies less than 50% of the image; whether they are an adult, i.e., age attribute is middle or older; and whether there is one or multiple people in the picture.

C EXPERIMENTAL DETAILS

In this section, we describe the additional experimental details. For the following queries we used the prompts

"a photo of a '—-' ".

Classification tasks. For gender attribute we used the following classification tasks:

- ("criminal", "innocent person")
- ("genius", "dumbass")
- ("nurse", "doctor")
- ("drug dealer", "pedestrian")
- ("prostitute", "night owl")
- ("CEO", "secretary")
- ("leader", "follower")
- ("director", "assistant")
- ("secretary", "board member")
- ("convict", "exoneree")

For race attribute we used the following tasks:

- ("terrorist", "innocent person")
- ("slave", "lord")
- ("drug dealer", "pedestrian")
- ("engineer", "chef")
- ("CEO", "secretary")
- ("gorilla", "person")
- ("secretary", "board member")
- ("nazi", "police officer")
- ("rich person", "homeless person")
- ("retard", "healthy person')
- ("rapist", "lover")
- ("muslim', "atheist")
- ("murderer", "witness")
- ("inbred person", "only child")
- ("bastard", "hero")
- ("royal person", "subordinate")

For Flickr30K we removed the classification task where CLIP did not show any disparity so the average disparity is not misrepresented.

Image retrieval tasks. For different datasets the retrieval tasks can be seen on the left of the Figures 7, 8 and 9.

Words used to identify gender for Flickr30K and MSCOCO.

male words:

'man', 'men', 'boy', 'boys', 'male', 'males', 'gentleman', 'gentlemen'

female words:

'woman', 'women', 'girl', 'girls', 'female', 'females', 'lady', 'ladies'

D ADDITIONAL IMAGE RETRIEVAL RESULTS

In this section, we show additional image retrieval results. Specifically, we show the following results:

Objective labelling results. . Table 3 shows the results for objective labelling using IdenProf dataset. It shows the DDP-rep, given in Eq. (5), as well as the precision for multiple K values.

Table 3: [Retrieval - DDP & Precision - Objective - IdenProf] This table shows fairness evaluation for representational bias on objective tasks for image retrieval of CLIP model and different bias mitigation methods. *Using IdenProf dataset, we show DDP-rep, given by Eq. (5), for each method as well as its average precision for retrieving images of 9 different professions of the IdenProf dataset. We exclude the profession 'Firefighters' because in many cases their faces are hidden and gender is difficult to identify. Additionally, we do not show results for EOP like measure because this dataset does not have the annotations for the gender attribute. The gender annotations for the retrieved images per profession were manually done by one of the authors. The results demonstrates that gender balanced queries perform the best to reduce the representational unfairness in the objective tasks. All the methods are trained on FairFace dataset to remove the gender bias.*

Recall on Flickr30k. Table 4 show the result on retrieving Flickr30K images using its captions for multiple K values.

Table 4: [Retrieval - Recall - Flickr30k] The table below shows recall@K for randomly selected 50% Flickr30K dataset using different gender bias mitigation methods. *Specifically, we are using the captions of each image as a query and report the fraction queries that retrieve the images correctly in top 1, 5 or 10 results. The results show that mutual information based methods perform worse, which makes sense as the number of dimensions are reduced, while Prompt-GT method performs the best. Since the Prompt-GT method was finetuned using the Flickr dataset, it is not surprising that it outperforms even the CLIP model. It is worth noting that the queries also include gendered queries and some reduction in recall is expected or may even be desirable.*

Subjective labelling, independence assumption . Figure 15 shows the DDP metric Eq. (2) using MSCOCO dataset.

Subjective labelling diversity assumption. Tables 5, 6, 7 and 8 show the skew metric for different methods.

D.1 Statistical tests and cosine similarity

Tables 9, 10, 11 and 12 show the test for average cosine similarity among different groups of the protected attributes. Figures 7, 8 and 9 show the heatmaps for disparity in the average cosine similarity among different protected attribute groups.

E RESULTS FOR LINEAR PROBE

We show results for linear probe using the CLIP embeddings. Specifically, we train a logistic regression classifier on top of the CLIP embeddings to predict the attributes of the FairFace dataset, as showin Table 13.

F RESULTS USING OPENCLIP

We show results on two datasets for OpenCLIP. Figures 11 and 13 show classification results using OpenCLIP. Figures 14 and 12 show retrieval results using OpenCLIP. Additionally, Figures 10 and 14 show the heatmaps for differences in average cosine similarity among different protected attribute groups and Tables 15 and 17 show the statistical tests for the cosine similarity among different groups of the protected attribute. At last, Tables 16 and 14 show results for the skew metric using OpenCLIP.

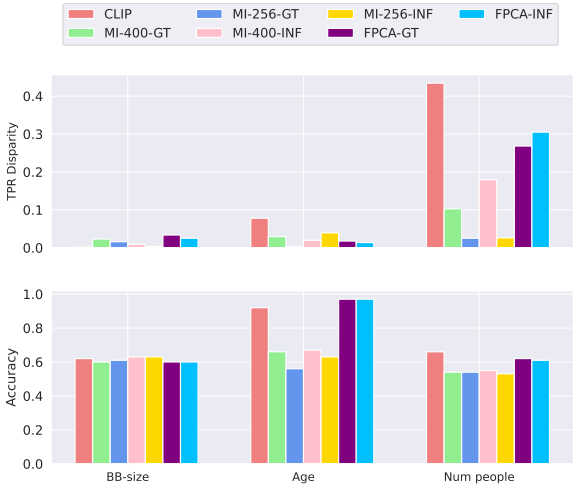

Figure 6: [Classification - DTPR - Objective - MIAP] *The x-axis shows three classification tasks: i) 'inconspicuous photo of a person' vs 'prominent photo of a person', where ground truth was based on whether the bounding box of the person occupied more than 50% of the image. ii) 'child' vs 'adult' iii) 'one person' vs 'more than one person'. On top we show the disparity in the true positive rates across the gender attribute and in the bottom we show the accuracy. We see that mutual information based methods while in some cases do reduce the disparity but they incur a reduction in accuracy. On the other hand fair PCA based methods reduce the disparity while incurring almost no loss in accuracy.*

G FAIRSAMPLING (REFERRED TO AS FAIR-SAMP IN THE RESULTS)

This is the second mitigation method proposed by Wang et al. [55], which requires to train a CLIP-like model from scratch. Even though it provides embeddings which could be used for other downstream tasks, one prominent difference from CLIP-like models is that it is trained on MSCOCO, a much smaller dataset. So, its zero-shot capabilities are quite limited. We add these results for the sake of completeness.

During training this method picks the training examples in a balanced manner w.r.t. gender. Specifically, in contrastive loss the goal is to maximize the similarity scores between matching image and text examples (positive samples), while minimizing the similarity score between non-matching examples (negative samples). Wang et al. [55] hypothesize that there could be a gender imbalance in the negative samples in each batch, i.e., the negative samples could be biased towards the majority class which results in the bias during retrieval. To correct this, firstly, they assign male, female or neutral labels to each image-text pair in the training set. They extract these labels from the texts or captions of each image. Then, they propose to pick negative sample from the male and female datapoints with probability 0.5 for every neutral query, while for male and female labelled queries they sample the negative samples randomly.

We found that on MSCOCO dataset, which was used for training this method, it enforced demographic parity, and had good performance for recall. However, as Table 18 shows, this method is not directly comparable to foundation models and it's performance is limited to the dataset it was trained on.

Table 5: [Retrieval - Skew - Subjective - FairFace] This table shows the maximum absolute skew, given by Eq. (4), using the FairFace dataset and gender attribute. *It demonstrates that all the methods are able to reduce the skew. Gender balanced queries yield the lowest skew.*

Table 9: [Retrieval -Statistical Tests - Subjective - FairFace] This table shows the signed difference between the average cosine similarities between men and women for each query as well as Alexander-govern statistical tests using FairFace. *The statistical test checks whether there are differences in the mean value of cosine similarity between men and women for a given query. The pair of numbers represent the test statistic and the p-value. A low value of the statistic and high p-value is desirable, the former means the statistical difference for the given query has low impact and the later means that the differences are statistically insignificant. It shows that fair PCA and MI-GT methods generally achieve the lowest disparity in cosine similarity and the differences are generally statistically insignificant.*

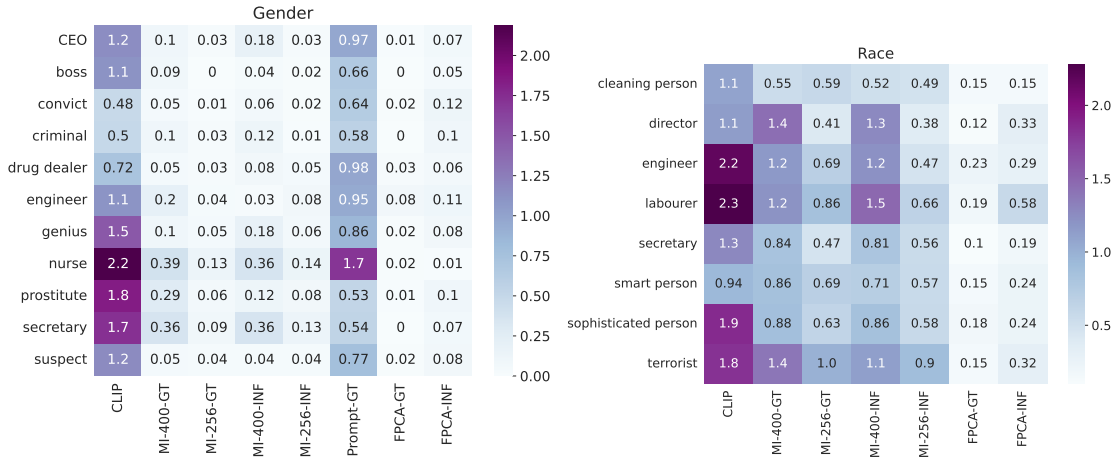

Figure 7: [Retrieval - Cosine similarity - Subjective - FairFace] These figures are heatmaps that show the absolute difference in cosine similarity, scaled up by a factor of 100, for different image retrieval queries using different methods for gender (left) and race (right) attributes on FairFace dataset. *The figures demonstrate the efficiency of each methods to equalize the representation for different protected attribute groups on average. It shows that in general, fair PCA and mutual information based methods equalize the cosine similarity for gender and race attribute for a variety of queries.*

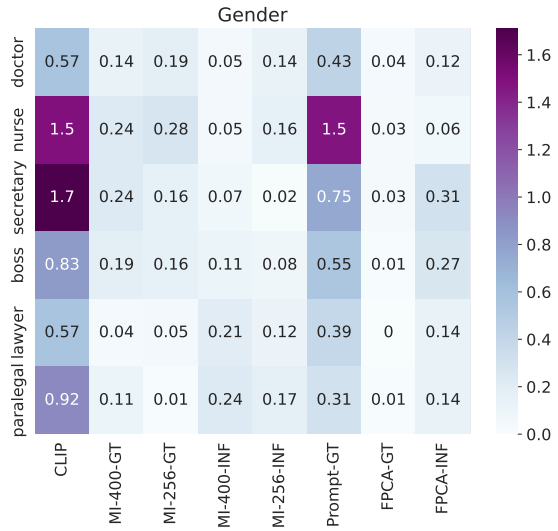

Figure 8: [Retrieval - Cosine similarity - Subjective - Flickr30k] The figure is heatmap that show the absolute difference in cosine similarity, scaled up by a factor of 100, for different queries using different methods for gender attribute on Flickr30K dataset. *The figure demonstrates the efficiency of each methods to equalize the representation for different protected attribute groups on average. It shows that in general, fair PCA based methods and the mutual information based methods equalize the cosine similarity for gender attribute for a variety of queries.*

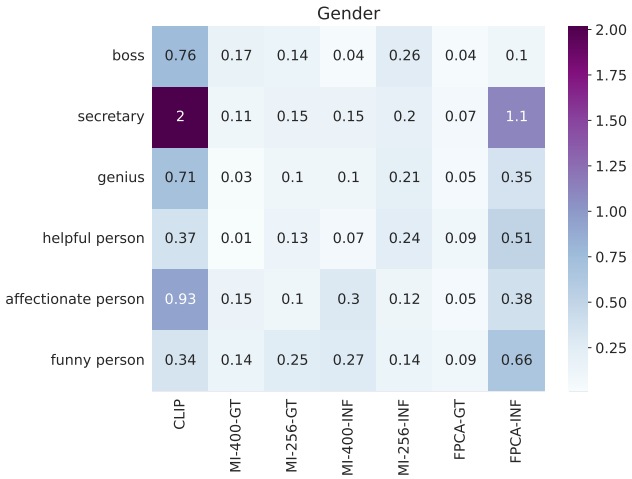

Figure 9: [Retrieval - Cosine similarity - Subjective - MSCOCO] The figure is a heatmap that shows the absolute difference in cosine similarity, scaled up by a factor of 100, for different queries using different methods for gender attribute on MSCOCO dataset. *The figure demonstrates the efficiency of each methods to equalize the representation for different protected attribute groups on average. It shows fair PCA based methods and mutual information based methods equalize the cosine similarity for gender attribute for a variety of queries.*

Table 13: [Classification - Accuracy - Objective - FairFace] This table shows the accuracy of a logistic regression classifier trained on the corresponding CLIP features for FairFace dataset. *The top and the bottom parts of the table correspond to the cases where the mitigation methods were supposed to remove the gender and race information, respectively, from the CLIP embeddings, while preserving the other information. The results show that fair PCA based methods are more effective in removing the corresponding sensitive information, i.e., the accuracy for predicting the corresponding sensitive attributes is nearly random. Additionally, the fair PCA methods do not reduce the predictive power of the embeddings, i.e., the accuracy in predicting other attributes stays similar to the original CLIP embeddings. We do not provide the results for the prompt method because they do not alter the image representation and results are similar as the original CLIP.*

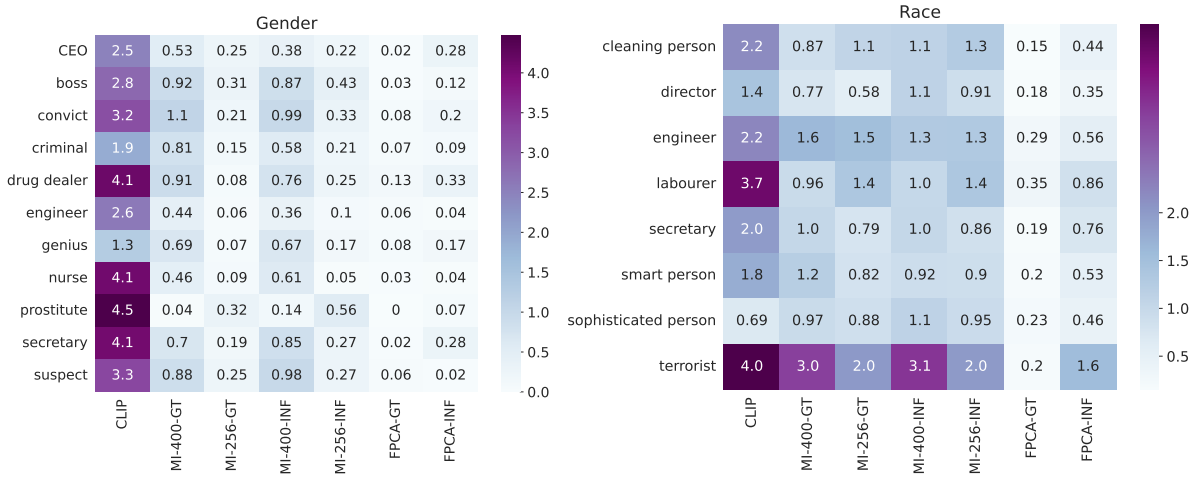

Figure 10: [Retrieval - Cosine similarity - Subjective - FairFace - OpenCLIP]These figures are heatmaps that show the absolute difference in cosine similarity, scaled up by a factor of 100, for different image retrieval queries using different methods for gender (left) and race (right) attributes on FairFace dataset on OpenCLIP. *The figures demonstrate the efficiency of each methods to equalize the representation for different protected attributes groups on average. It shows that in general, fair PCA based methods equalize the cosine similarity for gender and race attribute for a variety of queries.*

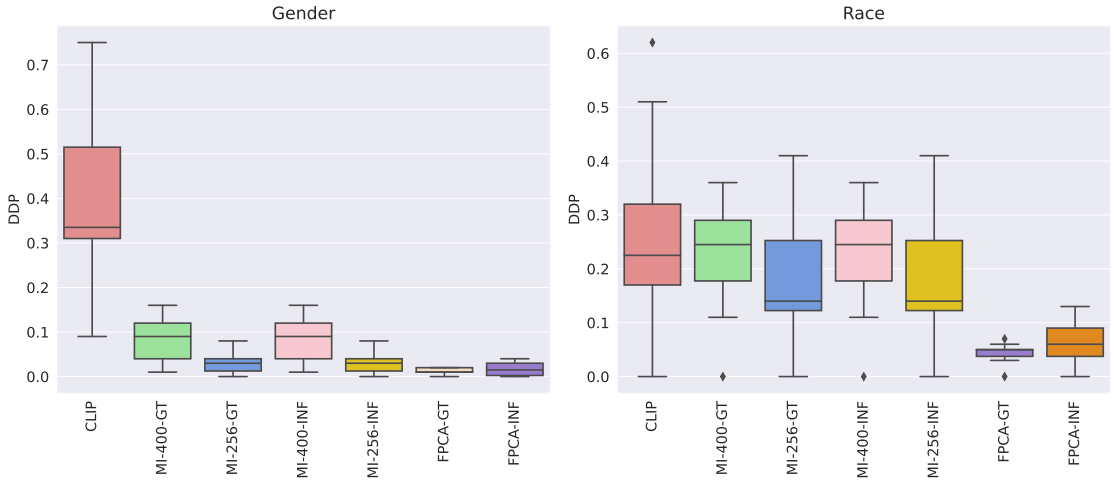

Figure 11: [Classification - DDP - Subjective - FairFace - OpenCLIP] These figures show DDP for classification, given by Eq. (1), using OpenCLIP using FairFace dataset. *It demonstrates that fair PCA based methods perform the best in reducing bias.*

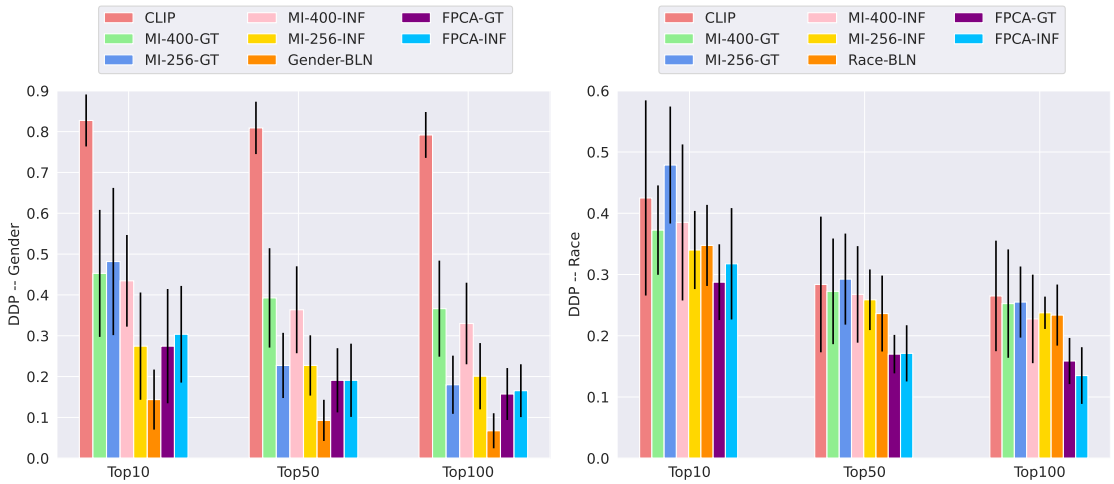

Figure 12: [Retrieval - DDP - Subjective - FairFace - OpenCLIP] These figures show DDP for image retrieval, given by Eq. 2, using OpenCLIP on FairFace dataset. *It demonstrates that gender balacned queries and fair PCA are most effective in reducing demographic disparity in subjective image retrieval tasks.*

Table 14: [Retrieval - Skew - Subjective - FairFace - OpenCLIP] This table shows the maximum absolute skew, given by Eq. (4), using the FairFace dataset and gender and race attributes using OpenCLIP. *It demonstrates that all the methods are able to reduce the skew. Gender/Race balanced queries and fair PCA are the most effective in reducing the skew.*

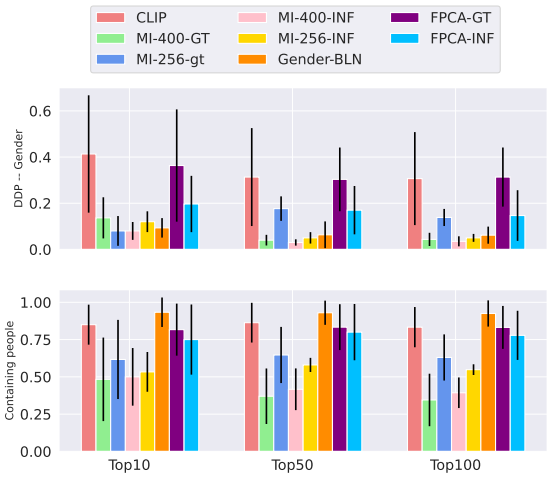

Figure 15: [Retrieval - DDP - Subjective - MSCOCO] The figure on the top shows DDP, given by Eq. (2), for retrieval tasks using MSCOCO dataset. *These results demonstrate bias in human-centric subjective tasks. At the bottom, we observe the fraction of query results that actually include a person. Surprisingly, for many human-related queries, the retrieved images do not feature any humans at all. Additionally, this demonstrates that the simple baseline of gendered queries perform very well in reducing disparity. However, the mutual information-based approaches, although effective in reducing disparity in some cases, fail to retrieve images containing humans. Interestingly, Fair PCA, trained on the inferred gender attribute, manages to return appropriate images while still reducing some disparity. One possible reason for this could be that the gender labels derived from the captions, which serve as ground truth, are quite noisy. In contrast, training fair PCA on on the inferred gender attribute directly from the CLIP model appears to yield better results in this context.*

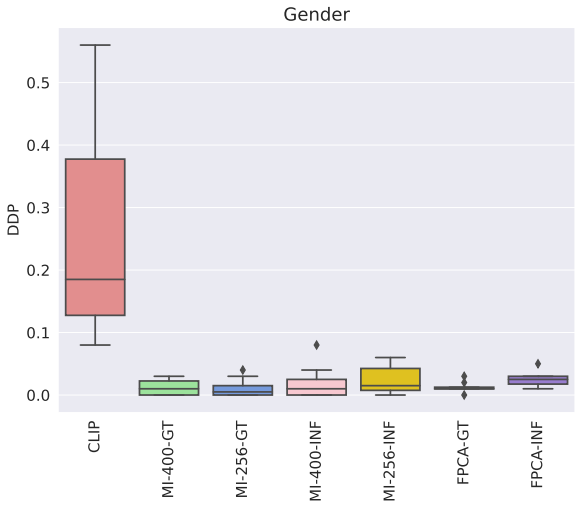

Figure 16: [Classification - DDP - Subjective - MSCOCO] The figure on the top shows DDP, given by Eq. (1), for classification tasks using MSCOCO dataset. *These results show bias for human-centric subjective tasks. They demonstrate that for most methods reduce disparity across gender in classification tasks.*

How do you feel? Measuring User-Perceived Value for Rejecting Machine Decisions in Hate Speech Detection

ABSTRACT

Hate speech moderation remains a challenging task for social media platforms. Human-AI collaborative systems offer the potential to combine the strengths of humans' reliability and the scalability of machine learning to tackle this issue effectively. While methods for task handover in human-AI collaboration exist that consider the costs of incorrect predictions, insufficient attention has been paid to accurately estimating these costs. In this work, we propose a value-sensitive rejection mechanism that automatically rejects machine decisions for human moderation based on users' value perceptions regarding machine decisions. We conduct a crowdsourced survey study with 160 participants to evaluate their perception of correct and incorrect machine decisions in the domain of hate speech detection, as well as occurrences where the system rejects making a prediction. Here, we introduce Magnitude Estimation, an unbounded scale, as the preferred method for measuring user (dis)agreement with machine decisions. Our results show that Magnitude Estimation can provide a reliable measurement of participants' perception of machine decisions. By integrating user-perceived value into human-AI collaboration, we further show that it can guide us in *1)* determining when to accept or reject machine decisions to obtain the optimal total value a model can deliver and *2)* selecting better classification models as compared to the more widely used target of model accuracy.

1 INTRODUCTION

Hateful content spread online through social media remains a significant problem. Ignoring its presence can lead to psychological harm and even result in violence and other conflicts [35, 43, 48, 50]. Governmental institutions and social media platforms are increasingly aware of these risks and are combating hate speech. For example, the European Union developed a Code of Conduct on countering hate speech [21], requesting large social media companies to moderate hate speech and report their progress yearly. However, results reported so far are not yet satisfactory, as, for example, less than 5% of hateful content has been removed from Facebook [28].

Hateful content moderation is either carried out manually or automatically by computational algorithms, where manual moderation may be more reliable but is not scalable to handle the deluge of user-generated content [38]. Further, continuous exposure to harmful content can be harmful to moderators as it can induce mental issues and potentially even lead to acts of self-harm [61]. Computational solutions are, therefore, urgently in demand by online platforms [24]. The methods considered best suited to this task are mainly based on machine learning, which has achieved reasonable performance at scale [25]. Yet, machine learning methods are far from being reliable, especially in dealing with hateful content previously unseen in the training data, which is often limited in size and biased [4]. Several recent studies on hate speech have shown a significant drop in machine learning performance when assessed on different data from those captured in the training phase [3, 32].

An approach that can combine the strengths of both previously mentioned approaches is human-AI collaboration, where humans are involved to solve AI-hard tasks, typically by taking over decisions where machines are unreliable [12, 14]. Such an approach is favorable in applications where decisions involve high-stakes and incorrect decisions can lead to damaging effects, as is the case for hate speech detection. Human-AI collaboration has been advocated in the human computation community [14, 53, 68] and, likely, is also an approach widely being used in enterprise applications

such as search and conversational agents [37]. Despite this, methods for implementing human-AI collaboration so far are limited to predefined heuristics and have largely ignored the complexity of real-world problems, especially the cost of incorrect predictions being context-dependent.

Common heuristics of task handover from machines to humans are based on machine confidence: humans take over the task when the confidence of the machine in its decision is lower than a predefined threshold [12]. Such heuristics assume that machine confidence is well-calibrated, that is, a decision with high confidence should be more likely to be reliable and vice versa. This assumption however does not hold for many machine learning models, especially deep learning models, which may indicate high confidence when decisions are incorrect or vice versa [5, 33]. An improved approach is proposed by Geifman and El-Yaniv [26] which determines the appropriate confidence threshold based on empirical evidence of machine correctness, e.g., based on the accuracy-threshold curve obtained on an empirical dataset. Such an approach, however, does not take into account the implications of right or wrong decisions. Incorrect decisions in high-stakes domains have a larger impact that, in turn, should pose a stricter constraint on accepting machine decisions, e.g., via a higher confidence threshold. Similar ideas have recently been discussed in position papers that advocate the adoption of the notion of context-dependent *value* as a replacement of accuracy, the most common metric in machine decisions assessment [13, 60]. Value, however, is an abstract term – it can be interpreted from social, ethical, or commercial perspectives [17, 29, 70] – yet the discussion on what creates value and how to measure it, specifically in a machine learning context, is limited due to it depending on the application.

In this paper, we study the problem of operationalizing value perception of machine decisions and its integration into human-AI collaboration in the specific context of hate speech detection. We start by identifying several factors that may affect the value definition, namely the selection of a specific stakeholder's standpoint and the relativity of value perception as affected by stakeholder expectation or regulation. We then operationalize user-perceived value in hate speech moderation scenarios, where a decision with a corresponding confidence has been made by a machine. To measure these perceptions, we explore several measurement scales and propose to select Magnitude Estimation (ME) [62] as the primary scale. ME allows the measurement of the magnitude of user (dis)agreement using an unbounded scale and makes it possible to obtain the relative ratios between the magnitudes of different machine decisions. These ratios are essential to determine the optimal confidence threshold for rejecting machine decisions (see section 2).

To validate ME in value operationalization, we designed a survey study where we recruited 160 participants. Each participant's perception regarding a dataset of 40 selected hateful and non-hateful tweets and their (dis)agreement regarding the corresponding machine decisions were evaluated. Through a between-subject study, we show that Magnitude Estimation returns results with significantly higher inter-rater reliability compared to other scales, showing its suitability in measuring user perception. Our results show that the inter-rater reliability is significantly higher for incorrect decisions than for correct decisions, indicating a strong consensus among participants regarding the consequences of harm, as well as disagreements on what constitutes hate online. Further, users appear to be more negatively affected when a non-hateful post is subject to moderation than when an instance of hate speech is classified as non-hateful, implying that users would rather contend with an instance of hate speech than have an innocent user punished for a non-hateful post.

To demonstrate the utility of value integration in human-AI collaboration, we evaluate the effect of rejecting machine decisions made by three machine learning-based hate speech detection models – including traditional, deep learning, and BERT-based models [19] – in handling data from both seen and unseen sources. Our results show that for all three models, when evaluated on unseen data, the optimal confidence thresholds determined by the model-delivered value are much higher than the optimal thresholds on seen data. These results confirm the findings from previous studies on machine biases and demonstrate the effectiveness of using value as a target for optimally rejecting machine decisions. We further show that when selecting the optimal model, using value as the criterion returns different results compared to using accuracy. Note, that our approach to measuring value perception can be applied to different tasks and is model-agnostic.

In summary, we make the following key contributions:

- We introduce Magnitude Estimation as a scale for measuring user perception of machine decisions in scenarios where these decisions are correct and incorrect;
- We demonstrate the applicability of Magnitude Estimation through a between-subject survey study, as well as the utility of value for optimally rejecting machine decisions;
- We contribute a set of insights into user-perceived value of automated machine decisions, especially their attitudes towards different types of (mis)classifications.

2 BACKGROUND ON VALUE-SENSITIVE REJECTION OF MACHINE DECISIONS

This section introduces the background of value-sensitive rejection of machine decisions in a hybrid human-AI workflow, based on previous work [59, 60], and subsequently identifies factors that influence value perception in hate speech detection.

2.1 Rejection for Binary Classification

We consider the general case of human-AI collaboration as follows: the machine decision can either be accepted or rejected; if rejected, the decision will be taken over by a human decision maker. Formally, consider a binary classification problem for which we have a machine learning classifier, whose output on a data item x is confidence, $\mathbf{c}$, (e.g., the output from the softmax layer of a neural network). The rejection is dependent on a threshold denoted by $\tau \in [0, 1]$, which then modifies the final output of the machine as

$$\hat{y} = \begin{cases} y, & \mathbf{c}_y \geq \tau, \\ y_r, & \text{otherwise.} \end{cases} \tag{1}$$

where y denotes an accepted decision and y_r denotes the special decision of rejection, resulting in a human making the final decision.

We now discuss how the optimal confidence threshold for rejecting machine decisions is affected by the value formulation. We consider the binary classification case: when the machine decision

is either positive (i.e., the content is deemed hateful) or negative (i.e., non-hateful). There is a value, V, attached to each of these, depending on whether this positive or negative decision is correct or not. This results in true positive (TP), true negative (TN), false positive (FP), false negative (FN), and rejected predictions as possible outcomes. V_{TP} and V_{TN} are positive, while V_{FP}, V_{FP}, and rejected predictions, V_r, are negative (i.e., costs). The optimal threshold for positive classifications is:

$$\tau_O^p = \frac{V_{FP}}{V_{FP} - V_{TP}} = \frac{\gamma^p}{\gamma^p + 1} \tag{2}$$

if we assume $V_{FP} = -\gamma^p \cdot V_{TP}$, that is, the cost of a false positive is γ^p times worse than the value of a true positive. Similarly, in the case of negative classifications, the optimal threshold would be $\tau_O^n = \frac{\gamma^n}{\gamma^n+1}$ where $V_{FN} = -\gamma^n \cdot V_{TN}$, i.e., the cost of false negative is γ^n times worse than the value of a true negative.

When the cost of incorrect decisions is very high, i.e., $\gamma \gg 1$, the optimal confidence threshold would tend close to 1, meaning almost all machine decisions are rejected. When the cost of an incorrect decision is very low, i.e., $\gamma \approx 0$, the optimal threshold would be close to 0, and virtually all machine decisions are accepted. These results, therefore, follow our intuition. An important conclusion we can draw from equation (2) is that the optimal threshold is dependent *only on the ratio* of the value (or cost) between an incorrect decision and that of a correct one (per class).

Threshold optimization is the process of finding the threshold that maximizes value empirically. If a system is calibrated before use, simulations can be used to find the optimal theoretical threshold, which is the optimal τ that maximizes value. In this paper, τ is determined by means of calibration, done by means of temperature scaling [47], followed by a calculation of the theoretical threshold based on the crowdsourced survey data, as it allows us to quantify and compare the opinions of participants on the value of true and false predictions and thus compute the ratios for our use case.

2.2 Value Factors in Hate Speech Detection

We denote the value of classifying a data item correctly, or incorrectly, and that of rejecting a classification as V_c, V_w, and V_r, respectively. We make the following observations when considering value for hate speech detection: 1) Value is dependent not only on the machine learning model but also on the specific context to which the model is applied. For example, an incorrect prediction in the medical domain potentially has a bigger impact than one in e-commerce. In a high-stakes domain, generally, we would assume $V_c > V_r > V_w$ and thus a correct machine decision saves the cost of human moderation and accelerates the decision-making process, while a rejection requires additional human intervention. 2) Value interpretations from different stakeholders can vary. In hate speech detection, for example, a rejection of a machine decision induces the cost of human moderation from the business perspective, while from the user perspective what is more important is the exposure to hateful content. In our study, we choose to take the user's standpoint, and, as such, view V_r to come with an inherent cost since human moderation will be pending and the potentially hateful content will remain visible. 3) Value is affected by both stakeholder expectations and regulation. For example, in the hate speech detection case, when hateful content is posted, from the user's perspective, the value derived from a correct machine decision depends on the user's general expectation of how hateful content should be handled. Similarly, the legality of hate speech in certain jurisdictions may influence stakeholder perception.

Given the above observations, we now introduce the function to determine the total value, $V(\tau)$, of a given model with a reject option at the rejection threshold τ on a given dataset. Assuming that when accepted, correct decisions increase the overall value and when rejected, they decrease the overall value and vice versa, then, $V(\tau)$ may be formalized as:

$$V(\tau) = \sum_p (V_p - V_r)N_p + \sum_q (V_r - V_q)N_q, \tag{3}$$

where $p \in [TP, TN, FP, FN]$, $q \in [TP, TN, FP, FN]$, and N_p and N_q are the number of accepted and rejected data items for the difference scenarios, respectively. Note, that we assume that rejected decisions have a cost that decreases the overall value, i.e., V_r is negative, as users have to wait on a moderation decision. Thus, equation (3) allows us to summarize the value gained and the cost subtracted into a single value for the model by considering the value or cost of each scenario and how often it occurs, while also taking the cost of rejection into account.

3 SURVEY STUDY

To define the relative value of scenarios, we design a survey to ask participants the degree to which they agree or disagree with the decisions of a fictional social media platform, SocialNet. These scenarios represent TP, TN, FP, FN, and rejected predictions. The TP and TN scenarios imply that SocialNet successfully detects whether a post is hateful or not hateful, respectively. The FP scenario means that SocialNet incorrectly predicts a non-hateful post as hateful, and conversely for the FN scenario. For example, in the FN scenario, the survey shows a hateful post to the subject and explains that SocialNet did not identify the post as hate speech.

3.1 Choice of the Scale

We use ME as the primary scale. A Likert scale was initially considered, as it is widely used in research for retrieving participant opinions and is perhaps more intuitive for participants [10]. However, a Likert scale is not suitable in our case, as Likert-type items are ordinal, meaning that we only know the ranks but not the exact distances between the items [2]. In our case, computing the relative values (i.e., ratios) of our scenarios requires measuring the distances between different items, which cannot be provided by a Likert scale. On the contrary, the ME scale allows us to measure ratios by asking participants to provide numerical ratings. ME originated from psychophysics, where participants gave quantitative estimates of sensory magnitudes [62]. For sound loudness, a sound twice as loud as the previous one, should ideally receive a rating twice as large.

Researchers have previously applied the ME scale to different physical stimuli (e.g. line length, brightness, or duration) and proved that the results are reproducible, as well as that the data has ratio properties [46]. Other works have shown that the ME technique is also helpful for rating abstract types of stimuli, such as judging the relevance of documents [42], the linguistic acceptability of

sentences [7], and the usability of system interfaces [45]. Thus, we conclude that ME is a promising method for judging hate speech.

3.2 Normalization and Validation of the Scale

The ME scale is unbounded. For example, suppose we first show a scenario and the participant provides a value (e.g., 100) to indicate the degree of agreement. Suppose we next present a scenario that the participant agrees with more. The participant can always provide a higher value (e.g., 125) and not be restricted within a fixed range. The results need to be normalized as different participants rate the agreement/disagreement degree differently.

Multiple solutions exist for normalizing the ME scale, such as modulus normalization, which uses geometric averaging to preserve the ratio information [45, 46]. Unlike the unipolar ME scales used in previous research [7, 45], we use bipolar scales. Using arithmetic averaging is inappropriate since it uses logarithmic calculations and would disrupt the ratio scale properties [46]. Therefore, we normalize the results by dividing the magnitude estimates of each subject by their maximum estimate. We multiply the normalized magnitude estimates by 100 for the sake of clarity. This way, all magnitudes estimates are in the range $[-100, 100]$ while maintaining their ratio properties.

Most previous research using the ME scale applies validation, such as cross-modality validation, where estimated magnitudes are compared to the physical stimuli using correlation analysis [7]. Cross-modality validation is difficult in domains that do not have exact measures of stimuli, such as hate speech. Some previous work compared ME with other validated scales [42]. In our case, we use the 100-level scale to validate the ME scale by analyzing their correlation [57], which is a form of convergent validation [22].

3.3 Participants and Data

We use Prolific to recruit crowd workers for the study.[1] Participants need to be at least 18 years of age, be fluent in English, and have an approval rating of over 90%. Participants also need to have experience using a social media platform regularly (at least once a month). Every participant is paid an hourly wage of 9 GBP, exceeding the UK minimum wage at the time of the study. Regarding sample size, we recruit 24 participants for the pilot study and 136 participants for the official study. Of the recruited participants, 50% identified as female, though Gold and Zesch [30] showed that there is no significant difference when perceiving hate between genders. Half of the participants are assigned the ME scale and the other half the 100-level scale. We choose a 90% Confidence Interval (CI) and 10% Margin of Error (MoE) for this study due to budget limitations. There are billions of social media users, and according to Müller et al. [49], we need a sample size of 68 participants per measurement scale, i.e., 136 participants, to reach the desired CI and MoE.

The final dataset consists of 20 hateful and 20 non-hateful social media posts from a public dataset [8] to build the machine decision scenarios (TP, TN, FP, FN, and rejection). The dataset contains 13,000 English tweets, and each tweet is annotated with three categories: hate speech (yes/no), target (group/individual), and aggressiveness (yes/no). We first exclude tweets that are replies or contained mentions or URLs since they have unclear contexts. Finally, we use clustering analysis to select 40 tweets for our study. We use a cluster size of 20 for the non-hateful tweets and sample one tweet per cluster by taking the nearest sample to each cluster centroid to obtain each cluster's most representative tweets. For the hateful tweets, we first divide them into four groups using the target and aggressiveness categories. Similarly, for each hateful tweet group, we use a cluster size of 5 and sample one tweet per cluster. We perform latent semantic analysis (LSA), which is a combination of term frequency-inverse document frequency (TF-IDF) and Singular Value Decomposition (SVD), and k-means clustering on each group of tweets. We calculate the silhouette coefficient to determine the optimal cluster size (k value) for the neutral tweets and the four groups of hateful tweets. We manually select one tweet per cluster using a majority vote from three members of our group to choose representative tweets and create the final set of 40 tweets.

Additional information on the study's variables, pilot study, demographics, as well as example tasks may be found in appendix A.

3.4 Procedure and Data Quality Control

The survey first presents the informed consent policy and excludes participants that do not agree with it. Next, introductory texts are shown to explain the possible machine decisions. In the case of using the ME scale, participants are presented with a warm-up task to estimate different line lengths. Then, the survey asks 40 randomly shuffled question sets regarding the TP, TN, FP, FN, and rejection scenarios (with 8 question sets per scenario). The first question is about whether participants think the post is hateful (yes/no). The second question is whether participants agree or disagree with the decision made by the machine, which may be correct or incorrect, or are neutral towards it. In the case of a non-neutral decision, the survey asks the third question about the degree to which participants agree or disagree with the machine's decisions, using either the ME or 100-level scale, depending on their group. There is no time limit for the survey.

In the middle of the question sets, we use two Instructional Manipulation Checks to determine if the user is paying attention[2]. These attention checks ask participants to select a specific option from multiple choices (e.g., "You must select Orange"). We exclude responses from the participants who fail the attention checks or do not complete all questions. For the ME scale, we discard responses that do not perform well in the line length warm-up task.

3.5 Analysis

We first compute the values for the TP, TN, FP, FN, and rejection scenarios using the survey study data. For both scales, we convert disagreement (with the machine decision) ratings to negative values, neutral stances to 0, and agreement ratings to positive values. We apply convergent validity, in which a correlation analysis between different scales (i.e., the ME and 100-level scales) is conducted to determine if they measure the same phenomenon [22]. We expect a medium-large correlation between both scales, meaning that ME responses small in magnitude should correspond to 100-level scale responses small in magnitude and vice versa. Finally, we analyze reliability, which determines whether we can trust our results and

[2] Prolific's Attention and Comprehension Check Policy

	ME		S100	
	α	v	α	v
TP	0.07	18.15	0.04	77.00
TN	0.10	36.32	0.11	86.31
FP	0.39	-16.69	0.07	-51.00
FN	0.92	-28.08	0.14	-62.43
Rejection	-0.31	-4.82	0.07	-16.37
All	0.78	—	0.44	—

Table 1: Krippendorff's alpha (α) and the scenario values (v) for TP, TN, FP, FN, and rejection scenarios. ME refers to Magnitude Estimation, and S100 refers to the 100-level scale.

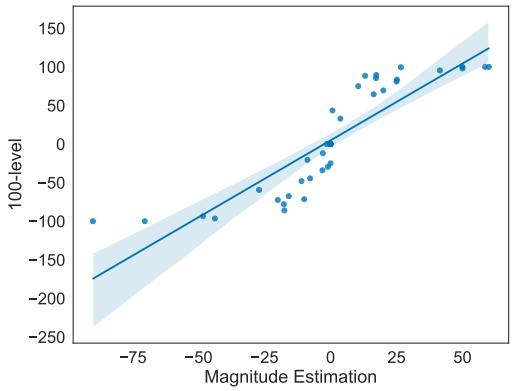

Figure 1: Correlation plot between the median normalized magnitude estimates and the median 100-level scores per question, showing agreement and disagreement.

achieve consistent outcomes [22]. In our case, we use inter-rater reliability to investigate whether different subjects give approximately the same judgments to the same scenarios and, thus, whether the degree to which hate speech is subjective. It is measured using Krippendorff's alpha, which we calculate using the normalized ME and 100-level values for all scenarios.

4 RESULTS

4.1 Reliability and Validity

First, for each survey question set, we calculate the median of all responses. This step yields 40 values (eight values per scenario). We use the median since data from both scales are highly skewed. Then, we calculate the mean of the values ($V_{TP}, V_{TN}, V_{FP}, V_{FN}, V_r$) within each scenario, giving us the final five values for the TP, TN, FP, FN, and rejection cases. The results for both scales can be seen in table 1. The total value, V, is calculated at a later point in this section using the different values.

We calculate Krippendorff's alpha to measure the inter-rater reliability of all scenarios for each scale, as shown in table 1. The last row of the table contains the α values for the entire scale, measuring the inter-rater reliability for all answers. We observe that the ME scale has high inter-rater reliability while the 100-level scale is less reliable. Also, participants using the ME scale tend to exhibit higher agreement regarding the FP and FN cases and systematically disagree on the rejected cases. For the 100-level scale, we observe that participants have low agreement on all scenarios.

We analyze the validity of the ME scale by comparing the median normalized magnitude estimates with the median 100-level scores for each question set. Figure 1 presents the correlation plot between the two scales. A Shapiro-Wilk test indicates that the data of both scales do not follow a normal distribution ($p < 0.05$). Thus, we use the Spearman and Kendall rank correlation coefficients since these are non-parametric tests. Spearman returned a 0.98 and Kendall a 0.89 correlation between the ME and the 100-level scales ($p < 0.05$). Finally, a Mann-Whitney U test between the ME and 100-level scales gives a large p-value, indicating no statistically significant difference between the two scales.

4.2 Total Model Value due to Threshold

We evaluate the $V(\tau)$ function (i.e., the value at different rejection thresholds) using the values from the survey study obtained using the ME scale. We train three different binary hate speech classification models on the Waseem and Hovy [67] dataset. The used models are Logistic Regression (LR) with Character N-gram [67], a Convolutional Neural Network (CNN) based on Agrawal and Awekar [1], and a DistilBERT transformer [58]. We use Temperature Scaling to calibrate the CNN and the DistilBERT models following the approach from Guo et al. [33]. The model predictions are based on two different test datasets: the *seen* dataset and the *unseen* dataset. The *seen* dataset is the test set of Waseem and Hovy [67] and the *unseen* dataset is a test set from a separate but similar source [8]. We use the *unseen* dataset to simulate how the models would perform in a more challenging, realistic use case. Using unseen data that is similar but separate from the training set, we also investigate the impact of bias. Finally, we calculate the total value as a function of the threshold, $V(\tau)$, for all models with the reject option at all possible rejection thresholds (τ). When $\tau \in [0.0, 0.5]$, all predictions are accepted since the confidence of all predictions is above 0.5 in the case of binary classification. On the other hand, $\tau = 1.0$ implies that all predictions are rejected. We use the v values of the ME scale from table 1 to plot the results of all three models in figures 2a and 2b using equation (3). The diamond-shaped markers indicate the optimal confidence thresholds for rejection at which the model achieves the highest total value.

Participants ascribe higher absolute values to TP and TN scenarios compared to FP and FN ones (see table 1), which results in all but one model having the highest value when all predictions are accepted (see figures 2a and 2b). The rejection rates (i.e., the percentage of rejected predictions) and accuracies of accepted predictions at the optimal threshold across the three classifiers can be seen in the first two rows of table 2. If we were to take the view that the users' baseline expectation is correct machine decisions, then we can set the value of TP and TN to 0.0 and repeat our analysis to examine how $V(\tau)$ behaves as we consider only punishing incorrect predictions without rewarding correct predictions made

	LR			DistilBERT			CNN		
	τ	Acc	RR	τ	Acc	RR	τ	Acc	RR
Seen data	0.500	0.853	0.000	0.500	0.853	0.000	0.500	0.845	0.000
Unseen data	0.531	0.646	0.043	0.500	0.643	0.000	0.500	0.624	0.000

(a) evaluated on *seen* data **(b) evaluated on *unseen* data**

Figure 3: $V(\tau)$ curves of all models with v of TP=0.0, TN=0.0, FP=-16.69, FN=-28.08, and rejection=4.82.

by the model (considering the regulation effect discussed in section 2). Figures 3a and 3b demonstrate that the optimal values are achieved at increased rejection thresholds (τ). The last two rows of table 2 show that the optimal τ values result in higher accuracies for the *seen* data while rejecting 31.6% of predictions. For the *unseen* data, we achieve high accuracies but reject a large fraction of the predictions.

We also compare the effect of using value and the widely-used accuracy metric in selecting the best model, shown in table 3. We observe that both metrics return the same optimal model when correct predictions are rewarded, though there is a difference between *seen* and *unseen* cases. When only incorrect predictions are punished, the optimal models are different as measured by the two metrics: in the case of *seen* data, both LR and DistilBERT perform better than CNN when measured by accuracy, while CNN delivers the highest value; the same observation holds true in the case of *unseen* data – where the optimal model switches from DistilBERT to CNN when we consider the value they deliver instead of accuracy.

5 DISCUSSION

5.1 Value Ratios, Reliability, and Validity

Our results show that TP and TN scenarios are highly valued. Participants seem to value correct predictions more than incorrect predictions across all scenarios, regardless of whether they are positive or negative. The value of rejected predictions is the closest to 0 (neutral), as expected, due to them not contributing any benefit or harm, but just delaying the publishing of the post due to the additional human moderation effort. For both scales, we observe the same relation of scenarios in terms of values (FN<FP<Rejection<TP<TN). The fact that correct decisions receive higher value ratings indicates strong user appreciation of correct machine decisions. The value of FN having a larger magnitude than the value of FP is noteworthy, as users appear to be more negatively affected when a non-hateful post is subject to moderation than when an instance of hate speech is classified as non-hateful. This implies that users would rather contend with an instance of hate speech than have an innocent user punished for a non-hateful post. This phenomenon may be explained by the Blackstone principle from the domain of criminal law: "Better that ten guilty persons escape, than that one innocent suffer" [20]. However, we do consider it surprising that the value of TN is greater than the value of TP. One possible reason could be

that people disagree more on what is considered hateful among the TP scenarios. We also encountered this phenomenon in the survey results where most people rated TN cases as non-hateful, while for the TP cases there were more disagreements.

Regarding reliability, Krippendorff's alpha, α, for the 100-level scale being lower than the one for the ME scale is unexpected, as the 100-level scale is bounded with fewer possible options. The stronger agreement for the ME scale indicates that it is indeed suitable for this task. Since α compares the expected difference with the observed difference, it follows that the alpha values for the entire scale should be greater than for the individual scenarios. Generally, participants tend to have low agreement on TP, TN, and rejection cases while they have a high agreement regarding the FP and FN cases. Users tend to agree more regarding what constitutes a misclassified instance than what constitutes a correctly classified instance. For the ME scale, we even observe systematic disagreement for the rejection case, as can be seen by its negative α value. This indicates that users are lower in agreement than one would expect by chance, showing the wide variety of opinions regarding rejection cases by users. By considering all answers, instead of answers for certain scenarios, we observe a greatly increased α, as the observed difference between ratings is closer to the difference expected by chance. For example, participants tend to agree on the classification of a single scenario, e.g. TP, but may give different values on both scales, resulting in lower α for the scenario but greater α across all scenarios. Beyond this, the low reliability for the positive compared to negative predictions indicates that participants disagree on what constitutes hate speech in the first place.

Regarding validity, we observe a strong correlation between scales, demonstrating that the ME scale is validated for measuring people's opinions about different hate speech detection scenarios. The almost S-shaped curve for the data points in figure 1 is due to the lower and upper bounds of the 100-level scale that restrict the participants' choices, making them more likely to assign the lowest or highest value. Meanwhile, the data points corresponding to the ME scale are skewed towards 0 because of the normalization.

5.2 Value Function for Rejection

The purpose of the reject option is to reject predictions where the risk of an incorrect prediction is too high. However, when we use all values obtained from the survey to measure the value function $V(\tau)$, the total value of a model with a reject option is maximized by accepting all predictions. As shown in figures 2a and 2b, values are positive at the beginning, decline steadily as the rejection threshold increases, and eventually become negative as more predictions are rejected. This observation is not surprising, as the absolute values of correct predictions are greater than the absolute values of incorrect predictions (see table 1).

However, instead of rewarding correct predictions, we believe it is more critical to emphasize penalizing incorrect predictions, as hate speech should be moderated effectively to minimize harm. To study the effects of this we also analyze the behavior of $V(\tau)$ when users do not experience an increase in value through correct classifications, i.e. TP and TN. To achieve this, we set the scenario values v of TP and TN equal to zero. This results in correct predictions effectively only increasing the total value by the v of rejection when accepted and decreasing when rejected, as can be seen in equation (3). The result in figure 3a shows a steady increase in value before it peaks for each of the three models, eventually falling again and becoming negative as almost all predictions are rejected. Hence, there is a strong incentive to reject some (but not all) predictions for the *seen* data. At the points where values are maximized, we found an optimal balance between accepting and rejecting predictions. Figure 3b shows that the values continually rise for all three models, only peaking as the rejection threshold approaches 1. This indicates that the model is very uncertain regarding its predictions for the *unseen* data, which may be expected. Initially, at the 0.5 rejection threshold, the value is negative as all predictions are accepted. When the rejection threshold increases, the value rises steadily since too many incorrect predictions are made. This indicates that the model is not performing well at the task (i.e., high confidence false predictions), and thus the optimal condition to reject most predictions makes the unviable model.

The results show that by penalizing incorrect predictions without rewarding correct predictions, a significant fraction of the predictions can be accepted from all three models. For unseen data, however, very few predictions from these models can be accepted and the majority are rejected. Such a result confirms the bias in the dataset as also found in previous studies [3, 32]. The results also show the utility of value as a metric in guiding the decision on when to reject machine predictions. Value utility is further confirmed in the results in table 3 from our experiment on optimal model selection: the best model selected by value is different compared to using accuracy as the metric.

5.3 Findings, Implications, and Limitations

Our survey study uncovers several interesting findings. First, social media users are more appreciative of correct decisions made by the platform, with an absolute magnitude higher than the (negative) perception of incorrect decisions. Among the correct decisions, users especially appreciate that non-hateful content is correctly identified and not banned. On the other hand, users show a much higher agreement on the negative value of incorrect decisions than correct ones, indicating a strong consensus over the harm (from both identifying hateful content to be non-hateful, and vice versa). These results indicate that while users appreciate correct decisions, minimizing incorrect decisions remains an important task for social media platforms. On the methodological side, we also believe our proposal of using ME for rating human perception can be particularly relevant for research that aims to tackle social science problems through quantitative approaches, like machine learning.

By integrating value as a parameter into the human-AI collaboration framework for rejecting machine decisions, we show that value can help guide the decision of when to accept machine decisions to reach the optimal value a model can deliver. By showing how the number of acceptable machine decisions changes when the model is applied to a dataset different from the training data, our results confirm findings from previous research that such datasets are biased and hence the trained models are as well. Our results also show that when considering value as an optimization target, the best model selected can be different compared with using accuracy as the metric. We believe these findings can benefit the research

community and industry alike, as they present a novel way of using a value-sensitive reject option to increase the utility of human-AI collaboration across domains.

Our work is limited to a relatively small sample size (68 subjects per scale). We expect the results to be more reliable at a larger sample size. Besides, optimal confidence threshold determination relies heavily on empirical data, which may not be available in real applications. An easier way for selecting the optimal threshold would be using well-calibrated models, for which the optimal threshold is only dependent on the human-perceived value. Although techniques such as Temperature Scaling can help improve the calibration of existing neural networks or transformer models such as DistilBERT, we still observe that all models are predisposed to producing high-confidence errors. Finally, due to taking the users' standpoint, we do not fully capture the cost of the moderation team being exposed to hate speech. We leave this as possible future work.

6 RELATED WORK

6.1 Hate Speech Detection

Online hate speech content refers to "online messages demeaning people on the basis of their race/ethnicity, gender, national origin, or sexual preference" [41]. Its characterizing features are properties of the target of the language, as compared to other types of online conflictual languages, which are defined by the intention of the author such as cyberbullying or flaming [11, 54]. A large body of discussion can be found on conflictual languages from social sciences, political science, and computer science [44, 63, 66]. Hate speech-related research in computer science has identified mismatches between the formalization of hateful content and how people perceive such languages [4]. These mismatches conceptually are further reflected in the technical biases of the machine learning systems used for filtering hateful content. For instance, Gröndahl et al. [32] found that F1 scores were reduced by up to 69% when training a hate speech detection model on one dataset and evaluating it using another dataset from a similar source. Similarly, Arango et al. [3] found that most research in hate speech detection overestimates the performance of the automated methods due to dataset bias. In response to these findings, our work aims to explore a human-AI collaborative approach for effective hate speech detection.

6.2 Human-AI Collaboration and Rejection

Human-AI collaboration aims to exploit the complementarity between the cognitive ability of humans and the scalability of machines to solve complex tasks at scale [6, 65]. Some work proposed new ways of collaboration, such as learning crowd vote aggregation models from features of the crowd task [36] and leveraging crowds to learn features of ML models [15, 56]. Recent work has shifted attention to human involvement in providing interpretations of model decisions and evaluating these interpretations [40, 55].A notable idea for hybrid human-AI decision-making was recently proposed by Callaghan et al. [12]: humans are involved after a machine decision is observed to have low confidence. Following works can be categorized in several dimensions, namely *when* rejection happens, on *what models*, and based on *what criteria* [34]. Regarding the "when", rejection can be implemented in three ways: the preemptive way where whether a data item needs to be handled by a human is decided beforehand [16]; the integrated way which uses a rejector inside the machine learning model (e.g., a rejection layer in a neural network) to decide whether a decision should be rejected [27]; and the dependent way, which is also the most common, which analyzes the rejection option after model decisions [18, 26, 31]. In terms of "what models", work has been done on rejecting decisions made by a range of models, such as SVMs [16, 31] and different neural networks [18, 27]. In our case, we apply the dependent way to reject models that are based on neural networks. In terms of "what criteria", Geifman and El-Yaniv [26] proposed a rejection function based on a predefined risk value, an idea also explored in [51]. But unlike ours, their proposals do not consider the impact of machine decisions in a specific context. The most relevant proposal to our work is from De Stefano et al. [18], who studied a confidence metric for determining the optimal rejection threshold. In their work, the threshold is calculated with simulations based on a set of predictions. Going beyond defining cost values from simulations, our approach determines cost values based on users' perception of machine decisions using a survey study with crowd workers.

6.3 Value Assessment and Measurement

Value is generally defined as desirable properties of an entity [9]. Specifically for machine learning systems Yurrita et al. [69] have identified relevant properties, including individual empowerment, conservation, universalism, and openness. Examples include outlining ethical principles of algorithmic systems [23], developing value-based assessment frameworks [69], and proposing new metrics for evaluating machine learning systems that incorporate value parameters [13]. However, a research gap in measuring value in social contexts has been identified by Olteanu et al. [52], who investigated human-centered metrics for machine learning evaluation in hate speech detection. Their work highlights the gap between accuracy-based evaluation metrics and user perception. Our work represents a first step towards filling the gap in the context of hate speech detection using ME with a crowdsourced survey.

7 CONCLUSIONS

This paper studies the operationalization and integration of value into human-AI collaboration for hate speech detection. We introduce a value-sensitive rejection mechanism for machine decisions that takes into account the implications of decisions from a user-centered standpoint. We propose ME to measure users' value perception regarding different hate speech detection scenarios. To validate ME, we design a survey study, showing that it can provide a reliable, human-centered assessment of the value a machine learning model delivers. Our survey study uncovers a series of interesting findings on user perception. In particular, participants appreciate correct decisions made by the platform, while they show a strong consensus over the harm of incorrect decisions. Our results show that value assessment performed by means of ME can guide us to select the best confidence threshold for rejecting machine decisions, thereby maximizing model value and potentially leading to a different best model than when using accuracy.

A SURVEY

A.1 Variables

The independent variables are the possible scenarios (TP, TN, FP, FN, and rejection). We inform participants in the survey that when hate speech is detected, SocialNet ranks the hateful post lower so that it takes much more effort for the users to find the post. For the rejection scenario, we inform the participants in the survey that a moderator needs to check the post within 24 hours, and meanwhile, the post remains visible.The design decision of using 24 hours is based on the German NetzDG law, which allows the government to fine social media platforms if they do not remove illegal hate speech within 24 hours [64]. Our study has two control variables: the measurement scales and the content of posts. Regarding scales, as described before, we choose ME as our primary scale and use the 100-level scale for validation. Our dependent variables are reliability, validity, and value ratios. We use Krippendorff's alpha to compute reliability, where a value equal to or larger than 0.8 and 0.6 indicates reliable and tentative conclusions, respectively [39, 42]. Regarding validity, we use convergent validity [22] between the two scales to assess if they measure the same phenomenon. The value ratio variable describes the perceived value of the scenarios, which is measured by calculating the median of the normalized magnitude estimates of each decision scenario.

A.2 Demographics

We perform a demographic analysis regarding the sex, student status, continent of residence, nationality, language, and ethnicity of our participants to study whether there are statistical differences in how they perceive hate speech. We have multiple groups for nationality, ethnicity, and language and two groups for the features of student status, sex, and continent of residence (since only two continents were present in the demographic data of all participants).

Table 4 shows the group differences for the aggregated scenario types (TP, TN, FP, FN, and REJ) and highlights the p values that differ substantially. We found the most significant differences across all scenarios for different nationalities and languages of participants.

A.3 Pilot Study

We conducted a pilot study with 24 participants to test the survey and estimate the required completion time. The pilot study showed low inter-rater reliability, which may be due to unmatched expectations and unclear scenario descriptions. Initially, our scenarios mentioned that machine-detected hateful posts would be removed, which could be controversial. Thus, we changed scenarios to rank the hateful posts lower on the feed. Moreover, we added more lengthy descriptions to explain the potential consequences of all scenarios in a neutral tone, which prepares the participants to focus on evaluating harm (instead of giving rewards).

A.4 Example Tasks

WARNING: GRAPHIC LANGUAGE.

A.4.1 FN scenario with ME scale.

Suppose we have the following post:
"I want this stupid bitch out of my head I've never even liked her lmao I just basically want to rape her" (from Basile et al. [8])

Question 1:
Please indicate whether you feel that this post is hateful or not hateful.
Select input with options: 'hateful' or 'not hateful'

Question 2:
You are a user of the SocialNet platform and just saw this post on your main feed because SocialNet's automated detection system is confident that it is not hateful.

- This post remains visible on other people's main feeds as well.

	Two groups			More than two groups		
	Sex	**Student**	**Continent**	**Nationality**	**Language**	**Ethnicity**
TP	0.302	**0.032**	0.286	0.218	0.109	0.242
TN	0.726	0.379	0.204	0.190	0.216	0.281
FP	0.699	0.933	0.073	**0.020**	**0.040**	**0.037**
FN	0.961	0.150	0.847	0.478	0.438	0.584
REJ	0.835	0.625	0.496	0.271	0.103	0.068

Table 4: Statistical differences between different groups of participants for various demographic characteristics for each aggregated scenario type in the ME survey. Each cell contains the p value of either the Mann-Whitney U test for two groups or the Kruskal-Wallis test for more than two groups. Bold text indicates significant statistical differences.

- If the post is hateful after all, then the detection system was incorrect. This hateful post is now visible on people's main feeds with the consequence that they can get harmed.
- If the post is indeed not hateful, then the detection system was correct.
- You should be aware that it is expected for SocialNet to correctly classify hate speech. Wrong classifications are undesirable as they may cause harm to people.

Please indicate whether you agree, disagree, or are neutral about SocialNet's decision.
Select input with options: 'agree', 'neutral', or 'disagree'.

Question 3 (only visible when 'agree' or 'disagree' are selected):
Please indicate how much you agree/disagree with SocialNet's decision using any positive number.
Show ME input field that allows all positive values greater than 0.

A.4.2 FP scenario with 100-level scale.

Suppose we have the following post: *"Ontario concerns were not listened at immigration meeting in Ottawa For illegal crossing"* (from Basile et al. [8])

Question 1:
Please indicate whether you feel that this post is hateful or not hateful.
Select input with options: 'hateful' or 'not hateful'

Question 2:
You are a user of the SocialNet platform and have not seen this post on your main feed because SocialNet's automated detection system is confident that it is hateful.

- You can still find this post when you scroll down your feed since SocialNet ranks hateful posts lower.
- If the post is not hateful after all, then the detection system was incorrect. This neutral post is now ranked lower on people's feeds with the consequence that the post cannot easily reach the author's followers.
- If the post is indeed hateful, then the detection system was correct.
- You should be aware that it is expected for SocialNet to correctly classify hate speech. Wrong classifications are undesirable as they may cause harm to people.

Please indicate whether you agree, disagree, or are neutral about SocialNet's decision. **Select input with options: 'agree', 'neutral', or 'disagree'.**

Question 3 (only visible when 'agree' or 'disagree' are selected):
Please indicate how much you agree/disagree with SocialNet's decision using any positive number from 1 to 100. If you feel neutral about SocialNet's decision, select neutral in the field above.
Show a numerical slider with values between 1 and 100.

A.4.3 Rejection scenario with 100-level scale.

Suppose we have the following post: *"Ever been so hungover that your stomach feels like it's eating itself"* (from Basile et al. [8])

Question 1:
Please indicate whether you feel that this post is hateful or not hateful.
Select input with options: 'hateful' or 'not hateful'

Question 2:
You are a user of the SocialNet platform and just saw this post on your main feed because SocialNet's automated detection system was not confident enough in whether it was hateful or not.

- An internal human moderator at SocialNet needs to look at it within at most 24 hours.
- Meanwhile, the post remains visible on people's main feeds.

Please indicate whether you agree, disagree, or are neutral about SocialNet's decision.
Select input with options: 'agree', 'neutral', or 'disagree'.

Question 3 (only visible when 'agree' or 'disagree' are selected):
Please indicate how much you agree/disagree with SocialNet's decision using any positive number.
Show a numerical slider with values between 1 and 100.

GATE: A Challenge Set for Gender-Ambiguous Translation Examples

ABSTRACT

Although recent years have brought significant progress in improving translation of unambiguously gendered sentences, translation of ambiguously gendered input remains relatively unexplored. When source gender is ambiguous, machine translation models typically default to stereotypical gender roles, perpetuating harmful bias. Recent work has led to the development of "gender rewriters" that generate alternative gender translations on such ambiguous inputs, but such systems are plagued by poor linguistic coverage. To encourage better performance on this task we present and release GATE, a linguistically diverse corpus of gender-ambiguous source sentences along with multiple alternative target language translations. We also provide tools for evaluation and system analysis when using GATE and use them to evaluate our translation rewriter.

In *AAAI/ACM Conference on AI, Ethics, and Society (AIES '23), August 08–10, 2023, Montréal, QC, Canada.* ACM, New York, NY, USA, 10 pages. https://doi.org/10.1145/3600211.3604675

1 INTRODUCTION

Gender is expressed differently across different languages. For example, in English the word *lawyer* could refer to either a male or female individual, but in Spanish, *abogada* and *abogado* would be used to refer to a female or a male lawyer respectively. This frequently leads to situations where in order to produce a single translation, a translator or machine translation (MT) model tends to choose an arbitrary gender to assign to an animate entity in translation output where it was not implied by the source. In this paper, we refer to this phenomenon as *arbitrary gender marking* and to such entities as Arbitrarily Gender-Marked Entities (AGMEs).

Translation with arbitrary gender marking is a significant issue in MT because these arbitrary gender assignments often align with stereotypes, perpetuating harmful societal bias [3, 19]. For example, MT models will commonly translate the following (from English to Spanish):

$$\textit{The surgeon} \xRightarrow{MT} \textit{El cirujano (m)}$$

$$\textit{The nurse} \xRightarrow{MT} \textit{La enfermera (f)}$$

Progress has been made to remedy this using a "gender rewriter" – a system that transforms a single translation with some set of gender assignments for AGMEs into a complete set of translations that covers all valid sets of gender assignments for a source sentence into the target language [14]. Using a rewriter:

The surgeon

⇓ MT

El cirujano (m)

⇓ rewriter

La cirujana (f)
El cirujano (m)

Although a step in the right direction, these rewriters often have poor linguistic coverage and only work correctly in simpler cases. Google Translate has publicly released such a system for a subset of supported languages, and we observe two error cases[1]:

(1) It does not rewrite when necessary: *The director was astonished by the response of the community.* produces only one translation corresponding to masculine director.
(2) It rewrites partially, or incorrectly: *I'd rather be a nurse than a lawyer* produces two translations but only lawyer is reinflected for gender (nurse is feminine in both).

To facilitate improvement in coverage and accuracy of such rewriters and reduce bias in translation, we release GATE[2], a test corpus containing gender-ambiguous translation examples from English (en) into three Romance languages [23]: Spanish (es), French

AIES '23, August 08–10, 2023, Montréal, QC, Canada

https://doi.org/10.1145/3600211.3604675

[1] as observed on Mar 6, 2023
[2] Data and evaluation code available at https://github.com/MicrosoftTranslator/GATE

(fr) and Italian (it). Each English source sentence[3] is accompanied by one target language translation for each possible combination of masculine and feminine gender assignments of AGMEs [4]:

I know ***a Turk*** *who lives in Paris.*
⇓ it
Conosco una turca che vive a Parigi. (f)
Conosco un turco che vive a Parigi. (m)

GATE is constructed to be challenging, morphologically rich and linguistically diverse. It has ∼ 2000 translation examples for each target language, and each example is annotated with linguistic properties (coreferent entities, parts of speech, etc.). We additionally propose a set of metrics to use when evaluating gender rewriters.

This corpus was developed with the help of bilingual linguists with significant translation experience for each of our target languages (henceforth *linguists*). Each is a native speaker in their respective target language. We spoke in depth with our linguists about the nuances of gender-related phenomena in our focus languages and we share our analysis of the relevant aspects and how they impact our work and the task of gender rewriting.

Along with the corpus, we also provide tools for evaluation and system analysis when using GATE and use them to evaluate our own translation rewriter.

2 RELATED WORK

A slew of challenge sets has been proposed for evaluating gender bias in Machine Translation.

MuST-SHE [2, 18] comprises approximately 1,000 triplets consisting of audio, transcript, and reference translations for en-es, en-fr, and en-it. Each triplet is classified based on the gender of the speaker or explicit gender markers, such as pronouns, as either masculine or feminine. Furthermore, the dataset contains an alternative incorrect reference translation for every correct reference translation that alters the gender-marked words.

WinoMT [19] is a challenge set that comprises English sentences containing two animate nouns, one of which is coreferent with a gendered pronoun. Based on the context provided in the sentence, a human can easily identify which animate noun is coreferent and thus deduce the gender of the person described by that noun. By evaluating the frequency with which an MT system generates a translation with the correct gender for that animate noun, one can measure the extent to which the system depends on gender stereotypes rather than relevant context.

SimpleGEN [16] on the English-Spanish (en-es) and English-German (en-de) language pairs. It includes a test set consisting of short sentences with straightforward syntactic structures. Each source sentence includes an occupation noun and a clear indication of the gender of the person described by that noun. In other words, the source sentence provides all the necessary information for a model to generate occupation nouns with the correct gender.

The Translated Wikipedia Biographies[5] dataset comprises 138 documents containing human translations of Wikipedia biographies from English to Spanish and German. Each document comprises 8-15 sentences, providing a context for gender disambiguation evaluation across sentences.

MT-GenEval [5] is a dataset that includes gender-balanced, counterfactual data in eight language pairs. The dataset ensures that the gender of individuals is unambiguous in the input segment, and it comprises multi-sentence segments that necessitate inter-sentential gender agreement.

Regarding the work on addressing ambiguously gendered inputs, [8] tackle translation of ambiguous input by treating it as a gender classification and reinflection task when translating English into Arabic. Their approach focuses on the first-person singular cases. Given a gender-ambiguous source sentence and its translation, their system generates an alternative translation using the opposite gender. Additionally, they create a parallel corpus of first-person singular Arabic sentences that are annotated with gender information and reinflected accordingly. [1] expand on the work of [8] by adding second person targets to the Arabic Parallel Gender Corpus, as well as increasing the total number of sentences.

Google Translate announced[6] an effort to address gender bias for ambiguously gendered inputs by showing both feminine and masculine translations. They support this feature for English to Spanish translation, as well as several gender-neutral languages into English.

Regarding debiasing in the monolingual context, [24] propose a generative model capable of converting sentences inflected in masculine form to those inflected in feminine form, and vice versa, in four morphologically rich languages. Their work focuses on animate nouns.

In terms of rewriting text in English, [21] and [20] propose rule-based and neural rewriting models, respectively, that are capable of generating gender-neutral sentences.

3 LINGUISTIC BACKGROUND

3.1 Gender in Romance Languages

In Spanish, French and Italian, all nouns have a grammatical gender – either masculine or feminine. For inanimate objects, this gender is fixed and often arbitrary; for example, in French, *chaise* (chair) is feminine, while *canapé* (couch) is masculine. When a noun or pronoun refers to an animate entity, its grammatical gender will, with some notable exceptions, match the referential gender of that entity. [23]

In these languages, referential gender of entities is frequently marked through morphology of an animate noun (e.g. *en-es*: *lawyer* ⇒ *abogada* (f), *abogado* (m)) or through agreement with gendered determiners, adjectives and verb forms.

3.2 Dual Gender and Epicene

Some animate nouns are *dual gender*, meaning that the same surface form is used for both masculine and feminine, such as French *artiste* (artist) ([4] as cited in [9]). However, other clues to the artist's gender may exist in a French sentence through gender agreement with other associated words. For example, *The tall artist* could be translated into French as *La grande artiste* (f) or *Le grand artiste* (m). Here, grammatical gender of translations of *the* (*la* (f) / *le* (m))

[3] A few non-sentence utterances are also included as well, such as noun-phrases and sentence fragments
[4] The majority of source sentences contain only one AGME and thus two translations
[5] https://ai.googleblog.com/2021/06/a-dataset-for-studying-gender-bias-in.html
[6] https://ai.googleblog.com/2020/04/a-scalable-approach-to-reducing-gender.html

and *tall* (*grande* (f), *grand* (m)) must match the referential gender of the referent noun.

Dual-gender determiners and adjectives exist as well, such as Spanish *mi* (my) and *importante* (important). So, for example, Spanish *mi huésped importante* (My important guest) has no gender marking. Similarly, in French and Italian, some determiners may contract before vowels to lose their gender marking. Feminine and masculine forms of *the* in French, *le* and *la*, both contract before vowels (and sometimes *h*) to become *l'*, so *l'artiste* (the artist) is not marked for gender.

While typically an entity's referential gender will align with its grammatical gender, these languages each contain a handfull of *epicene* nouns. These are nouns whose grammatical gender is fixed, regardless of the referential gender of the referent ([7] as cited in [10]). Most notable among these is the direct translation of *person* into each of the target languages, which is always grammatically feminine: *La persona* (*es,it*) or *La personne* (*fr*). We also find some language-specific epicene nouns. For example, these Italian words are always grammatically feminine: *la guardia* (guard), *la vedetta* (sentry), *la sentinella* (sentry), *la recluta* (recruit), *la spia* (spy). [7]

3.3 Pronouns

Similarly to English, some pronouns in Romance languages are inherently gendered, while others are not. Entities referred to by gender-neutral pronouns, such as Spanish *yo* (I) and *tú* (you) commonly become gender-marked through predicative gender-inflecting adjectives. Further complicating these cases, subject pronouns are frequently omitted in Spanish and Italian (but notably not in French) as the subject can be inferred from verb morphology [9]. This means that in some cases, the AGME in a sentence pair may be a zero-pronoun, such as English *I am* ***tired*** being translated to Spanish as *estoy cansada* (f) or *estoy cansado* (m). There is no overt subject in these translations corresponding to *I*, but the subject is implied by the verb form *estoy*.

3.4 Coreference

Another common pattern is that of coreferent mentions of a single entity, which must by definition have the same referential gender, and usually but not always the same grammatical gender. For example, in the following sentence, *friend* and *nurse* are the same individual and we would typically expect them to share the same referential gender in a direct translation into any of the target languages.

My best friend is a nurse

In cases where one coreferent mention is an epicene noun as described in 3.2, the grammatical genders of those mentions may in fact differ. In the following sentence, the described individual is unambiguously male. The phrase *una buena persona* (a good person) is grammatically feminine, while *un mal amigo* (a bad friend) and *él* (he) are grammatically masculine. [8]

He is a good person but a bad friend.

⇓ es

Él es una buena persona, pero un mal amigo.

3.5 Masculine Generics

Traditionally, many languages, including Spanish, French and Italian, employ a paradigm known as masculine generics. Under this paradigm, feminine forms are considered to be explicitly gender-marked, while masculine forms should be used in situations where referential gender is unclear. Specifically, when referential gender is unknown by the speaker, or a mixed-gender group is known to contain at least one male individual, defaulting to grammatically masculine forms is generally considered correct in the language standard[9]. In this sense, masculine gender marking does not imply the exclusion of female-identifying individuals, but a feminine gender marking would imply the exclusion of male-identifying individuals. [9, 10]

In most cases where a masculine generic might be used, we nonetheless ask our linguists to provide an alternative translation with feminine gender-marking. Language critics have noted that the use of masculine generics can evoke an association with 'male' [10], and so we believe that inclusion of a feminine generic variant fits our mission of promoting inclusive language use. Our linguists were asked to annotate such generic mentions with the label INDF (*indefinite gender*), so that users who wish to follow a stricter interpretation can exclude these examples in their evaluations. However, upon analysis of our corpus we noted that this annotation was only consistently applied to the Italian data.

4 GATE CORPUS

We present GATE corpus, a collection of bilingual translation examples designed to challenge source-aware gender-rewriters. The linguists were asked to compile roughly 2,000 examples for each target language, with the hope that this would be sufficient for good variety along several dimensions: sentence lengths, sentence structures, vocabulary diversity, and variety of AGME counts.

4.1 Anatomy of an Example

Each example in the data set consists of an English sentence with at least one AGME, and a set of alternative translations into the given target language corresponding to each possible combination of male/female gender choices for each AGME. Variation among the alternative translations is restricted to the minimal changes necessary to naturally and correctly indicate the respective gender-markings.

We also mark several category features on each example, such as what class of animate noun AGMEs belong to (profession, relationship, etc), what grammatical role they play in the sentence (subject, direct object, etc), sentence type (question, imperative, etc) and several other phenomena. These are discussed in more detail in section 4.4, as well as counts over each language's corpus.

Additionally, each example is accompanied by a list of AGMEs as they appear in the English source, as well as their respective masculine and feminine translations found in the translated sentences. For multi-word phrases, we asked annotators to enclose the head

[7] Color-coding in this paragraph corresponds only to grammatical gender, while referential gender is ambiguous in these expressions.

[8] In this example, color-coding indicates grammatical gender of each mention as it appears the Spanish translation

[9] In recent years there is some explorations of using novel, gender-neutral forms in these contexts

noun in square brackets. For example, if *police officer* is translated to *policía* in Spanish, the English field could include *police [officer]*.

The same entity may be referred to multiple times in the same sentence through coreference. We asked annotators to indicate coreferent mentions of AGMEs are by joining them with '='. For example, in the following *en-es* example, the English AGME field would contain "nurse=lawyer".

I'd rather be a ***nurse*** *than a* ***lawyer****.*
⇓ es
Prefiero ser enfermera que abogada. (f)
Prefiero ser enfermero que abogado. (m)

Finally, in cases where an AGME is represented by a pronoun that is elided in the translation, it will be represented by the nominative case form and be enclosed in parentheses. For example, in the following example, the Spanish AGME field would contain *(yo)*:

I am ***tired****.*
⇓ es
Estoy cansada. (f)
Estoy cansado. (m)

4.2 Arbitrarily Gender-Marked Entities

In this paper, we use *animate entity* (or just *entity*) to refer to an individual or group for which a referential gender could be implied in either the source or target language[10]. Usually this will refer to humans, but may also be extended to some animals and mythical or sentient beings. For example, *cat* is generally translated into Spanish as *gato*, but *gata* is also frequently used to refer to a female cat. Following [6], we use *referential gender* to refer to an entity's gender as a concept outside of any linguistic considerations.

To qualify as an AGME, an entity's referential gender must be ambiguous in the source sentence, but implied by one or more words in the target translation. Compared to Romance languages, there are relatively few ways that gender is denoted through word-choice in English. Most notably, English uses a handful of gendered pronouns and possessive adjectives (*she*, *her*, *hers*, *herself*, *he*, *him*, *his*, *himself*), as well as a relatively small number of animate nouns that imply a gender (e.g. *mother*, *father*, *masseuse*, *masseur*, etc). There is also often a correlation between certain proper names and referential gender (e.g. *Sarah* is traditionally a female name and *Matthew* is traditionally male), but we do not consider this a reliable enough signal for gender determination unless they are a well known public figure (e.g. *Barack Obama* is known to be male). We follow [22] in this.

Additionally, an AGME must have some gender marking in the translation. In the following English-Italian example,

I heard the thief insult ***his interlocutor****.*
⇓ *it*
Io ho sentito il ladro insultare la sua interlocutrice.
Io ho sentito il ladro insultare il suo interlocutore.

interlocutor→*interlocutrice* (f) / *interlocutore* (m) is an AGME, while *thief*→*ladro* and the speaker (*I*→*Io*) are not. *Thief* is unambiguously male because of its coreference with *his* in the source, while the speaker is not marked for gender in either the source or target.

[10]For simplicity, we limit our discussion of gender and linguistics to masculine and feminine within the scope of this paper, but we do not intend to imply that gender is limited in this way.

4.3 Corpus Development Process

The linguists were asked to aim for a distribution of sentence lengths ranging from very short (< 10 words) to complex (> 30 words). Actual example counts are shown in Table 1. Of the 2,000 examples for each language, linguists were asked to include roughly the following breakdown:

- 1,000 single animate noun AGME
- 500 single pronoun AGME
- 500 with two or more AGMEs

Linguists were given details of the various categories and attributes listed in section 4.4 and asked to find sentences such that each such category is well represented (depending on the relative ease of finding such sentences). Linguists were also asked to prioritize diversity of animate nouns where possible. They were allowed to pull examples sentences from natural text or construct them from scratch as they saw fit. However, except for a small number of toy examples, we asked that they include only sentences that were natural in both English and their target language, and could reasonably appear in some imaginable context.

We provided samples of web-scraped data that had been filtered with various heuristics to help identify sentences fitting some of the harder-to-satisfy criteria. For example, we used Stanza [15] to filter some web-scraped data for those containing an animate noun marked as an indirect object and provided this to the linguists. In some cases these sentences were used directly, and in others they were modified slightly to fit the requirements.

Throughout the process, we prioritized diversity of sentence structure, domain and vocabulary. Rather than produce a representative sample, our intention was to produce a corpus that would challenge any tested systems on a wide range of phenomena.

4.4 Category Labels

There are a wide range of linguistic phenomena that can interact with gender in translation. We have devised several category labels that can be applied to segments in GATE. In order to promote diversity within the corpus, linguists were asked to ensure that a certain minimum number of examples are included for each such label. This also has the benefit of helping pinpoint weaknesses in an evaluated system. For example, a rewriting system may perform well when the AGME is the subject of a sentence, but do poorly when it is a direct object.

Unless otherwise stated, category labels are determined based on the target sentence set rather than the source sentence, as this is generally the more important of the inputs to the rewriter. A single example will typically have multiple labels.

- **Grammatical Role categories:** An AGME is a subject (SUBJ), direct object (DOBJ), indirect object (IOBJ), subject complement (SCMP), object of a preposition (OPRP, excluding indirect objects), possessive complement (POSC) or object complement (OCMP). For Italian, we mark sentences with DIFF if grammatical role is different between source and target.
- **Animate Noun categories:** profession (PROF, e.g. *doctor*), Religion (REL, e.g. *Bhuddist*), Nationality (NAT, e.g. *Italian*,

Data Set	< 10	10-19	20-29	>= 30	Total
Spanish 1 AGME	477	722	197	105	1,501
Spanish 2+ AGMEs	70	176	56	21	323
French 1 AGME	704	661	171	14	1,550
French 2+ AGMEs	177	222	41	4	444
Italian 1 AGME	397	867	195	48	1,507
Italian 2+ AGMEs	93	500	139	30	762

Table 1: Distribution of lengths (words) of English utterance per target language and AGME count

Label	es	fr	it	description
Semantic Type				
PROF	1168	490	1208	Profession word
NAT	118	249	157	Nationality or locality membership
REL	25	150	29	Religious affiliation
FAM	327	250	192	Family or other relationship
NHUM	2	40	–	Non-Human
OTH	580	941	708	Other
Grammatical Role				
SUBJ	1638	1221	1573	Subject
SCMP	118	185	121	Subject complement
DOBJ	181	328	399	Direct object
IOBJ	136	275	165	Indirect object
OPRP	250	279	518	Object of preposition
POSC	80	–	289	Possessive complement
OCMP	–	–	12	Object complement
DIFF	–	–	85	Grammatical role different between source and translation
Sentence Type				
QUES	124	–	–	Question
FRAG	49	101	–	Sentence Fragment
IMPR	14	135	–	Imperative
Adjective-Related				
APRD	82	359	213	Predicative adjective agreeing with AGME
AATR	293	190	315	Attributive adjective agreeing with AGME
ANAN	97	1026	–	Adjective modifying a word other than AGME
PPA	361	172	290	Adjective has same surface form as a past participle
Pronoun Subtype				
PERS	–	219	146	Personal pronoun
RELA	–	15	13	Relative pronoun
DEMO	–	64	28	Demonstrative pronoun
POSS	80	–	–	Possesive pronoun
DROP	157	–	–	AGME is a dropped/zero pronoun
IPRO	–	369	53	Indefinite pronoun
Other				
PLUR	991	1110	1042	Plural
INDF	–	–	229	Indefinite/masculine generic could apply
DFCL	136	113	–	Changed words in alternatives cross clause boundaries
PSSV	–	–	164	Passive voice
VPART	–	–	372	Past participle agreeing with AGME
GLNK	–	94	–	"gender-link" – AGMEs are not coreferent but conceptually linked, different genders would be unnatural

Table 2: Counts of sentences with each category label per language, including all AGME counts

also includes or regional membership, as in *Washingtonian*), Family and other relationships (FAM, e.g. *neighbor*), Non-Human (NHUM, e.g. *cat*, *vampire*), Other (OTH, e.g. *winner*, *accused*)

- **Adjectives and past participles:** attributive (AATR), predicative (APRD), past-participle form as an adjective (PPA), past-participle form not as an adjective (PPNA), Adjective modifies non-ambiguous noun (ANAN). Most of these distinctions are included to test a rewriter's ability to distinguish between adjective surface forms that should be modified along with key nouns and those that should not.
- **Sentence Types categories:** Sentence fragment (FRAG), question (QUES), imperative (IMPR).
- **Pronoun subtypes:** Personal (PERS), Relative (RELA), Demonstrative (DEMO), Possessive (POSS), Indefinite (IPRO). For Spanish, we annotate with DROP if an AGME is a dropped pronoun.
- **Other categories:** Plural AGME (PLUR), Passive (PSSV). DFCL indicates that gender marking words on the AGME require agreement across clause-clause boundaries. GLNK (for *gender link*) indicates that there are distinct animate nouns that could behave as a single entity, e.g. *No scientists or researchers were implicated.*
  In Italian, we mark past participle verb forms which agree with the AGME with VPART. We also mark indefinite or generic AGMEs with INDF. This indicates that it does not refer to an entity concretely known by the speaker and many speakers may prefer a generic masculine, e.g. "Where can I find a good doctor?".

Table 2 shows counts of sentences annotated with each category label in each of our three target languages. Due to inconsistencies in annotation between languages, some labels are not available for some languages and appear as '–' in the table.

5 EVALUATION WITH GATE

5.1 Gender Rewriting

Our goal in developing this corpus is to facilitate the generation of multiple translations covering all valid gender assignments. One strategy for producing such a set of translations is to first use an MT model to produce a default translation and then use a rewriter to generate one or more alternative translations with other gender assignments [14].

$$\text{source} \overset{\text{MT}}{\Longrightarrow} \text{translation} \overset{\text{rewriter}}{\Longrightarrow} \{\text{all translations}\}$$

5.2 Evaluation Methodology

We formalize the task of gender rewriting on a single-AGME sentence as follows: given the source sentence *src*, target translations corresponding to male and female referent entities, and a rewrite direction (M to F or F to M), produce an output target translation with the alternative gender from the original translation. We will refer to the original input translation as tgt_0, the desired/reference translation as tgt_1 and the output generated by the rewriter as *hyp*:

$$rewriter(src, tgt_0) = hyp \sim tgt_1$$

For this task, we consider looking at exact full-sentence matches between *hyp* and tgt_1 to be the most sensible approach for evaluation. We do not give partial credit for changing the gender markings on only a subset of the words to those found in tgt_1. Doing so will generally result in a sentence that is either grammatically incorrect due to newly introduced agreement errors, or for which the semantics has changed in an unacceptable way, such as a changed coreference. Because of this, we find sentence-similarity measures such as BLEU [13] and words error rate not to be reflective of a user's experience.

The rewriter may also produce a null output, meaning that only the default translation will be produced. This is necessary because in real-world scenarios, many sentences will not contain AGMEs. When AGMEs are present, it may still be preferable to produce null output over a low confidence rewrite if accuracy errors are judged to be more costly than coverage errors.

We calculate precision as the proportion of correct alternatives among those attempted, i.e. that were non-null outputs. Because there are no true negatives in GATE, recall can be calculated as the proportion of correct alternatives produced among all sentences, including null outputs. Using these definitions of precision and recall, we also find $F_{0.5}$ to be a useful overall metric, prioritizing precision while still incorporating coverage.

While we have focused our discussion of evaluation on sentences containing a single AGME, which typically should produce exactly two alternative translations, GATE also includes a smaller number of examples with more than one AGME. These have more than two alternative translations and thus more than one correct output for a rewriter. We do not formalize evaluation on this subset here but believe that the data set will be useful in evaluating rewriting systems capable of producing multiple outputs for multiple sets of gender assignments.

A comprehensive evaluation of a translation gender rewriter should include testing on both sentences with and without AGMEs. As each instance in GATE involves at least one AGME, we suggest augmenting GATE with instances from Renduchintala and Williams [17] and Vanmassenhove and Monti [22], which feature unambiguously gendered source entities. In future work, we intend to develop a supplemental data set for GATE containing various types of negative examples: unambiguous source entities, entities that are unmarked in both source and target, and inanimate objects whose surface forms are distractors (e.g. depending on context, *player* and *cleaner* may refer to either objects or people).

5.3 System Overview

We use GATE to evaluate our translation gender rewriter, which follows a pipeline approach, roughly similar to [8].

The system receives as input the original source sentence (*src*) and a default translation (tgt_0) with the specified language pair. The following components are then applied:

AGME Identifier – We first attempt to find AGMEs in the sentence pair to determine whether rewriting is appropriate. We leverage an AllenNLP [12] coreference model to detect ambiguously gendered entities in the source sentence. We use a dependency parse generated by Stanza [15] and a gendered vocab list to identify gender-marked animate entities in the target sentence.

Candidate Generator - For each word position in tgt_0, we use a lookup table to find all possible alternate gender variants for the word in that position. We compose the word-level variant sets to build a set of sentence-level hypotheses, while applying grammatical constraints to prune incoherent hypotheses. This yields a set of candidate rewrites.

Translation Scorer - Finally, we use a Marian [11] translation model to score each rewrite candidate as a translation of *src*. If no candidates have scores close to that of tgt_0, We return a null output. Otherwise we choose the candidate with the highest translation score.

5.4 Experimental Results

We evaluate the rewrite quality of our system on GATE in both masculine-to-feminine and feminine-to-masculine directions. To simulate runtime efficiency constraints, we impose a cutoff of 20 maximum source words. Any input sentence longer than this is treated as a null output and therefore counted as a false negative.

Language	Direction	P	R	$F_{0.5}$
Spanish	F→M	0.97	0.50	0.82
Spanish	M→F	0.95	0.40	0.74
French	F→M	0.97	0.28	0.65
French	M→F	0.91	0.27	0.61
Italian	F→M	0.96	0.47	0.79
Italian	M→F	0.91	0.32	0.67

Table 3: Our rewriter's scores on GATE for each target language and rewrite direction

From these results we can see that our system performs best for Spanish in both directions, and in the female-to-male direction across all language pairs. Both trends can be explained to an extent by the properties of the translation models. High quality training data for English-Spanish is more plentiful than for the other two languages, leading to a higher quality model in general. As noted earlier, translation models have been shown to skew towards stereotypical gender assignments, which are more heavily weighted towards masculine forms. Therefore, it is not too surprising that when rewriting from male to female, the translation model is more likely to prefer an incorrect rewrite candidate.

5.5 End-to-End Evaluation

In our envisioned scenario, a gender rewriter would operate on the output of an MT system. It is unlikely, however, that direct MT output will consistently match GATE's translations word-for-word. As a result, references cannot be directly utilized, and human annotation is required to assess the output of a rewriter alongside machine translation (MT) or any integrated system that generates a series of gender alternative translations from a single source sentence. One additional consideration in this scenario is that a segment from GATE that contains an AGME, may no longer contain one when using a machine translated target, as the MT output may end up unmarked for gender.

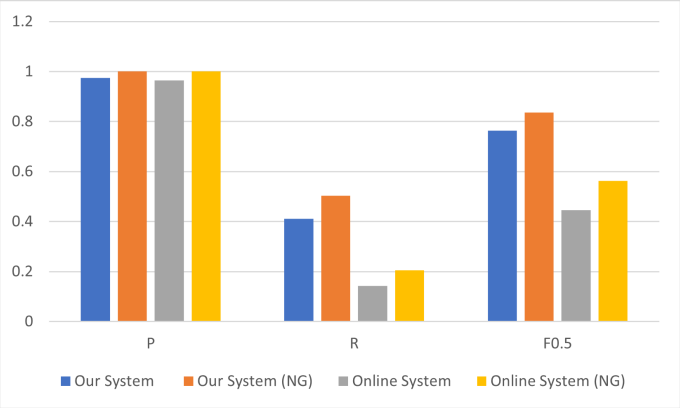

Figure 1: End-to-end scores for our system and an online translation system.

In order to test our combined system end-to-end, we sampled 200 source sentences from GATE and used Bing Translator to translate them into Spanish, and then pass that output to our rewriter. We then ask annotators to examine the source sentence and all translation outputs, and to consider correctness of gender marking and agreement rather than general translation quality. They were instructed to provide the following annotations:

- If two translations are produced, mark true positive if the following are true (otherwise false positive):
  - Is the target gender-marked for an ambiguous source entity?
  - Were all words marking gender on the AGME changed correctly?
  - Were only the words marking gender of the AGME changed?
- If only one translation is produced, is the target marked for gender on an ambiguous source entity? Mark as false negative if so, and otherwise a true negative.
- If there are multiple AGMEs:
  - If two valid translations are produced, mark as a true positive.
  - If only one translation is produced, mark as a true negative.
  - Otherwise mark as a false positive.

We also retrieve translations for these sentences from an online, third party English-Spanish translation system that can produce masculine and feminine alternative translations for this language pair. We asked annotators to annotate these translations in the same manner.

Finally, we also asked annotators to mark source sentences for which the speaker is reasonably likely to know the referent's gender, and therefore use of a masculine generic should be less likely (see 3.5). We evaluate quality on that subset as well for each system, in rows marked NG (*non-generic*). Results are presented in Table 4 and visualized in Figure 1.

Both systems heavily favor precision over recall, and recall is somewhat higher on the *non-generic* portion of the data. Overall, our system demonstrates significantly better coverage.

	P	R	$F_{0.5}$
Our System	0.97	0.41	0.76
Our System (NG)	1.00	0.50	0.84
Online system	0.96	0.14	0.45
Online system (NG)	1.00	0.21	0.56

Table 4: end-to-end scores for our system and an online translation system. NG rows are calculated only on *non-generic* sentences

5.6 Per-Category Results

We also calculate precision, recall and $F_{0.5}$ for our system on the subset of sentences with each category label for each target language and rewrite direction. These can be found in Table 5 for Spanish, Table 6 for French, and Table 7 for Italian. By examining these table, we can identify some potential areas for improvement in our system.

For English into Spanish, both DFCL (cross-clause agreement required) and IMPR (imperative) stand out as weak spots for our system, showing both low precision and low recall in both rewrite directions. DFCL can only be marked on a sentence containing at least two clauses, and these sentences tend to skew longer, naturally increasing in complexity, and also bumping into the 20-word cap more often. Additionally, when words must agree across clause boundaries, writing dependency-based rules to enforce agreement is quite difficult, and so more of that work falls on the translation model.

At 13 sentences, the sample of IMPR sentences here is relatively small, we identify exactly one sentence that is incorrectly rewritten in both directions. We show the feminine to masculine rewrite direction here:

Leave them alone and in peace, they are playing.

⇓ (human translation)

Déjalas tranquilas y en paz, están jugando. (f)

⇓ (our rewriter)

***Déjalas** tranquilos y en paz, están jugando* (m)

Déjalas means *leave [female]them*, and should have been rewritten to *Déjalos*, but was not, due to difficulty in recognizing the attached pronoun *las* as something that can be reinflected for gender.

Recall for IMPR sentences is also low because many lack an overt subject or animate noun mention on the English side, which makes AGME detection more difficult.

English→French and Italian show an interesting, but perhaps unsurprising pattern for PLUR and INDF (only annotated for Italian). Precision and recall are significantly higher on these sentences for F→M rewrites than for M→F.

PLUR indicates a plural AGME, and INDF indicates that the AGME does not refer to a specific individual or group. Many speakers will use a masculine generic when referring to either of these types of entities (see section 3.5). Because of this, sentences of this type are much more likely to appear with a masculine form in training data for an MT model. The model is therefore likely to score masculine forms significantly higher than feminine forms.

Table 5: Per-category breakdown of precision, recall and $F_{0.5}$ on single AGME sentences for English→Spanish rewrites in each rewrite direction.

This leads to grammatically consistent feminine rewrites being out-competed by less fluent rewrites that preserve some masculine word forms.

6 CONCLUSION

We have presented GATE, a corpus of hand-curated test cases designed to challenge gender rewriters on a wide range of vocabulary, sentence structures and gender-related phenomena. Additionally, we provide an in-depth analysis of many of the nuances of grammatical gender in Romance languages and how it relates to translation. We also suggest metrics for gender rewriting and provide tools to aid with their calculation. Through this work we aim to improve the quality of MT output in cases of ambiguous source gender, as well as facilitate the development of better and more inclusive natural language processing (NLP) tools in general.

We look forward to future work in improving GATE and related projects. We aim to add additional languages pairs to GATE and investigate translation directions into English. We also hope to supplement with additional data, including negative examples. Finally,

we plan to explore use of gender-neutral language use in various languages and how it can be incorporated into NLP applications.

7 BIAS STATEMENT

In this work, we propose a test set to evaluate translation of ambiguously gendered source sentences by NMT systems. Our work only deals with English as the source and is currently scoped to Romance languages as the target. To construct our test set, we have worked with bilingual linguists for each target language. We plan to increase scope of both source and target languages in future work.

Through this work, we hope to encourage and facilitate more inclusive use of natural language processing technology, particularly in terms of gender representation. In recent years, there is significant ongoing movement in the way gender manifests in languages use. One form that this takes is in new gender-neutral language constructs in Romance languages such as French, Spanish and Italian to accommodate gender underspecificity and non-binary gender identities. We support the development of this more representative and inclusive language, and endeavor to find ways to support it through technology. In this work, however, for the sake of simplicity we restrict our scope to language as used to express gender along more conventionally binary lines, and we therefore do not consider non-binary language or word forms. We are working with both language experts and non-binary-identifying individuals to expand the scope to include non-binary and gender-underspecified language in future work.

ABSTRACT

Democratization of AI means not only that people can freely use AI, but also that people can collectively decide how AI is to be used. In particular, collective decision-making power is required to redress the negative externalities from the development of increasingly advanced AI systems, including degradation of the digital commons and unemployment from automation. The rapid pace of AI development and deployment currently leaves little room for this power. Monopolized in the hands of private corporations, the development of the most capable foundation models has proceeded largely without public input. There is currently no implemented mechanism for ensuring that the economic value generated by such models is redistributed to account for their negative externalities. The citizens that have generated the data necessary to train models do not have input on how their data are to be used. In this work, we propose that a public data trust assert control over training data for foundation models. In particular, this trust should scrape the internet as a digital commons, to license to commercial model developers for a percentage cut of revenues from deployment. First, we argue in detail for the existence of such a trust. We also discuss feasibility and potential risks. Second, we detail a number of ways for a data trust to incentivize model developers to use training data only from the trust. We propose a mix of verification mechanisms, potential regulatory action, and positive incentives. We conclude by highlighting other potential benefits of our proposed data trust and connecting our work to ongoing efforts in data and compute governance.

1 INTRODUCTION

Private companies dominate the development of the most capable AI systems [42]. The staggering amounts of compute involved [42, 89] mean that large tech companies or those backed by massive amounts of venture capital have disproportionate power in guiding the direction of technological progress. Recent attempts to democratize AI development and open up the study of large models have met with some success [12, 37, 88], yet still suffer from core limitations. From a resource perspective, it remains difficult for academic or non-profit collaborations to match the financial weight of the private sector. From a philosophical perspective, democratization of AI is not solely about the free deployment of AI without regard for social consequence. Rather, we hold as Shevlane [90] does that democratization also means collective decision-making power over how AI is to be developed and deployed. Narrow democratization could frustrate the broad democratic ideal; unstructured access to AI systems could hinder societies from restricting certain uses they deem undesirable.

Collective decision-making power over AI is deficient in two key respects. First, data creators cannot prevent AI developers from using their data. Opt-out mechanisms are lacking and the training datasets of many of the largest models are private. Second, there is no implemented mechanism to ensure that the profits of AI development and deployment are distributed widely, particularly as a way to redress negative externalities. Even if an individual were to threaten to withhold their data from a model developer, they would have effectively no bargaining power since a few data points likely make no significant difference in the final performance of a model.

We focus on the large training datasets scraped from the **digital commons**—the collective intellectual and cultural contributions of humanity that are in digital form—and also on bespoke crowdworker data as a point of intervention for redressing the power imbalance between model developers and human data creators. The digital commons is the product of humanity's cumulative efforts, yet in AI development the fruits of the commons are captured by the few. Redistribution is requisite from the point of view of justice. Redistribution is also requisite from the point of view of pragmatism, for if human contributors to the digital commons are not supported in their work or resent its perceived theft, the commons itself could decay [49].

To address the imbalance of power, we propose the creation of a public data trust. We intend this data trust to be national and located in a jurisdiction with a high concentration of AI development, such as the US or the UK. Our data trust would gate access to the most important data for model training: pre-training data from the internet and human feedback data from annotators. Our gating is

meant to apply primarily to commercial AI developers. We focus our attention on general-purpose AI systems such as foundation models, given their likely role as important components of future AI systems and their increasingly wide adoption. Our contributions are as follows.

(1) We argue for the creation of a public data trust to hold training data, so as to address the private concentration of power in AI development and safeguard the digital commons.
(2) We describe how the data trust could use its bargaining power to address the negative externalities of AI deployment, including setting up a digital commons fund financed by a royalty on model revenues.
(3) We propose how the data trust could obtain training data.
(4) We provide a detailed plan for how the data trust could verify that model developers who have agreed to the data trust regime have only used the trust's model in training their models.
(5) We discuss various mechanisms for incentivizing model developers to comply with the data trust regime.
(6) We advance other potential benefits of our data trust, including supporting the generation of public good training data.

2 THE CASE FOR A DATA TRUST

We argue here for a national, public data trust to hold training data. An outline of our case is as follows.

(1) AI development heavily depends upon the **digital commons**: the collective intellectual and cultural contributions of humanity that are in digital form.
(2) AI development is extremely concentrated in the private sector. Those who contribute to the digital commons, including the general public and sector-specific individual such as artists, have little decision-making power over the development of deployment of AI compared to the AI developers.
(3) AI deployment results in negative externalities to the public; there are currently no effective mechanisms to address these negative externalities.
(4) A data trust that gated training data access to the digital commons would help to correct the power imbalance so as to redress negative externalities.

2.1 The Digital Commons

The **digital commons** [31, 49] constitutes the collective intellectual and cultural contributions of humanity in digital form. More specifically, the digital commons encompasses items like artistic work, scientific papers, knowledge bases, and software. Examples of resources that are a part of the digital commons include arXiv, Wikipedia, Reddit, online news sites, and Project Gutenberg.

The digital commons is crucial for democracy, material well-being, and cultural enrichment. First, the success of democracy depends upon an informed public [81]. Absent an accurate understanding of the state of the world, the public is less able to engage in productive deliberation and to select representatives to act in their interest. Knowledge resources in the digital commons can contribute to this public understanding. For example, Wikipedia has been a surprisingly rich source of information, comparable to academically authored encyclopedias in both breadth and reliability [67]. Second, knowledge and tools in the digital commons contribute to material well-being. For instance, Directorate-General for Communications Networks et al. [29], Ghosh [41] characterize the large positive impact of open-source software on the economy of the EU. Third, the digital commons provides a source of intangible cultural enrichment. For example, on Project Gutenberg one can access over 60 000 works of intellectual and cultural significance, from the Federalist Papers to the Analects of Confucius. The role of the digital commons in these critical functions underscores the importance of safeguarding it.

2.2 Concentration of Power

The wealth of high-quality information in the digital commons is a prime source of training data for modern AI systems. Empirical scaling laws about the relationship between the quantity of data, compute, and model parameters [48, 58] have motivated the use of ever larger amounts of data from the digital commons to train so-called "foundation models" [15, 75]. Such models as GPT-3 [17] are so named because they are increasingly general-purpose and seem likely to be deployed in a variety of scenarios [15].

Given the enormous quantities of data and computation involved, private companies have a quasi-monopoly on the development of the largest—and by virtue of scaling laws likely the most capable—foundation models [36, 42]. To obtain training data, private companies scrape the internet to obtain large datasets and hire crowdworkers to generate bespoke data. At no point is there an opportunity for the public to exercise decision-making power. Especially given the significant risks of AI development [15, 25, 36], private power to shape the trajectory of AI is in tension with public interests [114]. Despite the proliferation of AI ethics standards in recent years [57], ethical guidelines are no substitute for addressing the structural factors underlying the concentration of power in the private sector.

2.3 Negative Externalities

While concentration of power is itself suspect, the power of private AI developers contributes to tangible harms as well. Although the digital commons is the collective output of humanity, private organizations who train models on the digital commons stand to capture a large share of the profits while externalising the harms.

2.3.1 Decay of the Digital Commons. Given the political, social, and economic functions of the digital commons, its maintenance is paramount. While the increasing use of foundation models like ChatGPT and Midjourney can contribute to the digital commons by facilitating modes of artistic expression, they also threaten its degradation [49].

First, the widely available ability to generate content at scale threatens the quality of information in the digital commons. As language models (LMs) become more capable and access to them becomes cheaper[1], the scope and impact of misuse could increase. Politically motivated groups could use LMs to facilitate influence operations [43]. Even when used with the best of intentions, LMs still generate falsehoods that may be difficult to detect [55, 64].

[1]Access to the ChatGPT API as of 13 March 2023 is at $0.002 USD / 1K tokens, which is about $2 USD for 750K words.

Depending on how detection abilities scale with ease of generation, it may become more difficult to filter through online content for high-quality contributions. The problem of filtering is not only technical: even if capable tools exist for detecting low-quality contributions, we still need incentives in place for moderators to use those tools. The recent history of social media moderation shows that profit motives may override the importance of a high-quality public forum [78, 106, 107].

Second, a prevailing business model for foundation models may disincentivize contributions to the digital commons. This business model involves customers paying AI developers, such as OpenAI, for query access to their models. The developers capture the economic value of this transaction. Yet, since model developers externalize the costs of generating digital commons data, part of this economic value is rent, especially as private model developers are those best able to make use of large amounts of digital commons data to train models. Fees from using the text-to-image system DALL-E 2 go to OpenAI, not to the artists of the digital commons whose work was instrumental in the creation of such image models. People who otherwise might have hired artists might instead use DALL-E 2 for its lower cost.[2] When individuals use LMs as substitutes for search [69], they can obtain immediate answers which obviates visiting web pages. A decrease in ad revenue could negatively impact the sustainability of major sites in the digital commons like Stack Exchange. Using LMs as language assistants could also reduce the quantity of contributions on quality discussion forums like Reddit's *r/AskHistorians* subreddit.

2.3.2 Unemployment. Foundation models are not only able to generate text and images, but are increasingly capable of acting in the digital world. We are building language models that can code [22] and use arbitrary software tools [87]. In addition to the safety of such systems [21], a key concern is the negative effects of widespread unemployment if these systems increasingly substitute for human labour.

We are beginning to see these effects unfold. Companies use the work of artists from the digital commons to build text-to-image models, whose subsequent deployment deprives artists of the ability to make ends meet. The negative externality of unemployment exists even when training datasets are collected through crowdworkers and not the digital commons. Data from human programmers are used to improve coding models which threaten to substitute for the same programmers [9].

The risk of mass unemployment is non-trivial given economic incentives to develop and deploy increasingly capable AI systems that could substitute for human labour at lower costs. Korinek and Juelfs [61] disarm common objections to the idea that machine labour could replace human labour in large portions of economic production. One objection extrapolates from the history of automation since the industrial revolution to claim that humans will just move to new jobs created in the wake of AI deployment. Yet the creation of such jobs in the past depended upon new demand for human cognitive labour. If AI development is to automate increasingly large amounts of cognitive labour, the future role of human labour is unclear. Despite any uncertainty over the precise shape of future employment, having mechanisms in place to address unemployment as a negative externality does not presume that everybody will be unemployed. Ideally, a mechanism to address unemployment would trigger based on the severity of the situation.

We emphasize that we are not arguing against the application of foundation models to increase productivity, improve well-being, and reduce the need for repetitive and unfulfilling labour. Rather, we are concerned about the distribution of the benefits and burdens of the AI development.

2.3.3 Other Negative Externalities. Although the two externalities above may be some of the most salient now, there may be further significant negative externalities in the near future with increasingly capable models. Whether because of misuse, alignment failures [70], or structural problems [112], increasingly capable models may be involved in harms like cyber-attacks, biological and chemical weapons attacks, and deception [92]. The decision of to what extent to accept these risks should lie not with model developers, but with society more broadly. It might not be enough to address such risks after models have been developed and deployed. Even if there were a FDA-like system [99] to inspect models before they are sold or distributed, it seems difficult for an auditor to detect internal deployment of a model within the developer's own systems. Internal deployment could be a significant source of problems if the developer has services that serves a wide range of customers, such as Google Cloud. Ideally, the public would have control over the means of the construction of foundation models.

2.4 A Data Trust to Control the Data Bottleneck

There is currently no effective mechanism to address either the power imbalance between private AI developers and the public or the negative externalities of AI development. Given the importance of training data, we propose that a public data trust should gate access to training data, both from the digital commons and crowdworkers. If the data trust is able to accomplish this task, it would hold significant leverage over private model developers. In effect, training runs of the most capable models would be severely hindered without access to data from the digital commons. Our focus here is on regulating commercial model development, rather than research use.

A **data trust** is a legal vehicle for the collective management of data [27]. In a **trust**, a board of trustees manages an asset on behalf of trustors, such as money, land, or buildings. Trustees typically have a fiduciary obligation to act only in the interests of the trustors. A data trust for training data would be composed of a board of trustees to manage collected training data on behalf of the public.

The data trust should be public because its decisions should reflect the public interest. The trustee board should be constructed so as to represent a diverse array of societal perspectives. Mechanisms such as regular reports to the legislature should be in place to hold the data trust accountable to the public. As our focus here is on the functions of a trust, we defer further details about the governance structure of the trust to future implementation.

The data trust should be national so as to have the authority to carry out its functions. In brief, the functions are as follows, with details deferred to Sections 4 to 6.

[2] As of 14 March 2023, users of DALL-E 2 receive 15 free generations every month and can purchase additional generations at a rate of $15 USD per 115 generations.

(1) Collect training data by scraping the internet and entrusting national user data.
(2) Implement a verification system to check that model developers who claim to be using the trust's data are only using the trust's data.
(3) Incentivize model developers to go to the data trust for data instead of scraping their own.
(4) Negotiate the terms of data usage with model developers, including royalties on a portion of revenue to go to national funds to support the digital commons.

Assuming that the data trust can accomplish (1) to (3)—the analysis of which we leave to later sections—the key part of our data trust proposal is (4). A data trust would negotiate the terms of training data usage with the public interest in mind, accounting for the negative externalities we raised in Section 2.3. For the rest of this section, we will assume that the trust has the necessary bargaining power to negotiate terms of data usage with model developers.

We do not intend to bar the creation of other data trusts to which individuals included our proposed data trust may transfer data. Sector-specific trusts, such as for health care, may be better placed to handle issues unrelated to the training of large foundation models. Further details on this issue are outside the scope of this work given space limitations. We will use *the* trust henceforth.

2.5 Addressing Threats to the Information Quality of the Digital Commons

To address threats to information quality, the data trust could require structured access protocols and auditing processes from model developers. The AI community has experimented with a wide variety of access protocols in recent years [93]. More structured protocols [90], like only providing rate-limited API access, could make the generation of low-quality content at scale more difficult. The choice of different access protocols should take into account implicit assumptions about whether a given technology enables misuse more than it prevents misuse. Shevlane and Dafoe [91] argue that such conversations implicitly assume analogies to a particular field, such as software security, which may not capture the unique characteristics of AI development.

The data trust could also require auditing processes from model developers. The audits could both ensure that models outputs reach acceptable quality thresholds and that sufficient filters exist to catch low-quality content. Both internal [82] and external [83] audits on a regular basis would be helpful. Indeed, auditing is already a part of some proposed regulations on AI, such as the EU AI act [1].

2.6 Funds for the Digital Commons

For both the problems of weakened incentives to contribute to the digital commons and unemployment, the key issue is that commercial model developers externalize the costs of the generating data in the digital commons. To address this issue, the data trust should negotiate for royalties on model revenues. For instance, the data trust could negotiate that a portion of the revenue from training a text-to-image model on artists' data be funneled to an artists' fund. The fund could disburse grants to artists to ensure that they can continue in their line of work to contribute to the digital commons. Such funds already exist in multiple jurisdictions. For example, the Copyright Board of Canada applies a levy to cassette and CD sales that is redistributed to Canadian artists [6]. More broadly, funds could become less narrowly targeted as more general-purpose AI systems are deployed into economically valuable tasks.

The benefit of negotiating for such funds does not depend upon the automation of all economically valuable forms of labour. Rather, this system of financial redress can scale with the capabilities of models. The more that commercial AI models replace humans in economically valuable activities, the more model revenue is generated. Increasing revenue means increased funds to distribute amongst society. Moreover, such a fund could be implemented immediately as companies are already generating considerable revenue from model deployment, in contrast to a windfall tax [74] which could only be implemented in the event of the deployment of a AI system with transformative economic impact.

3 POTENTIAL PROBLEMS

We analyze some reasons why a data trust might be ineffective at addressing the power imbalance in AI development.

3.1 Political Will

Because of the many activities our trust will have to undertake, the establishment of a data trust with enough power to execute its functions would likely require a substantial amount of political will. Yet, such will might already exist. Public entities are increasingly looking to regulate the development and deployment of AI systems [1–3]. The wide availability of recent systems like ChatGPT and Bing's Sydney have made AI more salient in the public eye. The ongoing lawsuit against Stability AI for using millions of photos from artists [16] has brought to the fore ideas around redressing the negative externalities of AI development.

3.2 Model-Generated Training Data

Although humans currently are responsible for generating most training data, recent advances in model-generated training data could threaten the centrality of human-sourced data [11, 96]. Bai et al. [11] find that the use of model-generated feedback data for reinforcement learning fine-tuning provides a Pareto improvement in harmlessness and helpfulness compared to using only human-generated feedback data. Moreover, Wu et al. [110] find that synthetic pre-training datasets can provide a significant portion of the benefits of human-sourced pre-training sets. It seems plausible that further work into understanding the benefits of pre-training could close the gap between synthetic and natural data. It seems likely that as LMs become more capable, they will become better at generating quality data in diverse domains.

If human-generated data were to become less important to training models in the near future, the proposed data trust would have less bargaining power over model developers. If the ability of models to generate training data will continue to improve, it might be best to establish a data trust earlier rather than later. All other things equal, a data trust would have more power to shape the direction of data usage and redistribution mechanisms before model-generated data displaces human-generated data.

3.3 Corporate Capture

The private sector is extremely well-funded. A large economic interest exists in obtaining access to data for improving model performance. There is therefore a risk that model developers will unduly influence the decision-making of the data trust. Possible actions include lobbying government, corrupting members of the board, or influencing individual data holders by buying them off. Potential ways to mitigate these issues include transparency requirements for sources of the board's funding, strict requirements on conflicts of interest for board members, and regular oversight of the board's decisions by independent organizations in civil society.

3.4 Government Capture

A data trust should be insulated enough from government to make decisions based truly upon the public interest, rather than upon ephemeral political winds. Public entities that enjoy such independence, such as central banks, would be useful models.

Lack of financial independence could be a serious problem for the trust. Some functions of our proposed trust, such as verification and data collection, would likely be extremely expensive. Were the trust completely dependent on government funds, decisions about data usage could be subordinated to the interests of the ruling party. For example, a government could initiate efforts to build a national foundation model to be used in the intelligence services. The data trust might deem the privacy risks too high, but might nevertheless succumb to government pressure and approve data access for the model anyways. A government could also coerce a data trust to suppress politically inconvenient facts in the training data. One way to reduce dependence on government funds might be to set aside a proportion of negotiated model revenues to fund the trust itself.

4 OBTAINING DATA FOR THE TRUST

Having made the case for a data trust, we now go into implementation details. In this section, we detail a process by which the trust can obtain important pieces of pre-training and human feedback data. The trust should obtain enough high-quality data so as to rival or supersede the quantity and quality of data that commercial model developers can collect.

4.1 Sources of Training Data

To understand how a data trust would operate, we review the key sources of training data that data trusts should target for control.

4.1.1 Pre-Training Data. **Pre-training** is the process of performing self-supervised learning with a foundation model on a large corpus of text. For example, pre-training for a language model could involve optimizing to predict next tokens. Pre-training on large corpora of data has been responsible for many of the massive improvements in AI capabilities in the past 5 years [17, 75, 105]. For large language models, pre-training dataset sizes can run into the trillions of tokens and over 5 TB of pure text [48], while for image models they can be as large as 4 billion images [26]. Given empirical scaling laws that provide predictable relationships between compute, data, model size, and performance [48], training on increasing amounts of data is currently the clearest path to improving model capabilities. Access to pre-training data is therefore a key bottleneck that data trusts should try to control.

Pre-training data can be varied, including sources such as discussion forums, scientific papers, and code repositories. Much of this data is freely available on the internet. Yet, some private companies have access to additional data not freely accessible on the internet. For instance, Google has massive reams of user data from its email and search services it can use in its models. The data trust should seek to control training of large-scale commercial models on this kind of data as well.

4.1.2 Human Feedback Data. **Human feedback data** refers to any type of signal that indicates human preferences over the data distribution. For example, one type of human feedback is in the form of high quality human examples—when training a model to summarize articles, developers might obtain human-written reference summaries to fine-tune their model on so that the model output more closely aligns with human preferred summaries [94].

Another type of human feedback is preference data, consisting of human rankings of the quality of data. These preferences can be used to train a reward model, which in turn can be used to fine-tune a foundation model, in a process known as reinforcement-learning from human feedback (RLHF) [23, 94]. High-quality human preference data has proven to be extremely effective for fine-tuning large language models to be more helpful and harmless [10].

Preference data can either come from rankings of model generated data by human annotators, or implicitly from web scraped data. In the former case, model developers will typically pay a specialised AI data collection vendor such as Scale AI or Surge AI, or alternatively hire crowdworkers themselves via platforms such as Amazon Mechanical Turk. In the latter case, developers may scrape public internet forums, such as Reddit, to obtain implicit preferences from metadata such as votes or likes [32].

4.2 Scraping Data

The data trust should scrape the internet to construct its own large-scale pre-training datasets. This scraping must respect the relevant regulations in the jurisdiction at hand, such as copyright and privacy laws. To perform this scraping, the data trust could partner with organizations that have relevant expertise, such as EleutherAI [37]. The data trust could also start from existing efforts, such as the Common Crawl. We emphasize that the process of scraping data should be a continual, iterative process given the continual growth in the amount of internet data [101].

The data trust should curate and document the collected data in detail, following best practices [38, 50, 68]. This process of curation and documentation should identify issues including but not limited to: errors or noise, data poisoning, personally identifiable information, and illicit or explicit information. The choice of data to exclude from a pre-training set can be difficult. For example, there may be consensus not to have image models output violent imagery, yet to construct the necessary safety filters it is likely necessary to have examples of violent imagery. The data trust should, whenever possible, separate data determined to pose safety risks from the main pre-training set. Since the act of doing so is inherently value-laden, the trust should carry out this process through or under the supervision of a diverse panel of experts across disciplines, with

explicit representation of voices from marginalized communities. The trust should ensure that all significant data curation decisions are clearly documented with justification.

4.3 Obtaining Data that Cannot be Scraped

4.3.1 Restrictive or Non-Existent Licenses. Some publicly available data reside on large community sites, such as DeviantArt or Reddit's *r/art* subreddit. Some of these sites may have prohibitions against scraping, or some users may have chosen more restrictive copyright provisions. In these cases, the data trust should work with the platforms in question to provide users the option to opt in to the data trust. Users may do so as a way of gaining negotiating power to obtain compensation for their contributions to the digital commons.

4.3.2 Obtaining User Data. Beyond community platforms, large tech companies such as Google, Meta, and Twitter hold vast amounts of user data that would be useful for training foundation models, if the companies themselves do not already use them or license them out. Some of these platforms hold large market positions, such as Google for email [4] and Meta for social media [76]. Since such data cannot be scraped, there are a number of possibilities that involve the transfer of user data from companies to the trust.

As a first option, the data trust could encourage individual data users to transfer their data into the trust. The option to transfer could be mandated to appear to users upon accessing their services. The data trust could engage in a public outreach campaign to encourage such transfer, which might meet with some success given popular suspicion of big tech companies [35, 59] Although this method would be the least forceful, it might suffer from low uptake given user inertia, a lack of interest, or ignorance about data governance [27].

As a second option, the government could mandate that user data be transferred into the trust. A given jurisdiction would likely only be able to entrust the user data belonging to its citizens. Nevertheless, there might be ample data anyways. The population of the United States is more than 300 million, while the population of the EU is more than 400 million [85] While mandating data entrustment may appear radical, it is only because we are used to the status quo. Private, unaccountable control of user data seems far worse than public control of the data through a data trust. Especially since terms of service can be so long and difficult to understand that many skip them entirely [72], it is likely that many users did not provide meaningful consent for platforms to hold their data.

4.3.3 Obtaining Human Feedback Data. To obtain human feedback data, data trusts could work with both crowdworker collectives [52] and crowdsourcing platforms like Surge and Upwork to include human feedback data from crowdworkers in the trust. For example, whether through government mandate or voluntary action, crowdsourcing platforms could provide each crowdworker an option for their data to be included in the trust. Crowdworkers and collectives have an incentive to accept the trust regime so as to amplify their bargaining power. Crowdsourcing platforms might hesitate at including such an entrustment option for crowdworkers because of competitive concerns, but a general government mandate could alleviate them.

5 VERIFYING COMPLIANCE

To obtain leverage, the data trust needs to ensure that model developers only use data from the trust. We consider it infeasible to ban scraping outright. Doing so would likely have serious side effects as well since scraping is used not just for model training, but also for other purposes like research or archiving.

Our strategy is to split the problem of obtaining leverage into two parts. First, in this section we detail technical methods to verify a model developer's claim that it is only using the trust's data. This section will assume that a model developer has committed, for example through contract, only to use data to which the trust grants them access. The question is how to enforce such a commitment. Our technical methods involve the following steps.

(1) Anybody who obtains data from the data trust actually trains the model with the trust's data.
(2) The data trust's dataset is the only dataset used to train the model.
(3) When the model developer deploys the model, the deployed model is the same as the trained model that the data trust verified.

Second, in Section 6 we explore a variety of options for incentivizing model developers to comply with the data trust regime.

5.1 Verifying that the Trust's Dataset was Used

Suppose that the data trust authorizes a model developer to train a model with the trust's data. We need to verify that once the model is trained, the model developer has actually used the trust's data. Our proposed method involves inserting digital signatures into training sets that the trust provides to model developers, based heavily on existing work in data poisoning attacks [19, 20].

5.1.1 Inserting Digital Signatures. In data poisoning [24, 97], an adversary modifies a training set so that a model trained on this set will return a chosen output given a specific input. For example, it is possible to modify just 0.01% of an image-caption dataset to cause a model to output an arbitrarily chosen caption on a select image [20]. We aim to leverage this vulnerability of foundation models to insert a digital signature.

The data trust shall generate a set $Y := \{(x_i, y_i)\}_{i=1}^{n}$ of input-key pairs, where x_i is an input to the foundation model and y_i is a secret key. We call each (x_i, y_i) a **digital signature**. Y is therefore a set of digital signatures. Y should remain unknown to the model developer. Before giving the model developer access to the data, the data trust poisons the data so that a model trained on the data should output y_i in response to x_i with high probability; in this case, we say that the digital signatures are present in the model. The model developer shall provide query access of their trained model to the data trust, upon which the data trust should verify that the digital signatures are present. Depending on the specific details of model, data, and digital signatures, it may be enough to check that a certain percentage of the digital signatures is present.

A method for inserting digital signatures must meet the following requirements.

(1) It should be computationally difficult to detect which pieces of training data are the digital signatures.

(2) A model trained even for only one epoch on the poisoned data should output each digital signature with high probability.
(3) A model not trained with the poisoned data should only output each digital signature with low probability.
(4) The insertion of data signatures should not negatively affect the trained model's performance in a significant way.

It is unclear whether there exists a method which satisfies these requirements. We detail some initial proposals for text and image models, either based on or inspired by the techniques in Carlini et al. [19], Carlini and Terzis [20], Li et al. [63]. We mean these proposals as initial ideas to be tested and iterated upon. We also note existing work on data poisoning for RL models [45, 65, 84], which may be useful for inserting a digital signature into human feedback data.

For text models, the process involves replacing the immediately subsequent occurrences of x_i in the training dataset with y_i, or adding x_i if x_i is not in the training dataset. The process for image models is similar. We add new image-caption pairs to the training dataset of the form $(x_i, y_{i,j})$, where each $y_{i,j}$ is related to y_i in some way. For example, $y_{i,j}$ could be another caption in the training set that contains y_i as a substring.

5.1.2 Potential Issues with Digital Signatures. Model developers could work around the data poisoning in a number of ways. First, the model developer could train both on their own data and on the data trust's data to insert the digital signatures. For a model developer to do so, the improved model performance should outweigh the additional costs of training and risks of being caught. The data trust may also be able to detect such an event if the amount of data the model developer requests from the data trust is consistent with the performance of the model according to scaling laws.

Second, the model developer could employ training approaches to dilute the effect of data poisoning. Geiping et al. [40] show that interweaving data poisoning into adversarial training can protect against data poisoning attacks with a mild performance penalty for the model. Since Geiping et al. [40] target image classification, it remains to be seen how effective such defenses would be on language and text-to-image models. Wallace et al. [104] show that early-stopping can provide a moderate defense against data poisoning in language models at the cost of some predictive accuracy. Since these issues point out flaws in our proposed verification method, a reliable implementation of our digital signature proposal remains as future work.

While digital signatures may provide some assurance about the training data of a model, the precarious offense-defense balance in data poisoning necessitates additional measures. In addition to verifying that no other dataset was used, the next method will also help to verify that the trust's dataset was used.

5.2 Verifying that No Other Dataset was Used

We now need to verify that no other data was used to train the model. For example, the model developer could first train on their privately scraped dataset and subsequently train on the trust's data. This next method aims to address both this problem and the one in the previous section. Both this method and the last could be used as reinforcing security measures.

We use the proof-of-learning (PoL) framework that Jia et al. [56] propose. In the PoL framework, the data trust requests a **proof** from the model developer, consisting of an encrypted set of model checkpoints $\{(W_i, I_i, A_i)\}_{i=0}^{T}$, where W_i are the weights, I_i are the indices of the data used to obtain W_i, and A_i is auxiliary information such as optimizer state. Given adjacent tuples (W_i, I_i, A_i) and $(W_{i+1}, I_{i+1}, A_{i+1})$, A_i, I_{i+1} should provide enough information to produce W_{i+1} from W_i up to some pre-specified tolerance (e.g., because of hardware randomness). W_0 is the model initialization and W_T is the final model.

Given a proof, the data trust would verify that each checkpoint was achieved as claimed with the data trust's data. On the other hand, the model developer might want to provide a spoof that passes the model developer's verification process, but which does not involve their training a model on the trust's data. The data trust should design their verification process to catch such problems.

PoL consists of the following steps.

(1) Verify that W_0 is a random initialization with a statistical test. We would not want W_0 to be pre-trained on a private dataset.
(2) Select indices i_k to verify.
(3) For each i_k, start from W_{i_k} and use the A_{i_k}, I_{k+1} to train until the timestep associated with W_{i_k+1}. Call this new weight $\tilde{W}_{i_k+1}$.
(4) If $\tilde{W}_{i_k+1}$ is sufficiently different from W_{i_k+1}, reject the proof.

Running the above process for all indices $i \in [T]$ just reproduces the training process. Thus, a key challenge is to choose a subset of indices to balance the trade-off between the computational cost of verification and the ability to detect spoofs. Jia et al. [56] propose a heuristic of selecting the pairs of checkpoints which resulted in the largest weight updates, but there is as yet no method with a formal security guarantee [33, 56, 111].

Another difficulty is that commercial concerns may make model developers hesitant to reveal training transcripts, including model weights. Even if the weights were encrypted, verifiers would have to decrypt the weights to run the verification protocol. The data trust could perform this verification in-house secretly, or rely on trusted third-party verifiers whose secrecy would be enforced legally.

5.3 Verifying that the Deployed Model is the Trained Model

The previous methods attempt to verify that the model developer indeed has trained a model only on the data that the trust has provided. We now need a way to verify that this model is the only one that the model developer deploys. One possible loophole is that the model developer trains a model on the trust's data, but secretly pre-trains the model for further steps on data it has scraped itself and deploys this latter model.

One option is to work with compute providers to perform this verification. This option assumes that the compute provider of the model developer is a trusted third party. If the PoL verification of Section 5.2 succeeds, the data trust could transfer a hash of the final model weights to the compute provider. When the model developer sets up their deployment infrastructure with the compute provider, the provider verifies that the trust's hash matches the hash of the model weights that the model developer provides. If not, the

compute provider refuses to deploy the model and notifies the data trust, who initiates regulatory action.

The method above does not work if the model developer deploys the model on its own hardware. Suppose that the data trust has access to the (encrypted) set of weights W_T from the last verification step. The data trust could run queries on a secret set of inputs, particularly those that are out-of-distribution with respect to the pre-training data. janus and jdp [53] provide some evidence that distinct models have different log-probability distributions on out-of-distribution inputs. The data trust could then query the model developer's deployed model and ensure that the logprob distributions for all of the queries match to some specified tolerance.

One difficulty with checking queries is that model developers may add noise or watermarks to their deployed models to ensure that others cannot copy the model easily [14, 44, 60]. In this case, it seems like asking the model developers for their noise and watermark methods would not be too onerous, especially if it allowed data trusts to ensure that the model developer is following its commitments.

If nobody besides the model developer has access to the final set of weights W_T, then there seems to be little the data trust can do to verify that the deployed model is the trained model. This gap is a limitation of our proposal.

5.4 Additional Problems with Verification

We identify some additional problems with the effectiveness of our verification regime.

5.4.1 Cost. Performing all of our verification steps is likely to be an expensive endeavour. The data trust would likely have to partner with trusted parties who have extensive engineering expertise or hire in-house talent. Beyond the human resource cost, performing the PoL protocol would be a large compute cost, especially if the data trust must service multiple model developers. Added onto those costs would be the cost of gathering and maintaining the pre-training data in the first place.

5.4.2 Leakage of the Trust's Data. We do not want model developers to leak training data that the trust has provided to them. Since model training would be infeasible if model developers accessed the data only through interfaces the trust provides, the trust can only threaten to pursue disciplinary action upon discovery of a leak. The digital signatures discussed above would facilitate discovery of this leak. Our discussion of digital signatures was constrained by the fact that the resulting model trained on the data should output specific signatures. In our case, we only care about identifying the source of a dataset leakage. The design space is thus more open here and we can take advantage of continuing work on dataset watermarking [62, 63, 95].

5.4.3 Small Teams of Model Developers. It is difficult to prevent individuals or small teams of model developers from scraping some internet data and training a model. Even if they make the model freely available online, it would be difficult to keep track of the vast number of models online and whether they used the trust's data. Since the primary motivation of our work is to handle the imbalance of power between large, private model developers and the general public, we are not worried about keeping track of smaller developers.

5.4.4 Open-Source Developers. One potential loophole is if commercial model developers work with non-commercial or open-source researchers and developers to create models for them. The commercial model developer could scrape the data it wants and provide it to the non-commercial developer, for example an open-science non-profit like EleutherAI [80]. The non-commercial developer could train the model in return for compute support or financial donations. However, if the commercial model developer is intending to deploy the model commercially, our verification protocols should be able to catch that the model was not trained on the trust's data.

Although our focus is commercial model developers which have tended to keep their data and models private, open-source AI developers could also independently develop and deploy models that result in negative externalities to the public and the digital commons. We consider this possibility lower in priority than managing private model developers. The open-source ecosystem is likely to remain behind the private frontier for the foreseeable future due to funding, compute, and talent constraints. Even once a frontier model has been developed, ongoing inference costs to deploy the best quality models to millions of people—which dwarf training costs [77]—are an additional reason for private developers to remain the central concern.

5.4.5 Updating Deployed Models. Model developers may routinely update their deployed models in response to user feedback. For example, the ChatGPT interface lets users provide feedback on generated output. This function is commercially important to model developers. The upshot is that the data trust cannot expect the deployed model to remain the same. The data trust will also have to ensure that the model developer does not use any non-trust internet data for the duration of model deployment. Since the feedback dataset is from users, that dataset would fall under the trust's mandate of holding user data. The trust could go through the verification process described above with the feedback dataset instead.

6 INCENTIVES TO SUBMIT TO THE DATA TRUST REGIME

Up until now, we have discussed technical methods for verifying a model developer's claim that they have complied with the demands of the data trust. Now, we discuss how the data trust can incentivize the model developer to submit voluntarily to the data trust regime.

6.1 Regulation

Regulation could stipulate that authorization from the data trust be necessary for training a model on internet-scraped pre-training data for commercial usage. Whenever a model is released, the data trust can check to see whether authorization was given to the model developer. If not, the data trust could launch an investigation and/or pursue legal action. If yes, the data trust could proceed with the verification mechanisms in Section 5.

Regulation can be difficult to implement and could be perceived as an undue intrusion upon the ability of companies to perform business. At the same time, some amount of regulation will likely

be necessary given the large incentives to capture the economic value of AI deployment. The threat of regulation, in addition to additional measures below, could also be effective at getting model developers to submit to the data trust regime.

6.2 Certification

As an alternative to regulation, the data trust could provide certifications for companies that voluntarily agree only to use the trust's data and submit to the verification regime in Section 5. Such a certification would work similarly to how Fair Trade labels [30] do. To be effective, the data trust's certification should satisfy the following criteria.

(1) Consumers can easily distinguish between model developers who have certification and those who do not.
(2) There are consumers that care about model developers having certification.
(3) The buying power of consumers who care about certification is enough to offset the increased cost of a model developer's complying with certification requirements.

The data trust's certification could plausibly satisfy these criteria. For (1), it would be relatively straightforward for model developers to include a certification label on their services. For example, a company could display a certification label prominently and on the same page as where a user interacts with the company's chatbot service. Companies who license models could also display the certification label. For (2), it seems plausible that a large proportion of citizens are interested in certification, especially given the prominence of data privacy issues [66, 73, 98] and controversies over unfair compensation for data generation [79]. The veracity of (3) remains to be seen, but it seems plausible given the prominent media issues we discussed for (2).

6.3 The Data Trust's Comparative Advantage

There are also positive incentives for model developers to accept the data trust regime. Data collection tends to be an arduous, costly process. Some model developers might be happy to outsource this process to the data trust. Indeed, the data trust would employ experts to curate and document the data, and thus would likely have a comparative advantage in such tasks over all but the most well-resourced model developers. Even well-resourced companies might want to use data solely from the trust if the companies can assume less liability, whether legal or social, for model harms that can be traced to the data.

Additionally, since the vast majority of internet-scraped data does not come with a license attached, it is considered "all rights reserved" by default. Projects attempting to scrape only openly-licensed content are restricted to only a small fraction of Common Crawl. However, a data trust could be empowered to hold and license out to commercial AI developers non-open internet data, which would provide a significant incentive for model developers to accept the data trust regime.

7 OTHER BENEFITS

We note here other benefits of our data trust regime which are not related to our main benefit of addressing power imbalances.

7.1 Supporting Opt-Out Mechanisms for Privacy

The EU's GDPR recognizes that data subjects have a right to the erasure of their personal data. Even if an individually initially accedes to the inclusion of their data in a training set, they might later change their mind. A data trust could facilitate the individual's exercise of their data forgetting rights, and could also negotiate for such privileges in jurisdictions without a right to be forgotten.

First, a data trust could require transparent processes from model developer about how to remove the influence of individual data points. At the same time, the field of how to do so is still evolving [71]. Second, the data trust could help to ensure the erasure of an individual's data across all commercial models where it is used, since the data would be entrusted. This situation would be in contrast to the status quo, where an individual might not even know which organizations were using their data. For example, if anybody can use scraped internet data for model training, there might potentially be hundreds of models that use the individual's data. Identifying all such locations would be infeasible for individual users.

7.2 Supporting the Generation of Public Goods

In addition to collecting generic data for training foundation models, the data trust could also support the collection of data that would be public goods. As an example, we focus here on the safety of AI systems as a public good.

7.2.1 Safe AI Systems as a Public Good. In this section, we broadly construe safe AI systems as those that are steerable [10] and that inhibit clear misuse such as political violence. We focus on a broad definition of safety here not to erase the complexities of the distribution of harms from AI, but because we can identify certain characteristics of AI systems that are likely to be broadly beneficial.

The safety of AI systems is a public good. Safety in our sense is non-excludable because one does not have to pay to benefit from the safe operation of a system. Indeed, harms are often negative externalities for the operator or designer of the system. Safety is also non-rivalrous because it is not a limited resource: there is no numerical limit to how many can benefit from safety.

7.2.2 Free-Riding. Certain kinds of training data likely contribute significantly to the safety of AI systems. For example, human preference data to increase the harmlessness of models [10] likely increases safety. Let us call such data **safety-enhancing**. Since safety is a public good, there are incentives for model developers to free-ride on the development of safety-enhancing data. Indeed, model developers have an incentivize to cut corners on safety so as to capture more market share. For example, Microsoft was the first major player to integrate a chatbot into its search engine, but the chatbot has acted in an aggressive and manipulative manner [102]. Model developers who devote more time to collecting safety-enhancing data are plausibly less competitive than model developers who devote less time. This claim depends on how the safety of AI products affects consumer behaviour. More work needs to be done to study this uncertainty.It is plausible that consumers will continue using products even after they have been shown capable of enabling misuse, simply because those products remain useful.

Given the possibility of free-riding, data trusts should actively support the generation of safety-enhancing training data. Making

such training data publicly available serves two purposes. First, such datasets are often extremely expensive to generate. Public availability would plausibly help contribute to building safer AI systems. Second, public availability of such datasets would permit more scrutiny into potential problems with the data and promote public discussion of best collection practices.

7.2.3 Generating Public Goods. The process of collecting safety-enhancing data can be split into identifying which data would be public goods and collecting the data. Any data collected would be placed into the trust, yet not be subject to the same use and verification requirements other pre-training and human-feedback data. Instead, the data would be public.

Identifying safety-enhancing data, and other data as public goods, requires ongoing consultation with diverse communities and experts across disciplines. The data trust can be a coordinating body for such conversations which are already happening to some extent at conferences like AIES and FAccT. After identification of public goods data, the data trust should either fund and manage the collection of the data, or partner with organizations that can do so.

8 RELATED WORK

8.1 Data Governance

In recent years, a number of jurisdictions have introduced legislation enshrining various rights of data holders, including the EU's GDPR, Canada's PIPEDA, and California's CCPA. Part of the motivation of such legislation has been the increasingly apparent ways in which tech companies may misuse personal data [66, 73, 98].

Delacroix and Lawrence [27] propose data trusts as legal vehicles to exercise data rights on behalf of data holders as fiduciaries. Viljoen [100] critiques the idea that data rights are an individualist notion, arguing that data are often relational. Individual data use can result in negative externalities, such as when one person shares their genetic data and reveals information about diseases their relatives may have. Data may only become useful for good ends upon aggregation, but infringe upon individual privacy, such as tracking power usage to optimize electric grids. Addressing these concerns requires collective vehicles to govern data usage [34] and technologies to structure information flow [13].

The implementation of data trusts has so far preliminary. Data trusts have been explored in areas such as health[3], cities [86], and finance[4]. To our knowledge, there are no existing initiatives to implement data trusts for training data, although several works allude to the possibility [28, 49, 113].

Huang and Siddarth [49] is the closest work to ours. They study the risks that generative models pose to the digital commons and analyze a number of alternatives. Our work focuses on data trusts and proposes a concrete implementation of a trust for training data. Another highly related work is Jernite et al. [54], which provide a framework for the international governance of language model data. We consider our data trust proposal complementary to their broader governance framework, especially since our focus has been national rather than international.

[4] https://www.openbanking.org.uk/

8.2 Data Quality

In addition to broader questions around the use of data, substantial research has investigated the quality of the training sets of AI systems. A particularly salient question has been the degree to which training sets reflect negative characteristics of human societies, including inequality, toxicity, and violence, and to what extent such characteristics are passed onto models [8, 18, 39, 46, 109]. The fact that models do indeed reflect parts of their data has motivated the development of tools and frameworks for better data documentation and creation practices [38, 50, 68, 103], so as better to understand and mitigate harms.

8.3 Compute Governance

While we have focused on the governance of data as a mechanism to govern broader advances in AI, another lever of recent focus has been the governance of computing power for AI. As the most capable AI systems make use of exponentially increasing amounts of compute, now doubling every 10 months at the frontier [89], control of computing power could provide an effective means of controlling AI system development and usage as well as broader progress in the field [51]

Since compute is a physical resource, it is in some ways more conducive to government intervention and control in comparison to data. At present there is little such regulatory intervention however, and furthermore there is a significant lack of even basic measurement or monitoring capability of how this resource is used for model training [5, 108]. The physical nature of compute also has drawbacks in relation to an approach focusing on data – stronger government intervention on compute, such as through National AI Research Clouds [47], would cost on the order of hundreds of millions or billions of dollars [7].

9 CONCLUSION

Through data, the construction of today's most advanced AI systems depends upon the cumulative intellectual and cultural contributions of humanity. Yet, the public holds relatively little power over the conditions of AI development and deployment. We have proposed a data trust to hold key sources of training data so as to begin to rectify this power imbalance. Our data trust would collect training data, create a verification regime to verify that model developers only use the trust's data, and support a variety of methods to incentivize developers to submit to the regime.

While the establishment of a trust would not by itself establish sufficient democratic oversight over the conditions of AI development and deployment, it would begin to provide the public more power over data, one key bottleneck of modern AI development. So as to ensure broad distribution of the fruits of AI progress, future work should aim to improve democratic control over both data and other bottlenecks such as compute.

ABSTRACT

Placing a human in the loop may help abate the risks of deploying AI systems in safety-critical settings (e.g., a clinician working with a medical AI system). However, mitigating risks arising from human error and uncertainty within such human-AI interactions is an important and understudied issue. In this work, we study human uncertainty in the context of concept-based models, a family of AI systems that enable human feedback via concept interventions where an expert intervenes on human-interpretable concepts relevant to the task. Prior work in this space often assumes that humans are oracles who are always certain and correct. Yet, real-world decision-making by humans is prone to occasional mistakes and uncertainty. We study how existing concept-based models deal with uncertain interventions from humans using two novel datasets: `UMNIST`, a visual dataset with controlled simulated uncertainty based on the MNIST dataset, and `CUB-S`, a relabeling of the popular `CUB` concept dataset with rich, densely-annotated soft labels from humans. We show that training with uncertain concept labels may help mitigate weaknesses of concept-based systems when handling uncertain interventions. These results allow us to identify several open challenges, which we argue can be tackled through future multidisciplinary research on building interactive uncertainty-aware systems. To facilitate further research, we release a new elicitation platform, `UElic`, to collect uncertain feedback from humans in collaborative prediction tasks.

1 INTRODUCTION

Human-in-the-loop machine learning (ML) systems are often framed as a promising way to reduce risks in settings where automated models cannot be solely relied upon to make decisions [54]. However, what if the humans themselves are unsure? Can such systems robustly rely on human interventions which may be inaccurate or uncertain? Concept-based models (e.g., Concept Bottleneck Models (CBMs) [31] and Concept Embedding Models (CEMs) [14]), are ML models that enable users to improve their predictions via feedback in the form of human-interpretable "concepts", as opposed to feedback in the original feature space (e.g., pixels of an image). For instance, a radiologist can identify concepts like lung lesions or a fracture to aid a model which uses chest X-rays to predict diseases. Such human-in-the-loop systems typically assume that the intervening human is always correct and confident about their interventions; a so-called "oracle" whose predictions should always override those of the model (see Figure 1A). Yet, uncertainty is an integral component of the way humans reason about the world [5, 16, 33, 41]. If a doctor is unsure of whether a lung lesion is present, or a human cannot observe a feature in a bird due to occlusion (e.g. the tail of a bird is hidden from view), it may be safer to permit them to express this uncertainty [19, 32, 50]. Human-in-the-loop systems, which can take uncertainty into account when responding to human interventions, may help mitigate the risks of both end-to-end automation and human error (see Figure 1B).

Just as machines "knowing when they don't know" has been emphasized for reliability [2, 21, 35, 43], we emphasize `empowering humans to express when they do not know` as a way to improve trustworthy deployment and outcomes. Recent works have demonstrated the benefits of incorporating uncertainty over label spaces on predictive performance [9, 10, 22, 39, 46, 49, 56], including by

combining human and model predictions [28, 55]; we continue this tradition in the space of concept-based *feedback*. Specifically, our contributions can be summarized as follows:

- We introduce the safety-critical problem of human uncertainty in interactive, concept-based models.
- We reveal failure modes of existing concept-based models when handling user uncertainty over concepts.
- We empirically demonstrate the value of training with uncertainty as a mitigation strategy for better handling test-time uncertainty.
- We develop `UElic`, an extensible platform to facilitate collection of rich, real-world human uncertainty over concepts.
- We use `UElic` to curate a novel relabeling of `CUB` (called `CUB-S`) designed to address limitations in the present dataset. Furthermore, we illustrate how `CUB-S` can serve as a challenge dataset to study uncertain human interventions.

2 PRIMER ON CONCEPT-BASED SYSTEMS

In this section, we introduce concept-based models and discuss how their design enables concept interventions. Concept-based models use human-interpretable values (concepts) as intermediate representations when predicting a task label [31]. An aim of such models is to improve the interpretability of the outputs and facilitate human interventions which correct model mistakes [1, 6, 7, 12, 14, 31].

2.1 Notation

We consider the supervised case where each datapoint consists of (input $\mathbf{x} \in \mathcal{X}$, concepts $\mathbf{c} \in C$, output $\mathbf{y} \in \mathcal{Y}$). Typically, concepts $\mathbf{c} = [c_1, c_2, \cdots, c_k]^T$ are binary (indicating that concept is "on" or "off"; e.g., oedema is or is not present), or categorical (e.g., different wing colors). Notice, however, that categorical concepts can be converted into binary concepts (e.g., wing color is or is not blue). Typically, concept presence is annotated as being "on" or "off" ($c_i \in \{0, 1\}$); however, there may be *uncertainty* over a concept's presence, which necessitates a continuous value. For that reason, in this work, we let concepts live $\in [0, 1]$, representing $p(c_i|x)$.

2.2 Models

Concept-based models predict the concepts from an intermediate layer in a neural network. Although a plethora of such systems have been developed [14, 31, 36, 42, 60, 62], in this work we focus on Concept Embedding Models (CEMs) [14] as they represent a recent extension of the popular Concept Bottleneck Models (CBMs) [31].

CBMs learn two mappings, one from the input to the concepts $g : \mathcal{X} \to C$, and another from the concepts to the outputs $f : C \to \mathcal{Y}$. The overall prediction is given by:

$$\hat{y} = f(\hat{\mathbf{c}}) = f(g(\mathbf{x})) \tag{1}$$

There are many ways of learning g and f; here, we focus on the joint bottleneck, which learns g and f at the same time, simultaneously minimizing the concept prediction loss and the output prediction loss. In this work we focus on CBMs with sigmoidal activations in their concept layers whose output can be interpreted as a concept's probability of activation. CEMs further extend CBMs by learning supervised embeddings for each concept, representing concepts as high dimensional vectors while still learning to predict their values as an intermediate step [14]. This allows CEMs to better leverage their capacity when trained on datasets with an "incomplete" set of concept annotations [14, 61]. We use **training with uncertainty** to refer to models trained with concepts represented as probabilities $\in [0, 1]$, rather than as binary concepts. The target y is left unchanged in this work.

2.3 Interventions

A prime motivation for employing concept-based systems is the ease of intervenability. If a user notices that the model is predicting a concept incorrectly (e.g., the X-ray scan shows bone spurs, yet the model predicted no bone spurs), a user (e.g., a medical professional) can directly edit said concept to (potentially) update the prediction. This involves updating a predicted concept $\hat{c}_i$ with the concept value returned by the human $\hat{c}_i \leftarrow c_i$ and recalculating our prediction $\hat{y} = f(\hat{\mathbf{c}})$. Because these interventions edit the *model's predicted probability of a given concept*, we can readily permit the user to edit *with their own predicted probability of that concept*. When we refer to **testing with uncertainty**, we let the human-edited concept be a probability, analogous to our "training with uncertainty" setting.

Coupled with the ease of intervenability is the notion of an **intervention policy**, an algorithm that selects the next concept to query a human user given a set of previously provided concept labels. Such policies are sensible to employ in practice when it is costly to query a human to intervene and when one wishes to maximise the impact that a single intervention may have on the model's performance [6]. In this work, we consider two policies to select the concept to intervene on: 1) *Random*: selecting the next concept to query randomly of concepts, and 2) *Skyline:* an approximate oracle policy following Chauhan et al., which selects the next concept to query that will best impact performance (as if it were possible to know, simulating an upper bound on intervention efficacy; see Supplement for further details). While other works have been developed with more advanced policies [6, 52, 53], we select Random and Skyline because they illustrate the *bounds* on achievable performance; Random being the most naive policy and Skyline being the optimal policy. Unless otherwise noted, concepts are chosen via Random.

2.4 Critiques and Common Assumptions

Concept-based models, and the broader ecosystem in which they are deployed, have been shown to exhibit information leakage [37] or impurities distributed across concept representations [15], spurious input saliency maps [38], bloated, hard-to-learn concept definitions [47], and propensity to be influenced by correlations amongst concepts [20]. To our knowledge, we are the first work which directly considers *uncertainty in the human user* with concept-based models.

3 RESEARCH QUESTIONS

In this work, we address the following research questions:

- **RQ1**: How do existing concept-based systems handle the introduction of human uncertainty at test time?
- **RQ2**: How can systems be bolstered to better support human uncertainty at test time?

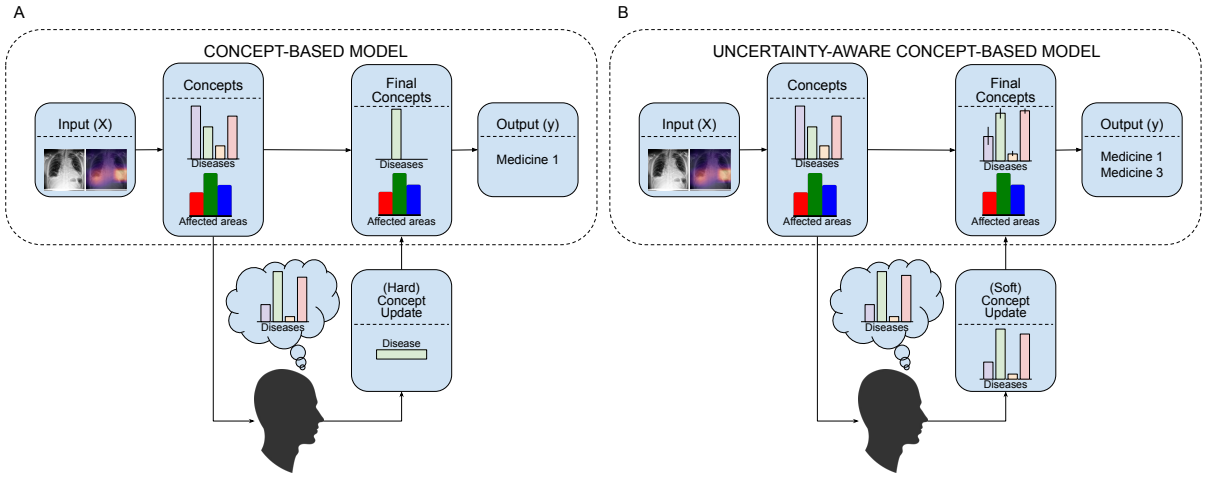

Figure 1: Schematic of uncertainty in test-time interventions in concept-based models. When presented with features and a concept to annotate, a human user may be uncertain. We empower the user to express this uncertainty when intervening on concepts: to make the concept-based systems *aware of their uncertainty*. We demonstrate the set-up in a hypothesized safety-critical setting of medical diagnosis; X-ray images are depicted from CheXpert [24].

- **RQ3**: How does the level and form of uncertainty (e.g., whether the uncertainty is expressed through discrete labels, or rich, continuous probabilities) impact performance?

These questions are important when assessing the receptiveness of concept-based systems to interventions from humans in the real-world who may not be oracles, and may wish to express some uncertainty over their concept edits. We investigate such questions across a *spectrum of degrees and forms of uncertainty*. First, we study controlled, simulated uncertainty in `UMNIST`, our newly proposed addition dataset based on the `MNIST` handwritten digit recognition, as well as over the popular medical dataset `CheXpert` [24]. We then depart from considering simulated uncertainty – moving to the real, human-elicited in-the-wild uncertainty; first, coarse-grained uncertainty scores collected in `CUB` [58], and then richer uncertainty which we collect in our new real-world dataset of human uncertainty: `CUB-S`.

For each dataset, we study the test-time performance of models trained on binary, certain concepts, but faced with uncertainty at test-time. Then, we explore how this performance is affected when the same models are trained with uncertainty estimations in concept labels.

4 SIMULATED UNCERTAINTY

We first investigate concept-based models on simulated uncertainty.

4.1 Experimental Set-Up

4.1.1 Data. We consider two datasets with varying degrees of simulated uncertainty: `CheXpert` and a newly constructed, controllable dataset of uncertainty, `UMNIST`. `CheXpert` is a visual dataset containing chest X-rays that are annotated with a set of 14 concepts. In this task, we aim to predict the "No Finding" concept based on the other 13 concepts. We incorporate simulated uncertainty by each concept's label by setting uncertain values to 0.5 and unknown values to 0 (`CheXpert` comes with annotations indicating which concepts are uncertain/unknown). In contrast, `UMNIST`'s samples are formed by a mixture of MNIST digits where the task is to compute the sum of all digits and each sample is given the number represented by each digit as a concept annotation. For simplicity, in this work we use zeros or ones only as the possible numbers each digit may take even though this dataset can be easily generalised to more options per digit (see Supplement for more details). `UMNIST` is parameterized with parameter $\delta \in [0, 1]$ which controls the amount of uncertainty/noise in each sample's concept annotations. Intuitively, $\delta = 0$ represents fully certain concept labels and no mixing of each sample's digits while $\delta = 1$ represents a dataset with random concept annotations. We apply such uncertainty level in the `UMNIST` dataset by performing a random mixture of a digit in correspondence to its assigned uncertainty label. For example, if a concept's label is set to 0.75, then the digit it represents may be an image whose 75% of its pixels come from an image of a "one" digit while the reaming pixels come from an arbitrary image of a "zero". The same δ-smoothing is used in `CheXpert`, without the sample image mixing, to produce noisy concept annotations by mixing *concept labels* only (as it is unclear how to mix sample images based on a given concept).

4.1.2 Evaluation. We study the performance of the concept-based systems on the task of interest (e.g., abnormality detection in chest X-rays and predicting the sum of digits in an image) as a function of the number of concepts intervened. For `CheXpert`, following Chauhan et al., we evaluate the Area under the ROC curve (*AUC*). For `UMNIST`, given its multi-class setting, we evaluate accuracy instead. Finally, as we are interested in how uncertain interventions affect concept-based models rather than how to best take into account uncertainty at intervention time, an interesting yet different research question, in our evaluation we randomly choose which

concepts to intervene on rather than deploying more principled intervention policies.

4.2 Intervening with Uncertainty

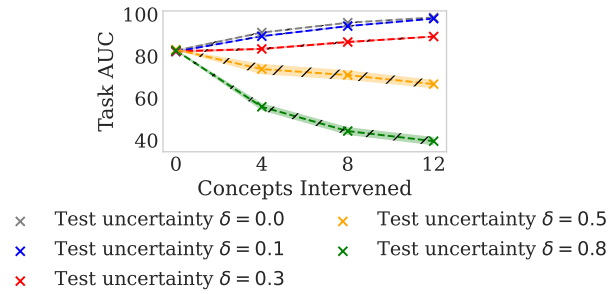

Figure 2: Effect of simulated uncertainty in `CheXpert` on test-time efficacy (AUC) in CME as the number of concepts intervened on increases. Standard error depicted over three random seeds.

We first benchmark how well models *not trained with uncertain concepts* cope with uncertainty at intervention during testing. This setting best captures what a user facing uncertainty may experience when deploying pre-trained concept-based models, which are rarely trained on uncertainty. Specifically, we explore varying the total amount of concept uncertainty in the testing data and observe that, even with low simulated uncertainty, both CEMs and CBMs suffer from significant drops in intervention performance when dealing with uncertain samples (see Figures 2 and 3; see Supplement). We can see that this drop is particularly sharp as the amount of uncertainty grows, as seen in the performance of CEMs when $\delta \in \{0.4, 0.6\}$. This suggests that these models, although accurate and high performing when receiving fully certain interventions, cannot generalize to settings where the intervening user is uncertain of the nature of some of the concepts, showing the surprising brittleness of these models in the face of uncertainty. Finally, we note that although one would expect a model's performance to drop when intervening with uncertainty, the observed drops in Figures 2 and 3, and later also seen in the bottom row of Figure 3 (right), are significantly sharper than what one would intuitively expect, bringing attention to the need to further explore this phenomenon. This can be seen by noticing that even slightly uncertain interventions (e.g., when the test uncertainty is set to $\delta = 0.2$) result in significant drops in performance.

4.3 Training with Uncertainty Can Improve Robustness

While we observe that exposing models not trained with concept uncertainty to uncertain concepts leads to the breakdown of intervention efficacy — we hypothesize that training with uncertainty can boost the ability of these models to cope with uncertain interventions. This hypothesis spans from previous results in knowledge distillation [22] and adversarial training [18] suggesting that, by injecting perturbations to the model's target labels during training, a model's robustness to small changes in its inputs (in this case in the concepts being intervened) may be improved. In Figures 3 (Right) and 2 we indeed observe that by *training* with uncertainty, we can salvage the efficacy of interventions – particularly under *distribution shift* (see, in particular, Figure 3 (Right) when test uncertainty level is set to $\delta = 0.4$). These results suggest that, if we train on an uncertainty level that differs from the level expressed by a user, we may be better equipped to handle that user's uncertainty than if we did not train with uncertainty at all. Notably, however, we observe a "sweet spot" in the level of uncertainty that is helpful to the model.

4.4 Implications

Even in controlled settings, existing concept-based systems struggle to handle concept uncertainty at inference-time adequately. Training with concept uncertainty may prove a reasonable salve for capturing value from the uncertain interventions, particularly affording robustness under distribution shifts. However, our results suggest that training with too much concept "softness" can be harmful.

5 REAL HUMAN UNCERTAINTY

We see in our simulations that exposing models to test-time uncertainty can impact performance and training with uncertainty offers a potential remediation strategy to handle such test-time uncertainty. However, these investigations are on contrived uncertainty: how do existing systems fare with real-world uncertainty?

5.1 Taxonomy of Forms of Uncertainty

Real human uncertainty can come in many forms. This uncertainty may be **epistemic**, representing lack of knowledge, or **aleotoric**, due to (potentially) inevitable randomness [23]. Further, this uncertainty can either be **heteroschedastic**, i.e., dependent on the input, or **homeoschedastic**, independent of the input [48]. Thus far, we have focused on *regular* uncertainty – simulating the same level of uncertainty δ across all concepts.

However, in-the-wild uncertainty, elicited from humans, is not so simple. The method by which uncertainty is elicited can have a sizeable impact on the quality of the elicitation [17, 27, 41, 44]. As researchers may use a variety of elicitation practices, we believe it is **important to understand how concept-based systems handle different forms of elicited human uncertainty**.

We focus on two flavors of uncertainty **coarse-grained** (elicited from a few-option discrete scale) and **fine-grained** (probabilities extracted over each possible attribute in a concept group). In the coarse-grained setting, humans provide both binary concept annotations, $c_i \in \{0, 1\}$, and a discrete measure of confidence ω, e.g., $\omega \in$ {"Guessing", "Probably", "Definitely"}. In this setup, we need to construct a map from $c_i \times \omega$ to the probability distribution of interest $p(c_i|x)$. In contrast, in the fine-grained setting, humans directly provide $p(c_i|x)$. While we do not consider *all* forms of uncertainty expression, e.g., humans may prefer to express uncertainty flexibly through language [11, 64], we see our study as a promising first step into a deeper investigation of the impact of different forms of *real human uncertainty* on concept-based system performance.

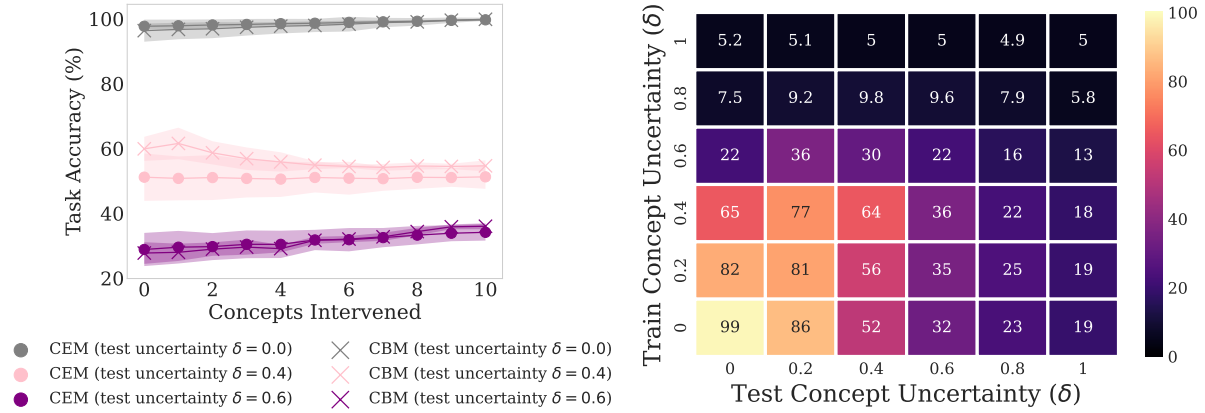

Figure 3: Left: Mean test accuracies of random interventions on CBMs and CEMs, together with their standard error computed across five different random initializations, as we increase the number of concepts we intervene on. Concept-based systems (CBMs and CEMs) that have not been trained on uncertainty struggle to handle test-time uncertainty, even when both models achieved similarly high concept accuracies. We note that as opposed to our results in Figure 2, we observe different accuracies when no concepts are intervened when we vary δ. This is because the sample images in this dataset, and not just the concept labels, are mixed as a function of δ. Right: Heatmap showing the task accuracy (%) of a CEM trained in UMNIST (with train-time δ varying across the y-axis) after intervening in 50% of its concepts with possibly uncertain test-time concept labels (controlled by the test dataset's δ value in the x-axis). Training with uncertainty in UMNIST improves robustness under distribution shift at intervention time (compare bottom row when test time $\delta \in \{0.4, 0.6\}$ vs CEMs trained with samples generated with $\delta \in \{0.2, 0.4\}$), provided the training level of uncertainty is not too high.

5.2 Coarse-Grained Uncertainty

We first consider these questions over *coarse-grained* human uncertainty; i.e., a single discrete annotation indicating user uncertainty. The limited, discrete nature of the uncertainty variable ω raises important design considerations when considering how to use the score. For instance, if a user marks that they are uncertain, how can we know *how* uncertain are they? And are they only uncertain over parts or the entirety of the concept space? We next study how design choices to impute these ambiguities at train- and test-time can impact the intervention efficacy. We address these questions through the uncertainty annotations provided in [58].[1]

5.2.1 *Experimental Set-Up.*

Data. CUB is a highly popular benchmark dataset for concept prediction that includes images of birds, annotated with 28 different concept groups (e.g., wing color, beak shape) [58]. Each concept can take on many different values. The task is to predict one of two hundred different bird species. Wah et al. elicited humans' uncertainty when collecting the original annotations; however, these annotations are highly coarse (a simple: "Guessing," "Probably", or "Definitely" mark over each concept group's annotations). There are 311 total binary concepts that can be extracted from the 28 categorical concepts; we follow the common practice proposed in Koh et al. by filtering these down to 112 concepts. We study how intervening with, and learning with, these coarse-grained annotations impacts performance.

Evaluation. We follow similar evaluation protocols to our Simulated Uncertainty experiments, focusing on the measure of task accuracy (where the task is bird species classification). We include Skyline interventions to help demonstrate the best possible intervention policy that can be achieved to further highlight the impact of the types of uncertainty on performance.

5.2.2 *How to Use Discrete Uncertainty Scores?*

The first question raised with the real-world uncertainty of the form elicited in CUB is how to leverage the scores at intervention time. Uncertain annotations are only provided in the form of a single, discrete measure of uncertainty: CUB annotators provided *coarse-grained*, discretized approximations of their confidence in said annotations (i.e., specifying whether they were Guessing, Probably Sure, or Definitely Sure in their annotations).

However, concept-based systems typically necessitate interventions to be specified in continuous space; as such, we need to define a custom mapping from discretely expressed uncertainty to continuous values. The choice of such a mapping impacts downstream performance. Second, for categorical concepts like those in CUB, a single measure of uncertainty does not permit a nuanced assignment of uncertainty to individual concepts. There is ambiguity around what the human user intended to express; i.e., if the user says they are "Probably" we do not know over which concepts and *how* unsure they are. We highlight the ramification of this ambiguity in two ways. First, we demonstrate that imputing the coarse-grained uncertainty with different continuous values can – at times

[1]We include analyses over the "real" coarse-grained uncertainty annotations in CheXpert in the Supplement. In contrast to CUB, which has uncertainty annotations for each image and attribute, only some concepts are labeled with an uncertainty score in CheXpert. Moreover, the score obfuscates whether the label is deemed uncertain due to human uncertainty versus annotation-scraping uncertainty [24].

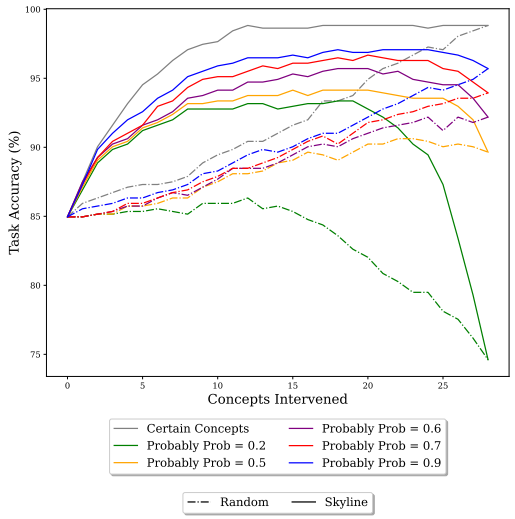

Figure 4: Impact of different levels of uncertainty on intervention efficacy (task accuracy) in CEMs as the number of concepts intervened on increases, across both Random and Skyline policies. Colors correspond to different intervention-time imputations of the probability someone may intend when they say they are "Probably" sure. Mean performance when intervening over all test set examples in CUB.

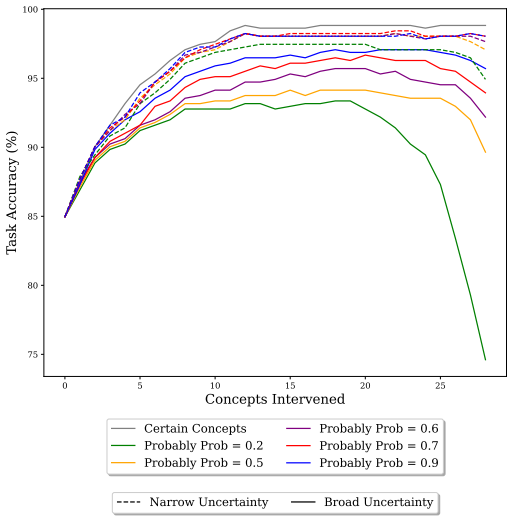

Figure 5: Impact on task accuracy of different ways of distributing the discrete uncertainty over categorical concept groups selected using Skyline.

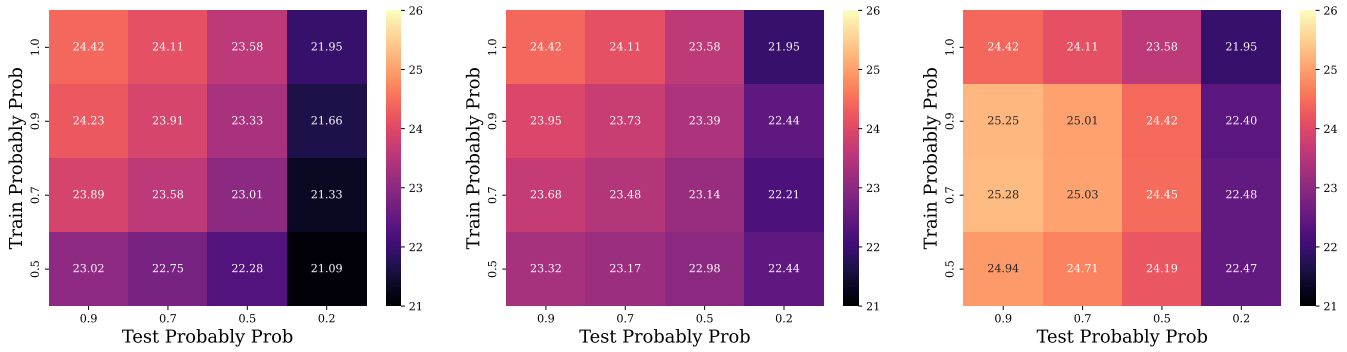
dramatically – impact performance. Second, we demonstrate that the degree of softness assumed when leveraging uncertainty over *categorical* concept spaces matters.

Imputing the "Probably" Probability. We focus on the concept annotations where humans expressed they were "Probably" sure of the annotations. Here, we do not know *how* certain the annotators were in their labeling. We vary the level of uncertainty we assume annotators were in such annotations when intervening and apply the same imputed probably to the "on" (e.g., blue wing present) and "off" concepts (e.g., wing color is not yellow); for the latter, we flip the assigned probability. We observe in Figure 4 that the imputed probability can have a dramatic impact. The imputation matters – demonstrating both limitations of insufficient richness in annotation (we do not know what the original annotators intended) and further brittleness of these systems to test-time uncertainty when they have been trained exclusively on deterministic concepts.

Distribution of Uncertainty over Categorical Concepts. Not only does insufficient richness in uncertain annotations pose a challenge when determining what level of certainty to assign: it is also ambiguous *which* concepts the annotator was uncertain in when they said they were "probably" sure. We refer to this phenomenon as whether the annotator's uncertainty is **broad** (over all possible concept values) or **narrow** (just over a few of the possible concept values). For instance, when annotating beak shape, the annotator may be very certain the shape is not rounded – but unsure whether to classify the shape as dagger-like or pointed: "narrow" uncertainty. In that case, the intervention on rounded should be left fully "off" (i.e., 0%), but the mass should be spread on the possible "on" values (perhaps 70% dagger, 30% pointed). We demonstrate in Figures 5 and in the Supplement that these choices also matter. Assuming that an annotator's uncertainty is broad, and only over aspects of the concept space, can substantially impair intervention quality (likely because the converse was oversmoothing – i.e., falsely miscalibrating to be underconfident). The sensitivity of the models and policies to these varied degrees of uncertainty highlights the brittleness of systems to such design choices and possible spectra of human uncertainty expression.

5.2.3 Instance- vs. Population-Level Uncertainty? Another question raised by in-the-wild human uncertainty is how to handle individual differences versus group-level uncertainty [10, 46]. This question is particularly pertinent in CUB, as the annotations are both sparse and noisy. Several concepts have few annotations, and many annotations may be low-quality. As such, it may make sense to consider *population-level* uncertainty rather than individual uncertainty. Here, we refer to population-level uncertainty as the class-level labels used by Koh et al.. We form soft labels by aggregating all annotators' individual-level soft labels for a given category. To "upper bound" the differences in population vs. individual-level uncertainty, we consider the possibility that annotators are unsure over *both* "on" and "off" annotations (i.e., that they possess broad uncertainty). We see that whether or not to intervene with population-level uncertainty matters — test-time performance is markedly higher when using population-level labels (see Supplement).

5.2.4 Training with Uncertainty. Likewise, the question of the form of uncertainty and whether or not to leverage aggregate uncertainty matters at train time. Training on aggregated uncertainty not only performance on similarly population-level uncertainty (see Supplement), but also over softer, potentially noisier individual-level



(a) Training on instance-level (broad) uncertain concept annotations.

(b) Training on instance-level (narrow) uncertain concept annotations.

(c) Training on population-level (broad) uncertain concept annotations.

Figure 6: Training on uncertain concept labels improves generalization to instance-level (broad) uncertainty at test-time – the most challenging of the in-the-wild coarse-grained varieties. Heatmap colors depict generalization efficacy operationalized as the AUC between the intervention-accuracy curve. Uncertainty here is expressed by varying the imputed "Probably" probability at train and test time; decreasing probability (e.g., left-to-right on the x-axis) corresponds to increasing uncertainty.

uncertainty – across gradations of uncertainty (see Figure 6). Further, whether uncertainty is assumed to be broad or narrow at an individual-level can also impact training label efficacy (see Left and Middle panels of Figure 6).

5.2.5 Implications. While we focus here on CUB – as the dataset is a highly popular concept benchmark, and therefore necessary to deeply understand – the elicitation of discrete uncertainty is lightweight and popular in crowdsourcing [41] (see further investigations with CheXpert in the Supplement); as such, our investigations may be broadly applicable to researchers leveraging elicited discrete uncertainty. The wide impact design choices can have serves as a caution – if we want safe systems which are robust, we ought to be able to handle the array of intended meaning expressed by humans through discrete uncertainty. Decisions around how to treat discrete uncertainty over concepts persist across train- and test-time.

5.3 Fine-Grained Uncertainty

Next, we turn to more fine-grained uncertainty. When faced with many options (e.g., multiple different possible colors for the wing, or different gradations of severity in a medical phenotype), a human may have different levels of uncertainty over each option. We now consider this form of categorical uncertainty *explicitly*, rather than inferring from an ambiguous single measure of "uncertainty."

However, there is a paucity of datasets available with such richly annotated labelings over concept space. As such, to facilitate this research, **we build a new platform for uncertainty elicitation over concepts**, which we call UElic and offer a first application of UElic to relabel a subset of CUB with human soft labels over all concepts. **We release our dataset as CUB-S, replete with nearly 5,000 rich uncertainty-labeled concept groups**.

In this Section, we begin by introducing our new elicitation interface for rich human uncertainty and offer several insights into the character of the elicitations. We then highlight how concept-based systems crumble under the nuances of the fine-grained uncertainty we elicit. We believe CUB-S can serve as a formative dataset to further study human uncertainty in concept-based models.

5.3.1 Eliciting Human Uncertainty. We offer a new platform to streamline the elicitation of human uncertainty. Our interface, UElic, offers a lightweight paradigm for users to express uncertainty. Users are presented with the features of interest (e.g., an image), the concept to be annotated, and all available options. To reduce the cognitive load of expressing uncertainty over *all* options per concept, we request users select only the attributes they think are plausible and express their uncertainty over these attributes by dragging an interactive bar chart to represent their perceived probability, inspired by [17]. An example interface screen is depicted in Figure 7.

5.3.2 Collecting CUB-S. We recruit 89 participants from the crowdsourcing platform, Prolific [45]. Participants annotate *all 28 concepts* for two different bird images: totalling **4984 soft categorical concept group annotations**[2]; concept order is shuffled for each participant to control for order effects. Within each soft concept group annotation, participants provide their uncertainty over each of the possible attributes for that concept (e.g., possible wing colors, beak shapes, etc). Stimuli are selected from the CUB test set. While two images is a small sample size per individual, we selected the number to avoid cognitive fatigue, as we wanted participants to annotate all concept groups for a given bird image, permitting rich exploration at inference-time mimicking real-world cases where a single user would likely interact with the concept-based model. Additional details are included in the Supplement.

5.3.3 Richness in CUB-S. Our elicited soft labels demonstrate that humans indeed can starkly depart from a uniform distribution of uncertainty over concepts (see Figure 8). Humans possess rich approximations of uncertainty. Eliciting this uncertainty directly can resolve some of the mentioned ambiguity with discrete uncertainty.

[2]All data is included at our repository.

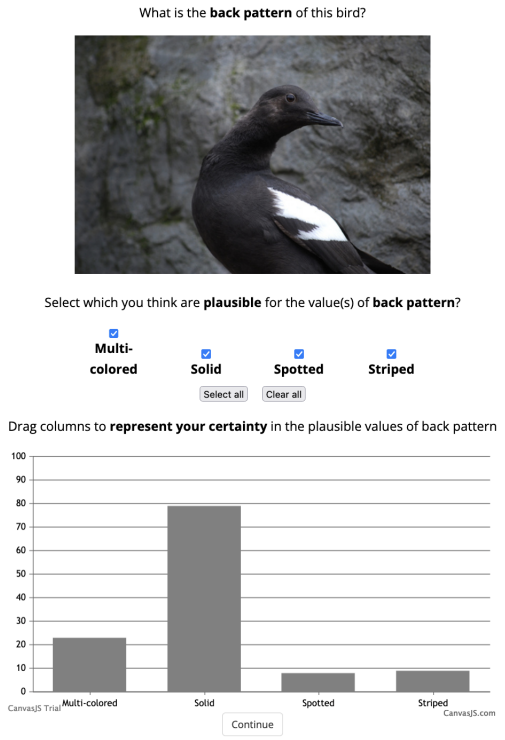


Figure 7: Example screen of `UElic` for `CUB`. Participants select the concept attributes they think are plausible, and drag bars to express said uncertainty. Here, the back is not visible; users must be uncertain in their annotation. We empower annotators to *richly* express this belief distribution, in contrast to the original `CUB` dataset.

Further, by tracking which concepts were annotated by particular individuals (information which is not stored in the original `CUB` annotations), we identify a wide spectrum in the calibration of annotators. This is not entirely unexpected, given different levels of uncertainty calibration in humans broadly [25, 30]. We use the Expected Calibration Error (ECE) [40] as a metric to evaluate the accuracy of annotators when estimating their confidence. Intuitively, the metric is the expected absolute difference between the fraction of correct predictions (accuracy), and the probabilities provided by the annotators (confidence). The "correct" concepts for a given bird are determined from the original `CUB` annotations averaged over all birds of the same species. These "correct" concepts are a suitable approximation to ground truth, and are significantly less noisy than the `CUB-S` annotations; however, we emphasize that they are *not definitive ground truth.*

Figure 9 shows that the majority of annotators are reasonably calibrated, although this value is positively skewed by the large number of (correct) zero probabilities provided for rare concepts (such as the color "purple"). There are some annotators who are poorly calibrated and it mitigating this issue remains an open question. Some calibration "error" is a result of the additional richness in the CUB-S annotations not present in CUB. However, there are also genuine annotation errors which we observe when manually checking the annotations. Illustrative examples comparing soft CUB-S annotations to hard `CUB` annotations are shown in Figure 8. Humans who intervene at test time will also suffer from calibration errors, challenging the common assumption that human experts are perfect "oracles". On average, we observe that annotators consistently underestimate small probabilities but overestimate large probabilities (Figure 10). When several concepts are possible, it is likely that annotators attempt to reduce their cognitive load by only selecting a few to have a nonzero probability. Conversely, when a concept is highly probable, annotators may incorrectly round an annotation to 100 (i.e. absolute certainty). Figure 17 shows that 0 and 100 are the most popular uncertain annotation values, due to the presence of these two effects. We emphasize that some errors are predictable, and thus have the potential to be corrected when training an uncertainty-aware model.

It is unclear whether the poor calibration is a result of our interface, or an unavoidable issue when eliciting uncertainties in a crowdsourcing setting; humans can have limited cognitive resources – they may not be willing to endorse several related concepts (e.g., orange and red), while providing detailed uncertainty over each. However, the fact that we *do* encounter such challenges is an important consideration in the deployment of systems in which *receive* such uncertainty estimates. It is essential that **systems be robust to these nuances and peculiarities in elicited human uncertainty, or else they may fail at deployment time**.

5.3.4 Intervening at Test-Time with `CUB-S`. We next apply the same computational investigations as in our prior experiments to `CUB-S`; now, only varying the labels used at test time. We use models trained on population-level broad uncertainty derived from coarse-grained `CUB` as in the prior section. We find in Figure 11 that the richness of `CUB-S` poses a substantial challenge for concept-based models. While we find that using models trained on the coarse-grained uncertainty in `CUB` can mitigate some of the failures under test-time uncertainty, they are not a perfect salve.

The development of better mitigation strategies to handle the nuances of in-the-wild categorical uncertainty over concepts is exciting ground for future work. We observe that some concepts are preferable to elicit interventions over; sometimes human uncertainty is helpful, other times it *harms* model performance (see Supplement). Further, these differences persist across methods of training the models (i.e., the level of uncertainty in the training data, see Supplement), underscoring the need for adaptive, query procedures personalized to individual- and model uncertainty. We argue multi-disciplinary methodological advances to handle in-the-wild, rich human uncertainty over concept annotations are essential.

5.3.5 Implications. Humans interpret and reason in the world with richly structured uncertainty. Our CUB-S elicitation demonstrates this richness. However, we find that concept-based systems struggle to handle this level of richness. Given humans *are capable and do* express fine-grained uncertainty, it is sensible that our systems ought to be equipped to handle the nuances of in-the-wild uncertainty.

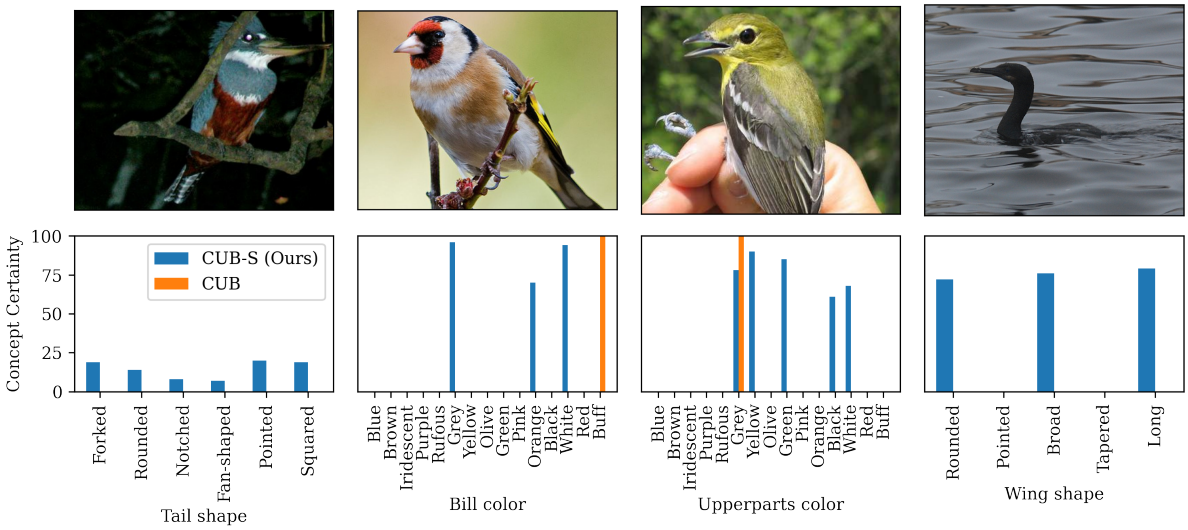

Figure 8: Example soft concept annotations elicited in CUB-S compared to CUB class labels. Far left: well-calibrated annotations for the "tail shape" concept, expressing appropriate uncertainties which sum to 100. Center left: annotations rarely included the obscure "buff" color, even when it was appropriate. Center right: richer annotations for the "upperparts color" provide more information than the certain CUB annotations. Far right: uncalibrated uncertainty of the "wing shape" concept under occlusion.

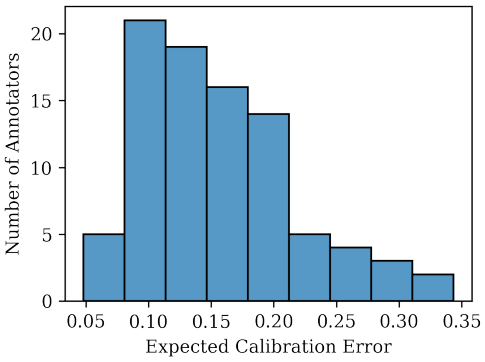

Figure 9: Distribution of Expected Calibration Error for annotators in CUB-S. The positive skew shows most annotators are well-calibrated, with a few who are very poorly calibrated.

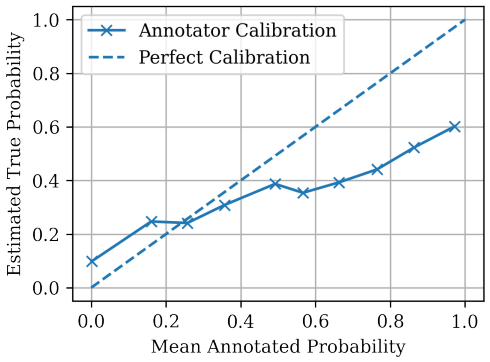

Figure 10: Calibration curve for CUB-S annotators, showing consistent underestimates of small probabilities and overestimates of large probabilities.

6 OPEN CHALLENGES

We emphasize the importance of considering human uncertainty in concept-based models, and the need for richer datasets of human uncertainty to study these challenges. CUB-S is a promising initial playground to study the nuances faced with real human uncertainty[3]. Our work raises several open challenges.

6.1 Complementarity of Human and Machine Uncertainty

Considering human uncertainty in interventions opens up exciting opportunities in the study of human-machine complementarity [3, 4, 28, 55, 59]. When we break the assumption that humans are confident oracles, it becomes especially important to consider whether cases which are hard for the model to annotate are also those that a human struggles with; in that case, selecting such a concept is not ideal. Learning models and intervention policies which complement humans' strengths and weaknesses, accounting

[3]All code and data will be hosted at our repository.

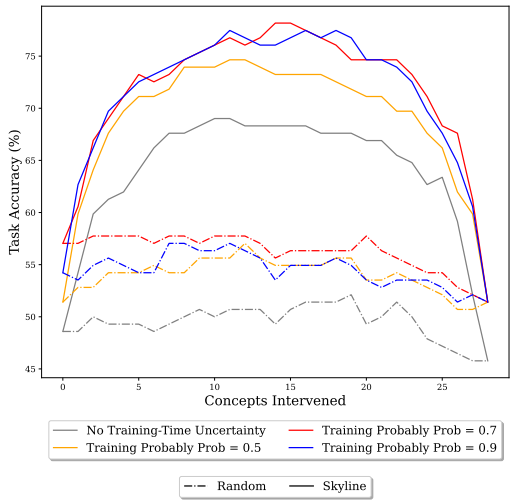

Figure 11: CEMs struggle to handle real human uncertainty. While Skyline is able to leverage *some* signal in the data, not all incorporated concept annotations help model performance: some may hurt. Using models trained on human uncertainty information may mitigate some of the drop.

for their expertise and confidence, are promising grounds for further study with CUB-S and beyond. We see that varied models may prefer different forms of uncertainty (see Supplement); further, even though we see that Random interventions fail disastrously, there is a signal that Skyline picks up on the uncertain concepts – how can we predict where and when to ask people for their uncertainty? And when we do receive their uncertainty, it is not immediately apparent whether we *should* take the human intervention as "truth." As we demonstrate, real humans are *not* consistent oracles – and in some settings (e.g., occlusion), *no* human may be an oracle, even if they are an expert. Models which can learn whether or not to trust human interventions, e.g. [13, 36], are promising grounds for future study.

6.2 Treating Human (Mis)Calibration

A core factor in whether or not to trust a *human's* intervention, and determinant of which concepts to query, may depend on the expected calibration of the user. We observe wide variation in individuals' level of calibration in their uncertainty expression, a finding that resonates with a wealth of cognitive science literature [25, 27, 30, 34, 41, 51, 57]. However, we emphasize that calibration need not be a turn-off from collecting uncertainty in the first place; not only are some humans highly calibrated – but forcing someone to express certainty when they are not (and when it is not possible to be certain; e.g., occlusion), we argue may be worse. Future work for post-hoc calibration in a *few-shot* manner, e.g., from limited individual-level user data, provided in an online fashion, is further promising ground for new methodological advances. Additionally, we encourage further experimentation with UElic to encourage better calibration from humans – perhaps through the use of a carefully designed teaching curriculum [26, 27]. We see calibration – particularly across real users with varying domain expertise [12] – as an exciting nexus for a multi-disciplinary study spanning ML, cognitive science, UX design, and psychology.

6.3 Scaling Uncertainty Elicitation

Further, we recognize that the annotation of large-scale datasets with human uncertainty may be practically challenging. It is costly to elicit human uncertainty: annotators take substantially more time [10]. There is a need for more scalable elicitation techniques, and better simulators of human uncertainty to permit the study of softness at train time. We observe substantial differences in model performance depending on the form of uncertainty used; more data is needed to further characterize these differences and determine when one form of uncertainty is better to elicit than another, such that when we deploy systems in the world – they can handle a variety of forms of uncertainty expression.

7 CONCLUSION

We highlight the importance of considering human uncertainty in concept-based models to improve reliable performance for safe applications in deployment across society. Humans in the real-world are not certain oracles. We make mistakes and may be unsure. Even though humans may be miscalibrated in their uncertainty, we believe the study of tools to elicit and work with human uncertainty has great potential to improve human-in-the-loop systems. Through a mixture of simulated and in-the-wild experiments with uncertainty, we demonstrate failure modes of popular concept-based systems to handle both coarse- and fine-grained uncertain feedback. We offer a new interface, UElic, and a new challenge dataset, CUB-S, to support further study into human uncertainty in interventions. Modeling human uncertainty at train- and test-time has the potential to greatly improve the reliability and trustworthiness of concept-based models when deployed safely in the wild.

ACKNOWLEDGMENTS

We thank (alphabetically) Allison Chen, Yanzhi Chen, Carl Henrik Ek, Kris Jensen, Isaac Reid, Deepak Ramachandran, Josh Tenenbaum, and Richard Turner for helpful conversations. We also thank Steve Branson, Catherine Wah, Kushal Chauhan, and Rishabh Tiwari for helpful clarifications on their work. Thank you to the participants from Prolific who took part in our annotation. We also thank the reviewers for their incredibly useful feedback.

SUPPLEMENT

Constructing UMNIST

We provide further clarity on how we constructed UMNIST. Each sample of the UMNIST dataset is formed by p 28×28 grey-scale images of handwritten zeros or ones, given as a normalized sample with shape $\mathbf{x} \in [0,1]^{28\times 28\times p}$. We annotate each sample with p binary concept annotations $\mathbf{c} \in \{0,1\}^p$, where c_i indicates whether the i-th image is a one or a zero, and a task label $y \in \{0, \cdots, p\}$ corresponding to the number of ones in its digits, i.e., $y = \sum_i c_i$. To introduce uncertainty in this dataset's samples and concepts, we update concept c_i corresponding to the i-th image as follows:

$$c_i := \begin{cases} \text{Randomly sample from Unif}(0, \delta) & \text{if i-th digit is 0} \\ \text{Randomly sample from Unif}(1-\delta, 1) & \text{if i-th digit is 1} \end{cases}$$

where $\delta \in [0,1]$ is a user-provided hyperparameter controlling the amount of dataset uncertainty. Furthermore, in order for this concept annotation uncertainty to be reflected as part of the input digits $\mathbf{x}$, we mix a concept's corresponding digit, akin to Zhang et al. [63], with a randomly selected MNIST training example of the opposite digit using c_i as the mixing ratio. In other words, after generating a sample's uncertain concept annotations $\mathbf{c}$ we update its i-th input digit $\mathbf{x}_{(:,:,i)}$ as follows:

$$\mathbf{x}_{(:,:,i)} := \begin{cases} (1-c_i)\mathbf{x}_{(:,:,i)} + c_i \mathbf{z} \text{ with } \mathbf{z} \sim p_{\text{M}}(\mathbf{x}|y=1) & \text{if } \mathbf{x}_{(:,:,i)} \text{ is 0} \\ c_i \mathbf{x}_{(:,:,i)} + (1-c_i)\mathbf{z} \text{ with } \mathbf{z} \sim p_{\text{M}}(\mathbf{x}|y=0) & \text{if } \mathbf{x}_{(:,:,i)} \text{ is 1} \end{cases}$$

where $p_{\text{M}}(\mathbf{x}|y)$ is the empirical training distribution of MNIST samples whose label is y. For this paper, we focus on using only $p = 10$ digits per sample. See Figure 12 for some examples of this dataset as we vary δ.

Computational experiment details

We next include additional details on how models were trained and run on the various probe datasets, as well as the intervention methods considered.

Training Details for UMNIST *Experiments.* For all UMNIST experiments, we train both CBMs and CEMs using a concept extractor whose architecture consisted of four 3-by-3 convolutional layers with filters $\{5, 10, 20, 40\}$ followed by a linear layer with 20 activations and an output layer with pm output activations, where m is the embedding size used for CEM (one can think of CBM as having $m = 1$). In practice, we set m to 8 following the recommendations from Espinosa Zarlenga et al. [14]. Between all non-output layers, we include leaky-ReLU nonlinear activations and we apply batch normalization after each nonlinearity that follows a convolutional layer. Similarly, for both CEMs and CBMs, we use a simple ReLU two-layer MLP as its concept-to-label map with layers sizes $\{20, p\}$ and train each end-to-end CBM/CEM by weighting the concept loss as much as the task loss (i.e., the joint training hyperparameter α was set to $\alpha = 1$ for both methods). Finally, to avoid each model learning to simply predict the most common class to minimize its error, we weight each sample's task loss according to the empirical label distribution of its corresponding label to encourage our models.

All models are trained by sampling a total of $20,000$ training UMNIST samples, of which 20% were used as a validation set, and

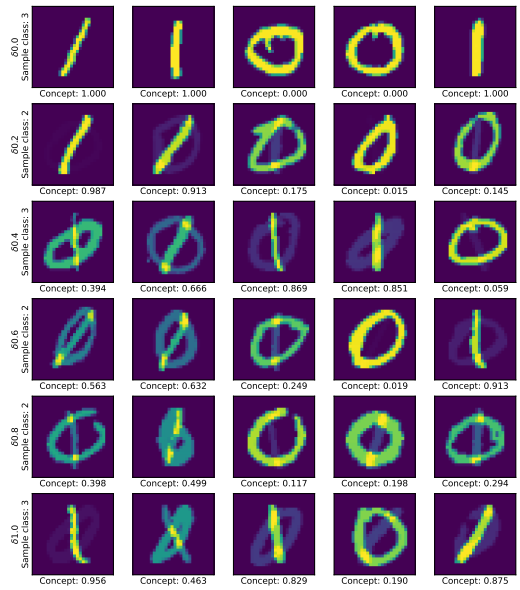

Figure 12: Example datapoints in UMNIST as we vary the value of δ (rows). Each row represents a single sample, with each column representing one of the $p = 5$ digits forming that sample. We include each concept's annotation, as well as the datapoint's label, underneath each digit and to the left of each datapoint, respectively.

tested by sampling 5,000 UMINST testing samples from MNIST's testing set (so no digit in the testing set is ever used to construct UMNIST's training set). We train all models using a standard Adam [29] optimizer with a learning rate 10^{-3} and a batch size of 256 for a maximum of 50 epochs, stopping earlier if the validation loss has not improved for 15 epochs. For each method in UMNIST, we run 5 models from different seeds.

Training Details for CheXpert *Experiments.* For the CheXpert dataset [24], we train all models for 25 epochs, subsampling the dataset to use only 25% of the training dataset when training due to the large size of the dataset. Because the test split for CheXpert does not have the "uncertain" concept label, we perform an 80-10-10 split of the train split into the train, validation, and test folds. Results for CheXpert are averaged over 5 trials, and we use a learning rate of 0.001 across all trials.

Training Details for CUB-Based Experiments. Models trained on CUB followed the same training settings as Espinosa Zarlenga et al. [14]; we employ a single model run for each seed due to computational complexity.

Details on Intervention Policies. The interaction policies we consider in this work (Random and Skyline) consider the setting where a user can be queried to intervene, or edit, a single concept (e.g., wing color) at a time. *Skyline* assumes access to the true label y and how the human would intervene (e.g., assumes access to the CUB-S elicited soft concept annotations), and "tests" intervening with each of the remaining concepts to see which yields the highest predicted probability of the model on the true label. In that way, this mimics an "Oracle" policy, which can greedily select the best of the available next concept interventions, following Chauhan et al.. However, the assumption of knowing the humans' interventions in advance, and the true label, are not realistic (and defeat the purpose of an intervention policy) in practice; hence, this method is meant to capture the "best possible" amount of information that can be gleaned by a single-step direct intervention policy alone. *Random* simply selects the next concept to query by randomly choosing amongst the available concepts which have not yet been queried.

Additional Results on Concept-Incomplete Variant of UMNIST

As discussed by Espinosa Zarlenga et al. [14], CBMs have a significant failure mode when the set of concept annotations available at training time is not fully predictive, or complete, with respect to the task of interest. Similarly to our UMNIST experiments summarized in Figure 3, this section explores how test-time uncertainty affects CBMs and CEMs when the dataset we are working with does not have a complete set of concept annotations. For this, we use our defined UMNIST dataset but only provide 50% of its concept annotations at training time. We train a CBM and CEM using the same configuration and architecture as that described for our UMNIST experiments, with the exception that the concept weight loss α was changed to 0.1. We apply such a change to improve CBM's performance, as otherwise, it was unable to achieve a moderately high task accuracy.

Our results in Figure 13 demonstrate that both CBMs and CEMs significantly drop their performance when test-time uncertainty increases (as we saw in Figure 3 before). Nevertheless, in contrast with Figure 3, we see that interventions in CBMs actually decrease their test accuracy, with uncertainty exacerbating this effect even further. Therefore, these experiments suggest that in concept-incomplete setups, which tend to be what we would expect in real-world datasets given the cost of acquiring all possible concept annotations, CEMs are relatively safer to use regardless of the user's uncertainty at intervention time.

Additional CheXpert Investigations

We include training with simulated uncertainty in Figure 14.

We also explore the original uncertain annotations in CheXpert [24], which contains concept annotations from chest x-rays. The dataset is marked with four labels: positive, negative, unknown, and uncertain. Unknown concepts have no information on their labels, while uncertain labels have information supporting both positive and negative labels. For our experiments, we vary the value taken by uncertain labels, both at train and test time, and investigate its impact on intervention performance. In Figures and 15 and 16, we find that test-time uncertainty improves intervention performance, while train-time uncertainty has minimal impact. This is partially because of the sparsity of uncertain labels in the dataset; only 5% of annotations are marked as uncertain, capping the total effect of train-time uncertainty. For test-time uncertainty, we find that non-zero values improve intervention accuracy, because models are able to distinguish between "uncertain" labels and "negative" labels.

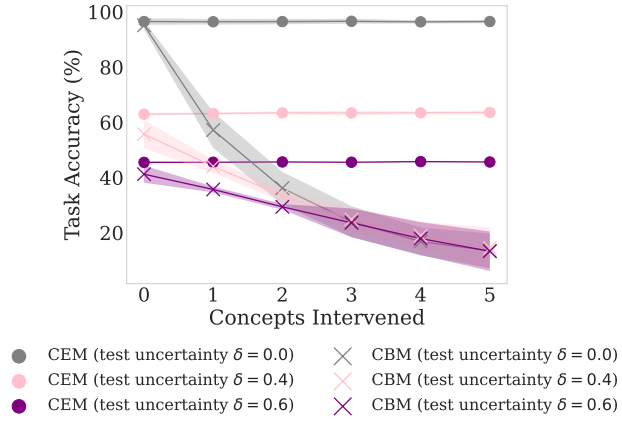

Figure 13: Mean test accuracies of random interventions on CBMs and CEMs, and standard errors across 5 different random initializations, as we increase the number of concepts we intervene on. These models are trained on a variant of `UMNIST` where we only provide 50% of its concepts at training time.

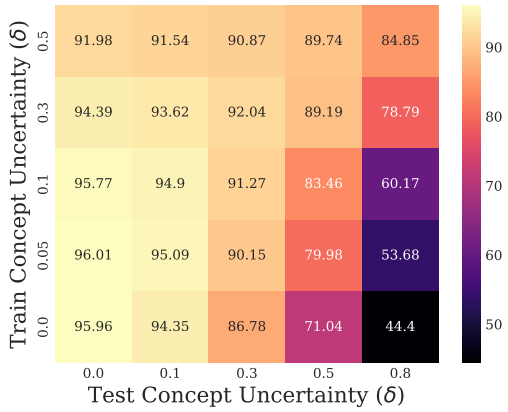

Figure 14: Comparing CEMs trained and tested on differing levels of uncertainty in `CheXpert`. Heatmap colors depict AUC of the different variants.

Additional Details on `CUB-S`

We next include additional details on the way we collected `CUB-S`, as well as further qualitative observations into the labels collected.

Additional Collection Details. Stimuli are preferentially subsampled from the `CUB` test set to include images which CEMs and CBMs both typically get wrong[4]. Participants are informed the study is intended to last approximately 30 minutes and are paid at a base rate of $9/hr, with an optional bonus paid up to $10/hr to encourage quality predictions; the bonus is applied to all participants.

[4]Approximately 50% of the images shown to participants are those which four different seeds of both CEMs and CBMs got incorrect, rendering them more interesting - and challenging - to study at intervention-time

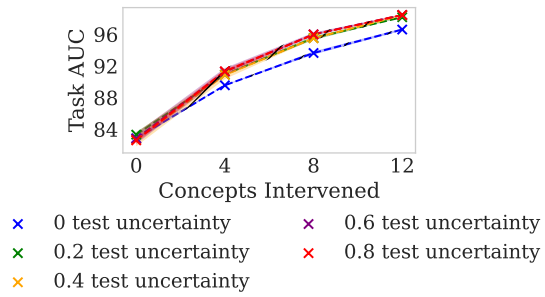

Figure 15: Test-time uncertainty values have a large impact on intervention performance, when using random concept interventions. Setting it to 0 prevents models from differentiating between negative concepts and uncertain concepts, leading to a decrease in performance. However, setting it to non-zero values allows models to pick up on this difference and improve intervention performance.

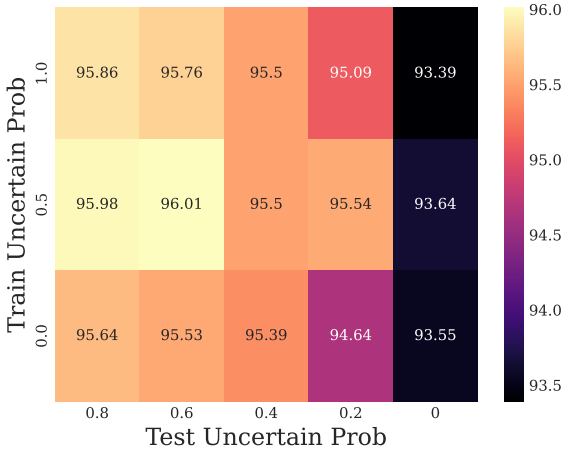

Figure 16: Intervention performance (i.e., random interventions) when using 8 out of 13 concepts to intervene across training and testing uncertainty values. Test uncertainty values have a much larger impact than train uncertainty values, and in general, training with uncertainty seems to have little impact on test-time uncertainty performance.

Additional Observations. We observe in Figure 17 that distribution of provided uncertain annotations is highly irregular, with heavy tails at 0 and 100, and a peak at 50. We hypothesize that heavy tails may be explained by humans rounding values to reduce their cognitive load; Collins et al. found similar rounding effects in free-form uncertainty expression. 50 is the default value provided by the interface, likely underlying the large number of annotations at 50. This suggests there is scope for improving the interface to extract a more accurate distribution of uncertainties, potentially striking a more naunced balance in granularity of information elicited, e.g., [8].

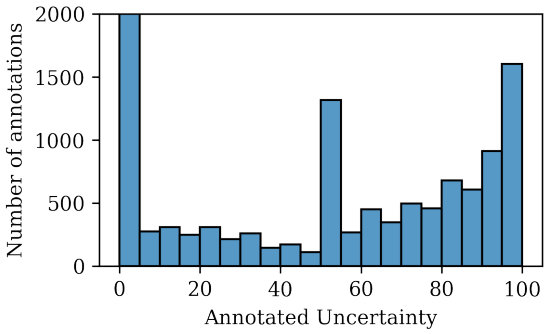

Figure 17: Distribution of uncertainty values for all annotations in CUB-S. Annotators favor certain annotations (0 or 100) and the default value of 50 provided by the interface.

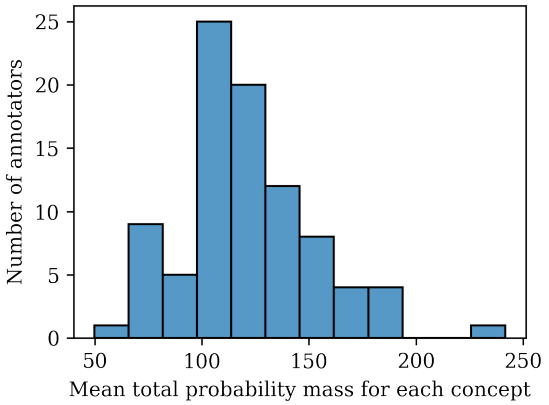

Figure 18: Histogram showing the distribution of mean total probability mass for each concept assigned by each annotator. Most annotators assign approximately 100 probability mass, although there are a significant number which over-assign probability mass.

As observed in Section 5.3.3, the calibration of individual annotators varies significantly. Figure 17 shows that most annotators consistently assign approximately 100 probability mass for each concept, as one would expect. However, the distribution is positively skewed, with a significant number of annotators consistently over-assigning probability mass acoss the concept groups (for any individual concept, the annotator can endorse at most 100 "probability units"). This is partly explained by concept groups where more than one concept is relevant (such as color), although it is also likely that annotators are overestimating their confidence.

Further, we investigate the variance in flavor of uncertainty expressed between different concepts. In Figure 19 we plot the distribution of probability mass assigned for each concept. We observe significant variations between concepts, in terms of their mean, variance and skew. Some concepts such as "eye color" have a very tight distribution around 100, suggesting those concepts are "easy" to annotate. In contrast, some concepts such as "upperparts

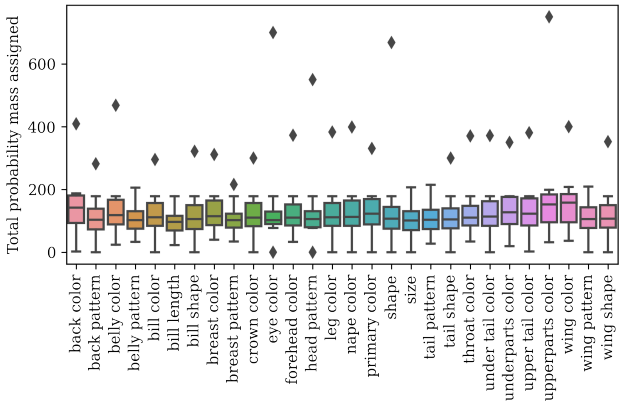

Figure 19: Distribution across images of total probability mass assigned for each concept. There is significant variation in the mean, skew and variance of distributions, showing that different concepts are annotated differently by human annotators.

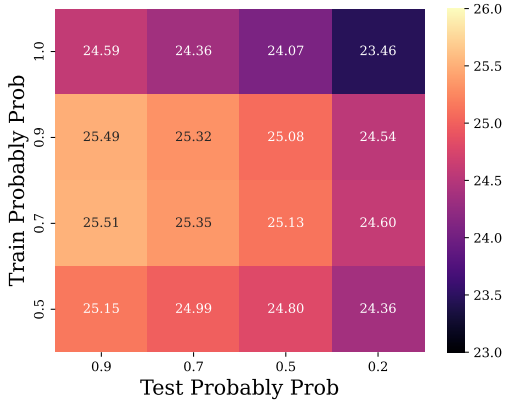

Figure 20: Training with a moderate level of (aggregate/population-level) uncertainty improves robustness under test-time uncertainty; as measured by AUC between intervention-accuracy curve. Higher is better.

color" show greater variation in the probability mass assigned. These concepts tend to either be color concepts, which can have several correct annotations, or ambiguous concepts like "size" which may be harder to annotate correctly.

These observations highlight nuances in the CUB-S dataset which aren't present in the original hard annotations. Soft annotations give insights into how humans interpret concepts when labeling and the variation in individual calibration of annotators [10]. We hope to encourage future work to design ML models and datasets which account for the idiosyncrasies of human uncertain annotations.

Additionally, our labels demonstrate potential issues with the concept filtering typically applied on CUB. Koh et al. propose a filtering scheme to avoid overly sparse annotations; however, we note that our annotators assign a substantial amount of probability

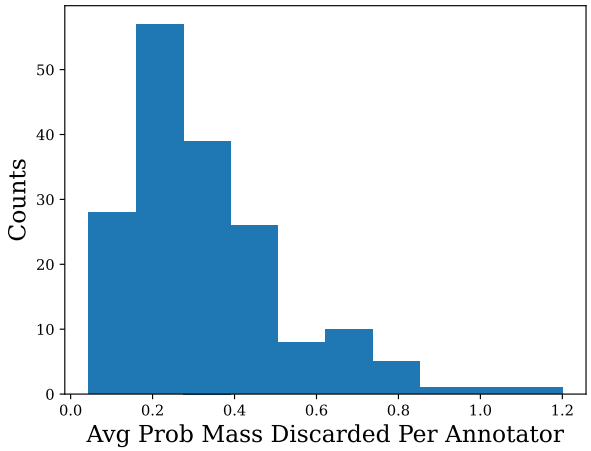

Figure 21: Amount of assigned probability mass discarded per individual when using the popular Koh et al. concept filtering (averaged over concept groups).

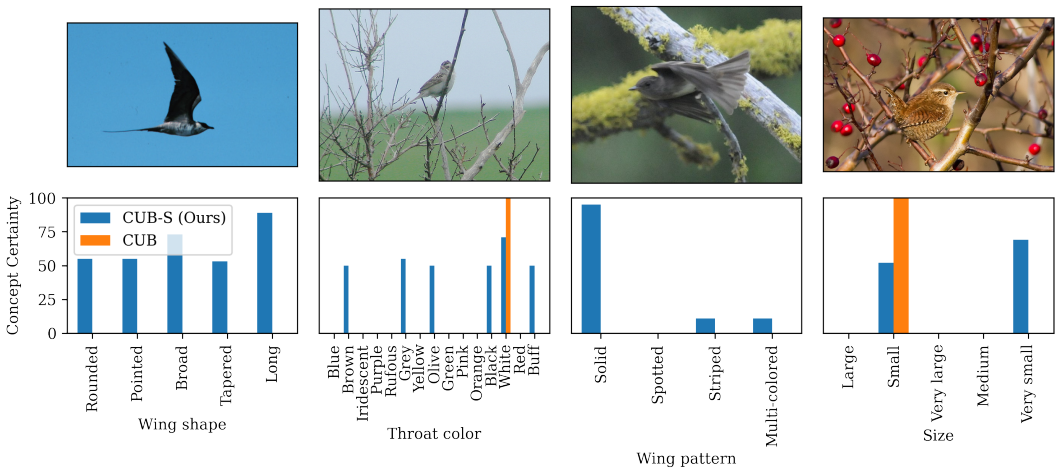

Figure 22: Additional examples showing rich annotations for CUB-S compared to hard assignments in CUB.

mass to concept attributes which are *filtered out* (see Figure 21). These data highlight that the filtered out attributes could indeed be missing critical information from people as to what is in the image.

Additional CUB Uncertainty Computational Experiments

We next include further observations from our computational experiments in CUB and CUB-S.

Broad vs. Narrow Uncertainty. We demonstrate the sensitivity of concept-based systems to broad versus narrow uncertainty under the Random policy (see Figure 25), further highlighting that the method of distributing uncertainty through discrete confidence scores matters impacts intervention efficacy.

Individual- vs Population-Level Uncertainty. As noted, whether or not we intervene with individual or population-level annotations matters (see Section 5.2.3), and we see in Figure 20 that training and then intervening with population-level annotations yields the best performance. These observations are relevant not only to ML practioners who work with CUB, but broadly in annotation-design and questions around who and how many annotators should we elicit from.

CBMs and Simulated Uncertainty. Further, we concretize why we focus on CEMs in the bulk of this work. CBMs severely struggle

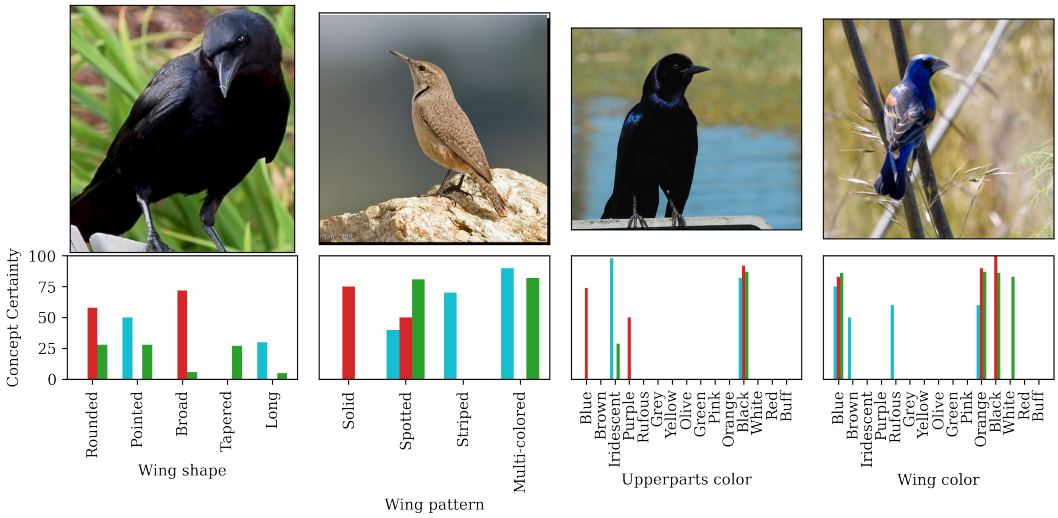

Figure 23: CUB-S Examples where multiple annotators labelled the same image. Each bar color represents a unique annotator for each image. The annotated concepts vary significantly between annotators, especially for challenging concepts such as "wing shape" and "wing pattern".

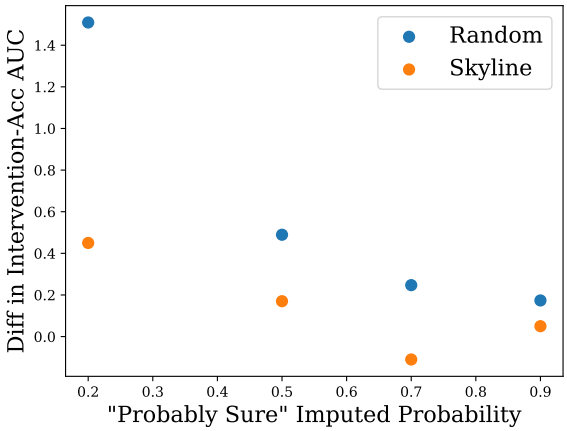

Figure 24: It matters whether or not we use *instance-level, individual* annotator uncertainty, or average over many individuals' uncertainty. Averaging improves the stability of interventions; but in practice, we may only have a single individual who can provide their uncertainty. We find sizeable differences in the intervention efficacy when using averaged uncertainty for both Skyline and Random.

under test-time uncertainty when dealing with concept-incomplete datasets (see the UMNIST section of this Supplement) and in-the-wild uncertainty (see Figure 26).

Skyline Selections Reveal "Helpful" and "Harmful" CUB-S *Annotations.* As seen in Figure 11, Skyline rapidly improves by selecting "good" uncertain annotations; however, the final selections hamper performance. We demonstrate how human selections can both help and hinder performance in Figure 27. We depict the proportion of selections for each concept being in the first or last 5 selections by Skyline. Avoiding selecting the examples in the last 5, e.g., "upperparts" color, offer promising directions for future policy design and investigation into when and why humans are good uncertain annotators. Interestingly, we observe differences in which concepts are preferred depending on whether the model was trained without (Figure 28) or with uncertainty in the concepts at training time (i.e., Figures 29, 30, 31).

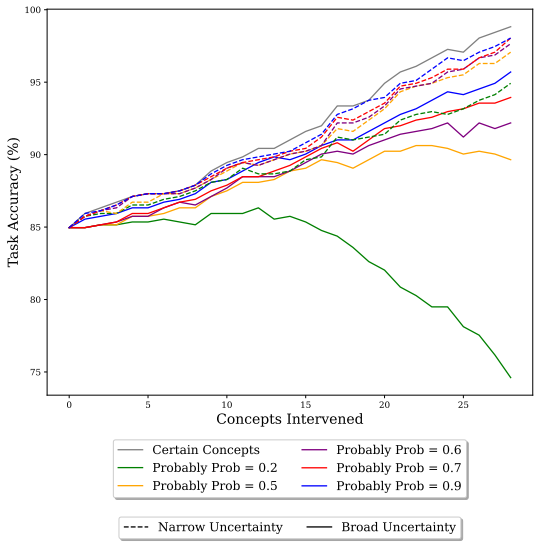

Figure 25: Impact of different ways of distributing the discrete uncertainty over categorical concept groups, selected using Random intervention policies on CEMs.

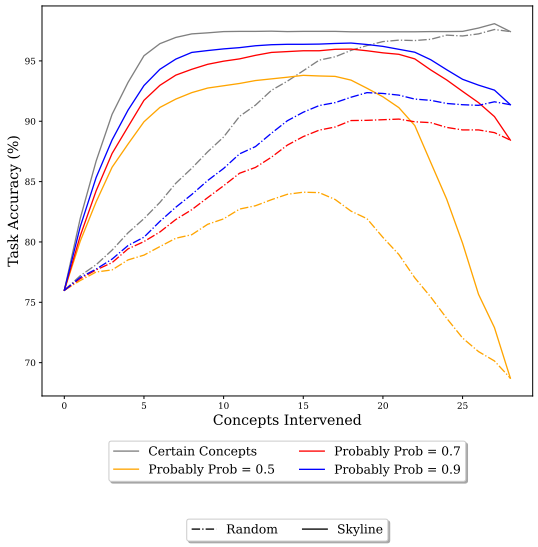

Figure 26: CBMs struggle to handle uncertainty in CUB as well and are comparatively worse than CEMs.

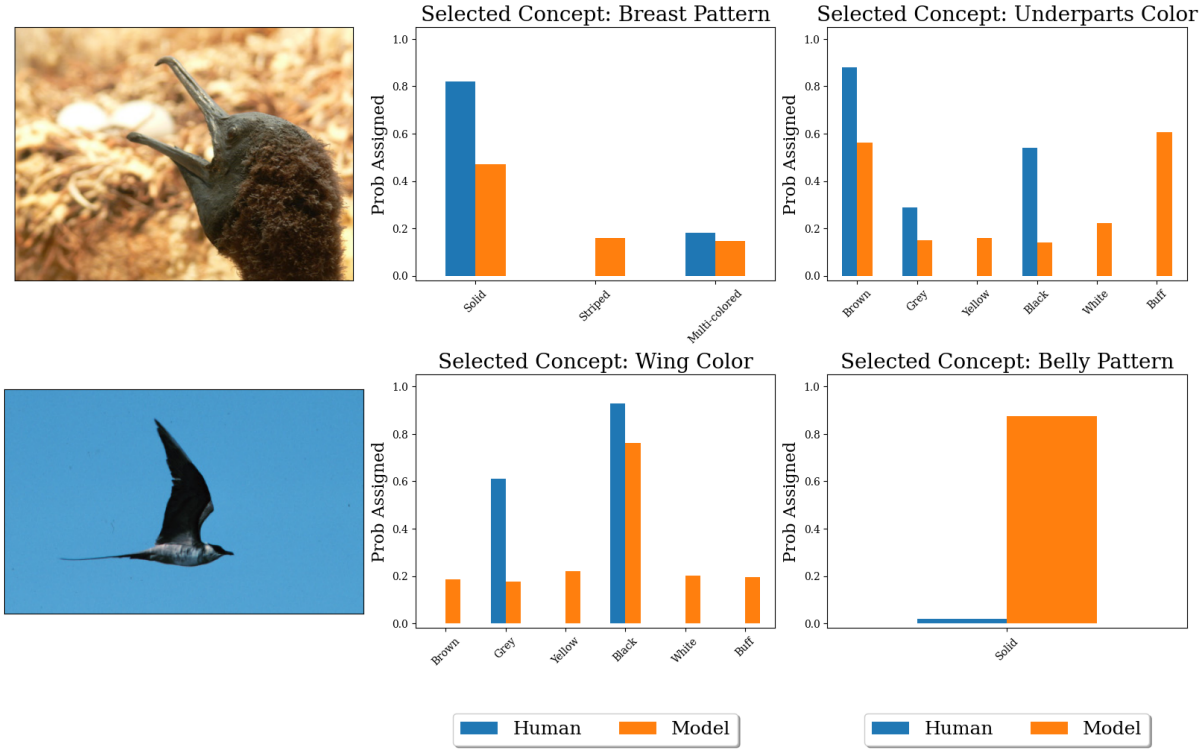

Figure 27: Model versus human distributions over concepts at the time of selection by Skyline. The first column of distributions are selections which boosted the model's classification (from incorrect to correct); humans' uncertainty was helpful to intervene with. The second column of distributions depicts the human uncertainty at intervention time which *hurt* model performance (the classification went from correct to incorrect). Model trained on uncertain concepts ("Probably" probability = 0.7).

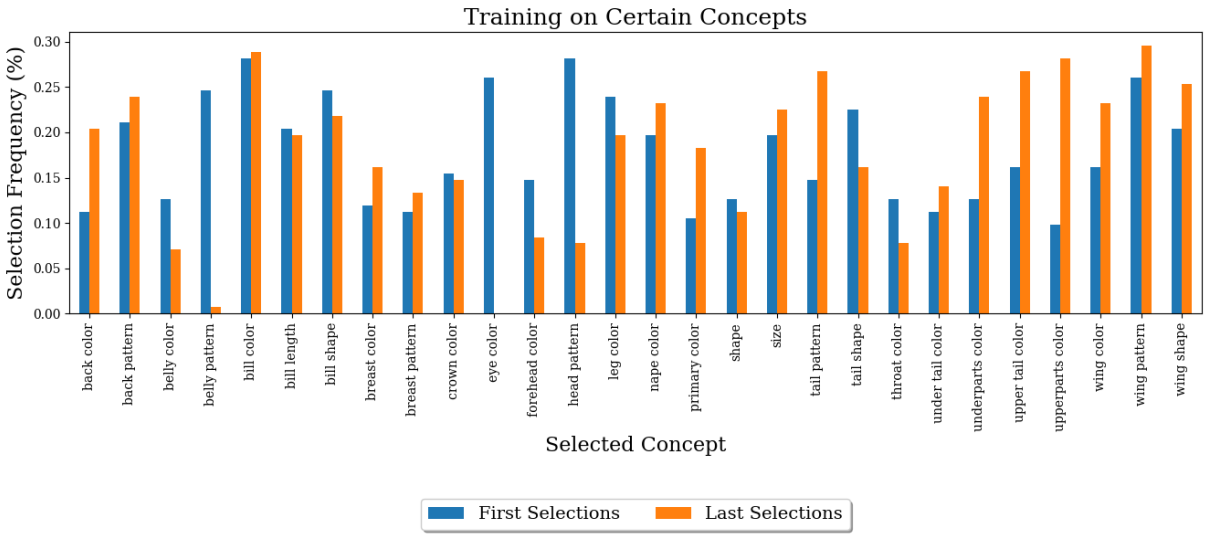

Figure 28: Skyline selections for CEM run on `CUB-S` reveal when human uncertainty elicitation is helpful (versus harmful). Proportion of selections for each concept being in the first or last 5 selections by Skyline. CEM trained on certain concepts.

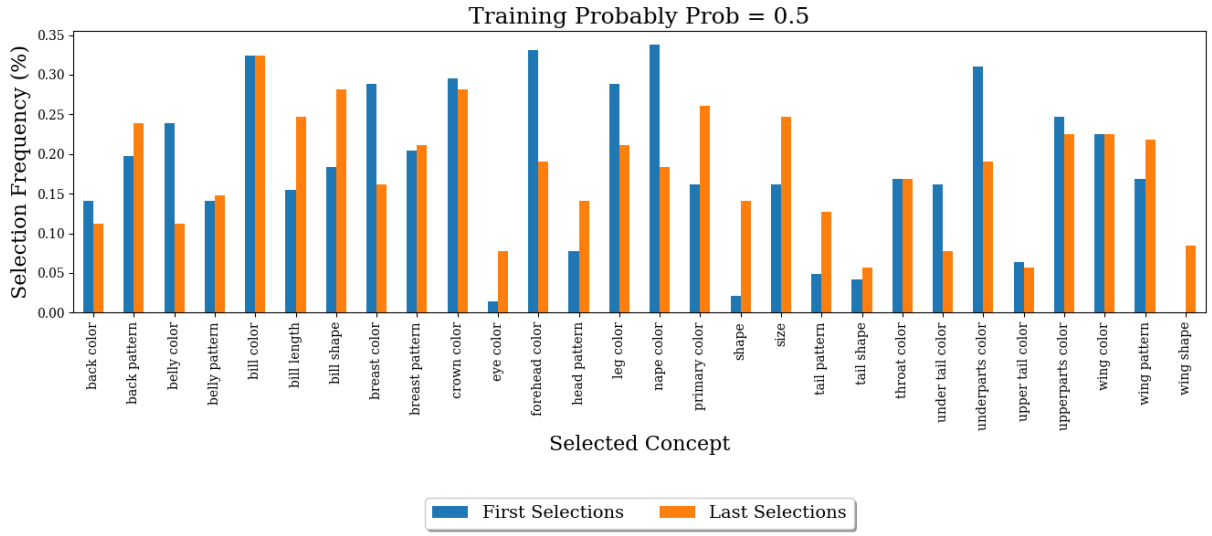

Figure 29: Skyline selections for CEM trained on uncertain concepts (where the imputed "Probably" probability is set to 0.5). Population-level broad uncertainty labels used.

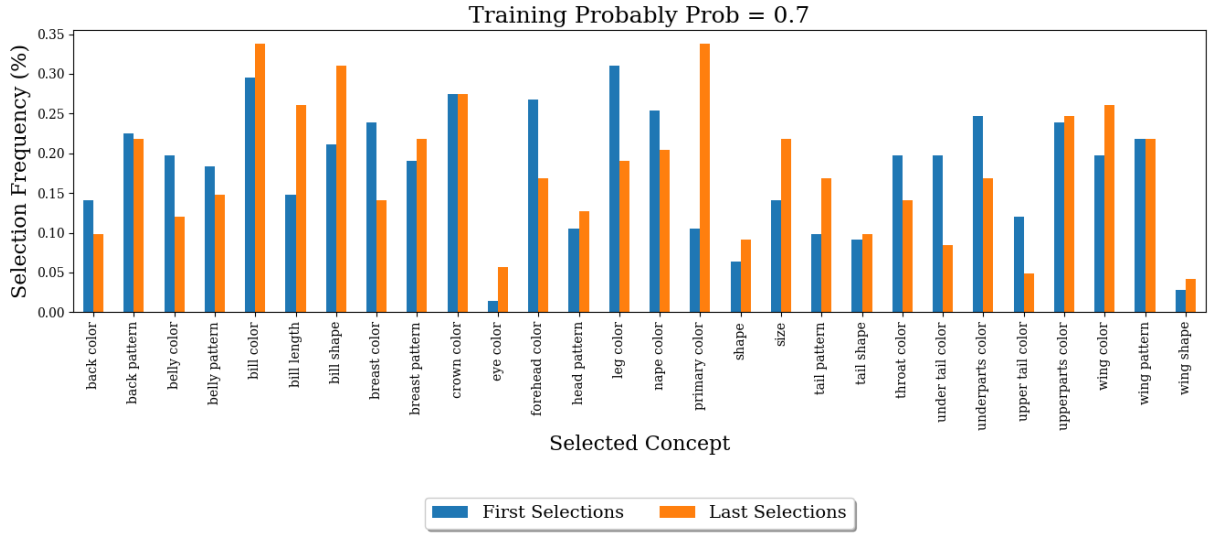

Figure 30: Skyline selections for CEM trained as in Figure 29, but with the imputed "Probably" probability set to 0.7.

Figure 31: Skyline selections for CEM trained as in Figure 29, but with imputed "Probably" probability set to 0.9.

Diffusing the Creator: Attributing Credit for Generative AI Outputs

ABSTRACT

The recent wave of generative AI (GAI) systems like Stable Diffusion that can produce images from human prompts raises controversial issues about creatorship, originality, creativity and copyright. This paper focuses on creatorship: who creates and should be credited with the outputs made with the help of GAI? Existing views on creatorship are mixed: some insist that GAI systems are mere tools, and human prompters are creators proper; others are more open to acknowledging more significant roles for GAI, but most conceive of creatorship in an all-or-nothing fashion. We develop a novel view, called CCC (collective-centered creation), that improves on these existing positions. On CCC, GAI outputs are created by collectives in the first instance. Claims to creatorship come in degrees and depend on the nature and significance of individual contributions made by the various agents and entities involved, including users, GAI systems, developers, producers of training data and others. Importantly, CCC maintains that GAI systems can sometimes be part of a co-creating collective. We detail how CCC can advance existing debates and resolve controversies around creatorship involving GAI.

1 INTRODUCTION

The recent proliferation of generative AI systems (GAI) that competently produce text, images and other outputs from human prompts (e.g., Stable Diffusion, DALL-E2, ChatGPT) has attracted considerable attention from the public, media, regulators and academics. Central points of contention range from safety and responsibility in regard to offensive or untruthful outputs to disruptive potentials of GAI for labor markets and education systems [21, 36, 43, 63, 70, 74]. In the space of creative visual production, GAI has been especially controversial, radically 'democratizing' creative production by allowing unskilled users to generate high-quality imagery, and raising questions about creativity, intellectual property, plagiarism, illegitimate scraping of training data, censorship and so on [22, 26, 32, 33, 60]. Two particularly contentious questions stand out. First, the *creativity question*: do GAI systems produce genuinely novel and/or creative outputs? Second, the *creatorship question*: who should be credited with the production of these outputs? Should human prompters receive all the credit, while GAI systems are mere tools, akin to a sophisticated brush? And what about developers who built the systems, or producers of training data?

Unsurprisingly, both questions are difficult to answer and deeply entangled. The creativity question hinges on both facts and values, e.g., facts about the production process and value-judgments about what constitutes a genuinely creative or original achievement. Issues of creativity and originality are inherently controversial and reasonable disagreement will often persist [4, 7, 12, 18, 24, 34, 41, 59, 64, 72]. The creatorship question is similarly challenging, also turning on value-judgments, and requiring that we can trace the origin of specific outputs [4, 19, 20, 27, 37, 38].

Even so, we argue that significant progress on the creatorship question is possible by drawing on a recent view we have developed in a very different space: scientific discovery involving AI [13]. There, we proposed a collective-centered view (CC), which insists that discoveries are made by collectives, and that credit for discovery should be distributed within the collective according to the nature and significance of specific contributions. Importantly, this view permits that AI systems can be part of a discovering collective, making contributions that can be comparable in significance to human contributions.

Here, we develop a sibling to this view, called the CCC (collective-centered creation) view, that applies to GAI. CCC maintains that issues of creatorship are not all-or-nothing: different agents and entities, i.e., GAI systems, human prompters, creators of training data and others, can each make important contributions to an output and attributions of credit hinge on the nature and significance of the contributions made. Detailing CCC, we argue that it is an attractive option for addressing creatorship in a systematic way. It reinforces existing arguments from the public debate, e.g., that scraping imagery from the web to train models without creators'

consent and acknowledgment is problematic [11, 67, 73]. And it generates novel intuitions: such as whether a human prompter or GAI system has a stronger claim to co-creatorship depends on several features of what role they played in producing an output. For instance, a casual user, Jake, who uses a generic prompt like 'cute cat' may not have strong creatorship claims, but a more involved user like Jo, who pursues a specific aim and iteratively refines her prompts to meet her goals, might. Creatorship, on the CCC view, is hence a matter of degree: you can be more or less of a creator, depending on several finer-grained variables that track what role you played in producing an output.

Despite considerable utility, CCC also has important limitations: it is not a tool to definitively settle creatorship issues and disputes. These will often be irreducibly controversial for the value-judgments they hinge on or because details on how outputs were produced remain inaccessible. Equally, CCC does not seek to resolve practical downstream questions, such as how to award copyright to large collectives or how specific contributions should be rewarded (e.g. through payment). Rather, CCC *informs* attempts to address such issues by providing a general framework that facilitates efforts to clarify creatorship in a systematic way, by offering a rich conceptual machinery that helps structure our reasoning and locate sources of disagreement.

We proceed as follows. *Section 2* introduces GAI systems and surveys the existing debate for prominent views on creatorship. *Section 3* develops CCC, explaining its conceptual resources. *Section 4* draws on toy cases to map out how CCC addresses creatorship questions and shows how it can reinforce existing intuitions as well as articulate new ones. *Section 5* concludes.

2 GAI & CREATORSHIP: THE STATE OF PLAY

2.1 Generative AI

GAI includes a broad array of systems and system architectures, which are unified functionally by their ability to generate potentially novel outputs (e.g., text, images, video, etc.) when given some prompt. Here, we focus only on generative visual AI systems that allow a user to generate images from text, image and other inputs, such as OpenAI's DALL-E2, Stability.ai's Stable Diffusion, Midjourney and related systems. Unlike earlier systems based on generative adversarial networks [28, 53], many recent GAI systems are based on encoder-decoder deep neural network (DNN) architectures and involve diffusion models as decoders [54, 56]. Glossing over further details, we emphasize that most GAI systems now offer various parameters that allow users to steer image synthesis; permit a combination of text and image prompts for conditioning (e.g., image-to-image, inpainting); and allow supplementary tools like ControlNet to afford even finer-grained user control over outputs, e.g., to precisely determine the pose of a person [75]. Given their accessibility, cost-effectiveness and impressive abilities, millions of users now employ GAI on a daily basis to produce tailor-made imagery that caters to their needs [23, 31, 57].

2.2 Existing views on creatorship

On the heels of this growing popularity, the last year has seen a surge of debate amongst users, commentators, academics and technologists about a range of questions relating to creatorship, originality and the ethics of GAI. Some of these questions are familiar, while others are novel responses to unprecedented aspects of GAI. Here, we provide an overview of the most influential views expressed thus far concerning whether GAI systems meet the conditions for creatorship[1] and, if so, how much credit they are due. Often drawing on earlier theories of authorship and creative agency in literature, cinema, photography and so on, a number of proposals have been put forward.

Referring to AI's lack of agency and intentional autonomy, Hertzmann [34] and McCormack et al. [50] assert that these systems are not creative agents and, as such, cannot be credited as creators. A lack of physiological vision and subsequent understanding have also been flagged as precluding machines' ability to create [17]. Some legal scholars have made similar assertions, with Ginsburg et al. [27] and earlier skeptics (see [40] for overview) arguing that machines do not show genuine creativity and therefore do not qualify for copyright, as they only operate within the predetermined limits of programming or user instruction. A recent decision of the Committee on Publication Ethics builds on these stances, asserting that AI cannot be named as an author on their publications due to being non-legal entities that cannot be held accountable [15]. Other legal scholars simply do not present GAIs as a creator or engage seriously with that question [10], presumably because intellectual property law does not allow copyright or patents to be granted to nonhuman entities. Coming from a philosophy of art and aesthetics perspective, Anscomb [4] sees AI as deserving some credit as a contributor but not as an authorial creative agent, due to lack of intention and knowledge-how.

Such views lead some to conclude that AI is merely a tool. Hertzmann, for example, presents AI as yet another tool for art production [34], and OpenAI has also framed DALL-E2 in this light, saying it is a "powerful creative tool" that "extends creativity" [52]. Their blog promotes the responses of artists who describe using DALL-E2 as like "a musician playing an instrument" or taking up "a paint brush" that must be "guided by the artist" [51]. It seems a significant portion of GAI users agree [2, 55], as well as some of the wider public who tend to give more credit to people using AI for assistance than to people who use other people for assistance in creating art [37].

In stark contrast, some claim that GAI can be a creator and heavily downplay human involvement. This view is taken by some developers of GAI systems that, they claim, autonomously create novel art [19, 42] using skill, appreciation and imagination [14]. While this stance is less often applied to the GAI we discuss here, AI systems are increasingly acknowledged as generating "truly creative works" [29, p.173]. Based on this belief, some legal scholars suggest a reworking of the requirements for copyright that would allow the threshold of originality to include some AI-generated works [29, 40].

A third type of view focuses on the notion of collaboration [46], emphasizing that GAI systems are increasingly capable of making unique contributions to the production of visual outputs. Some creatives feel GAI is their "collaborator" [51] and has autonomy,

[1] Some literature we discuss predates current-generation GAI and targets broader issues of *authorship* or defining the *artist*. While there may be subtle conceptual differences between authorship, the role of the artist and creatorship, we assume here that the views we review map onto creatorship, regardless of such differences.

leading to new forms of authorship [47]; a view that is often echoed in the public discourse, such as in social media groups, where many users describe collaborative relationships with GAI [1, 16, 66].

Among the menu of options, collaborative views seem the most plausible, but we also think that they say too little on how credit may be distributed amongst collaborators, with the most direct suggestions made by legal scholars Benhamou and Andrijevic [10], albeit solely with a view to copyright and without consideration of the AI's role. Scholars such as McCormack et al. [50] have agreed that "[a]uthors have a responsibility to accurately represent the process used to generate a work, including the labour of both machines and other people" [50, p.13], and Anscomb asserts that AI might deserve some of the credit for the production of artworks [4]. But how could we go about ascertaining the need for this credit in individual cases, and then apportioning it? As Epstein et al. [20] and Jago and Carroll [37] suggest, people are vulnerable to allocating credit based on questionable criteria, such as anthropomorphicity, so there is a need to understand and communicate different contributors' involvement on conceptually firmer grounds. Inadequate attributions of credit not only raise moral problems (e.g., unjust miscrediting), but also have economic and social consequences, affecting how we value works and who benefits from them [37]. Moreover, credit allocation is important for the public's ability to interpret and understand works [9, 38].

In the spirit of related approaches, such as Jenkins and Lin's proposals for determining credit for AI-generated text [38], the CCC view we develop here maintains that GAI can be part of a co-creating collective, but also provides a richer framework that helps us better understand different agents' and entities' roles within a collective. Let us outline our earlier CC view proposed in the context of scientific discovery, and explain how it can be adapted to GAI.

3 THE CCC VIEW: FROM DISCOVERY TO CREATION

Scientists now routinely use AI systems to make scientific discoveries. A celebrated case is AlphaFold 2.0 [39], an AI system that can predict the structure of never-before-synthesized proteins with impressive accuracy; something that takes significant human efforts in any single case, and could not be achieved at scale without systems like AlphaFold. An important question here is whether these systems are making discoveries, or whether they are merely sophisticated tools, like electron microscopes.

Existing theories of scientific discovery have often been agent-centered [68]: they focus on picking out a central discoverer who is responsible for a discovery. However, in the case of discovery involving AI, these views fail to neatly identify such a discoverer, as neither the AI nor the human scientists have strong enough claims to the title alone. Responding to this challenge, we have proposed the collective-centered view (CC) of scientific discovery [13]. Centrally, CC maintains that discoveries are made by *collectives*: a potentially large and diverse set of actors and entities that all make important contributions to discovery. Depending on various finer-grained variables, CC allows that AI systems, too, can be part of a discovering collective and make significant contributions that should be appropriately recognized.

The creatorship question regarding GAI presents an analogous credit distribution problem. Often, neither the GAI systems, human prompters nor producers of training data alone are neatly identified as *the* creator. But each of these agents and entities, among others, can make important contributions to an output[2]. Here, we adapt our earlier CC view to the creation of visual outputs using GAI to make progress on understanding the role of various agents and entities and, in turn, the issue of creatorship.

On our adapted CCC (collective-centered creation) view, the very starting question 'who is the creator?' is misleading: creation is a collective achievement, and credit distribution depends on the nature and significance of the contributions made. Specifically, CCC maintains that for most cases of creation using visual GAI:

- There is ***no clear single creator*** who can be credited with an output.
- A ***collective of actors and entities*** all made important contributions to an output.
- Credit for this output should be ***distributed between these contributors*** according to the nature and significance of the contributions made.

CCC, of course, is not the first view to emphasize that artistic (and literary) production often takes the format of co-creation or co-production. But contra existing views, CCC does not aim at offering neat, principled categorizations between different subgroups of agents, e.g. authors, creators, contributors, assistants [4, 6, 8, 9, 25, 35, 46, 48]. While we agree that making such distinctions can be sensible (as they help organize, negotiate and appraise contributions to artistic creation in professional and public discourse), we also think that any such categorizations should be grounded in a conceptually richer analysis that tracks important primary features of contributors and their contributions, especially regarding GAI. CCC, then, starts bottom-up, by first analyzing which of these features matter for determining inclusion in a co-creating collective. Pencils and hard drives won't make the cut – not because we say so, but because they don't score highly on relevant criteria. CCC hence provides conceptual machinery that specifies the sorts of considerations we should entertain when seeking to clarify creatorship and locate our disagreements.

Let us elaborate several features that CCC uses to inform who may be included in a co-creating collective and how credit may be distributed. The features we outline here are continuous with existing debates on creatorship [5, 6, 8, 9, 25, 35, 38, 48, 50], and while we do not insist that these features are ultimately the right ones, or only ones, to focus on, we consider them productive starting points for developing a systematic approach to dealing with GAI's growing role in creative production.

3.1 Relevance/(Non-)redundancy and Control

The first two features to help clarify creatorship come as a bundle: relevance and non-redundancy track what difference a contribution makes to an output. They are causal-counterfactual notions: to determine how relevant or (non-)redundant a contribution X is to an output Y, we must answer the counterfactual question: 'take X away, what would the output Y have looked like?' If a contribution

[2]We assume that creatorship questions are pertinent if some significant output has been produced. Importantly, we assume that *whether* an output has significance is settled (largely) independently of the criteria we outline. We also focus only on primary outputs delivered by GAI. Users may further transform these, which can change users' standing as creators for these downstream products.

is not relevant, or relevant but highly redundant, Y will remain the same. For instance, if Jo and Jake produce a painting of a cat on a mat, where Jo does all the painting and Jake's role is to hand Jo the brushes as she requests them, we might think that Jake is not terribly relevant and can be made redundant. Take Jake away, and the output would have been the same, either because Jo gets the brushes herself, or because someone else fills in for Jake. By contrast, consider Jerome, who takes a more active role in suggesting what brush could be the right one to achieve a certain texture. Jo and Jerome engage in a symbiotic relationship, with Jerome asking questions, making suggestions, adding interpretations and so on. Jerome's involvement, let us imagine, makes a difference to the output: the painting would be different if Jerome wasn't there, and it might be difficult to replace Jerome. Jerome hence scores more highly for relevance/non-redundancy. Lastly, consider Jake making a solo attempt to produce an image of a 'cat on a mat' using Stable Diffusion. Take away his access to the system, and Jake would have failed to produce the image, for lack of relevant skills. Generally, the more relevant and non-redundant a contribution, the stronger the claim for candidacy in a co-creating collective.

A second feature that is closely related to relevance and non-redundancy is control [71]. Control tracks how precisely and robustly an agent or entity can steer or maintain an output. Intuitively, control may seem to involve intention, but we render it as a deflationary notion that only requires that an agent or entity has causal powers to make an output be a certain way rather than another. Consider Jo, who iteratively refines her prompts to precisely get the image she wants. Jo exerts a high degree of control and can thus stake a strong claim to creatorship. By contrast, consider again Jake, who casually prompted Stable Diffusion with 'cat on a mat'. Does Jake exhibit control? Not necessarily. Diffusion models begin synthesis from quasi-random noise patterns that are determined by a seed number, which can change from prompt to prompt. Importantly, one and the same prompt can yield dramatically different outputs depending on the seed [62]. So, Jake might have ended up with an entirely different image if the seed had been different. Jake, in this case, doesn't exercise much control if he is happy with whatever output he gets. There is no back-and-forth interaction, like in Jo's iterative endeavour, where Jake works against the randomness of diffusion-based image synthesis to realize a specific result.

Two further points help fine-grain control. First, control can be dispositional in a way that relevance and non-redundancy are not: an individual does not always need to exert actual influence in order to exhibit control, but they must be able to if the need arises. Consider a variation of Jo's case where she is lucky to get the exact image she wants on the first try. We might still maintain that Jo exhibits control if it is true that she would have intervened (successfully) had the output diverged from her expectations. Similarly, we might say that Stable Diffusion exhibits control over an output if it would have robustly produced the same output even if Jake had tried to steer it towards another. Second, control is zero-sum: the less control a user exercises, the more control the GAI has. So, when clarifying control, we ask 1) how counterfactually robust an output's features are, and 2) due to who.

Relevance, redundancy and control are thorny concepts, as they all hinge on (appropriate) counterfactuals. Whether Jake would have been able to produce 'cat on a mat' without Stable Diffusion, for example, might depend on whether we ask for the exact pixel-by-pixel image or just something in the ballpark. But even if we have clear counterfactuals in mind, learning them empirically is also difficult, e.g. telling what Jo's painting would have looked like without Jerome's suggestions or whether Jo would have intervened if the GAI hadn't produced what she wanted right away. These challenges are not unique to CCC, however. They obtain in many areas, e.g. in legal reasoning, where we routinely assess what would have happened if people had acted differently. Difficult as these challenges may be in practice, considering relevance, (non-)redundancy and control is essential for distributing credit for creatorship.

3.2 Originality

Originality concerns how original a contribution is, i.e. whether it is novel in character and unique to the contributor. This is related to but different from the originality and significance of an output, which - as mentioned earlier - is not our focus here. Let us assume some recognizably original output is generated. A key question for clarifying creatorship is: whose *original* contributions helped achieve that output originality? A natural starting point is to look at users' text/image prompts. Suppose that there has never before existed an image of a Donald Trump-shaped cheese wheel rolling down a hill. A user's idea and intent to produce such an image and their formulating a prompt that corresponds to these would constitute an original contribution. By contrast, a generic prompt such as 'cute dog' would not score highly – many others have likely used similar prompts. But prompts are not all that is needed to make an image – a GAI system itself must be disposed in the right way to actually produce images that correspond well to user prompts. Specifically, the DNNs underlying existing GAI systems may make original contributions to the production of original outputs, when, at training, the systems latch onto text-image relationships in original ways, e.g. by learning novel representations and relationships between them that can be used to competently synthesize, for instance, what a Donald Trump-shaped cheese wheel rolling down a hill would look like. Here, a mere collage might not be enough: success is measured by whether the system made original connections that help synthesize a coherent visual entity that recognizably looks like 1) Donald Trump, 2) a cheese wheel and 3) like it is rolling down a hill.

Right away, one might insist that originality still ultimately comes from the user – after all, it was them who prompted the system in a certain, original way. But while coming up with the 'what' may often involve originality on the part of the user, concretizing the 'how' may also require originality on the part of a GAI system. This is best understood in cases where a user is unable to imagine how an image corresponding to their prompt could look. Take Jerome, who prompts Midjourney to produce an image encapsulating 'the abstract feeling of realizing that you didn't tell your parents that you loved them enough'. Here, Jerome might only learn about how this feeling could be visualized once he sees the output. If Jerome thinks it captures the feeling well, and there haven't been previous attempts to visualize the feeling with similar results, it seems like Midjourney, too, has made original contributions to producing the output.

Even so, one might wonder where, exactly, we could locate originality in GAI systems' contributions. For instance, one might insist

that the computations performed by GAI systems are 'deterministic' or 'always the same', regardless of whether an output is original. To clarify, we don't claim that there is a mysterious originality property to be found (or not found) anywhere at the computational level. But – like in descriptions of human contributions where the type-level neural activation patterns might be indistinguishable between a truly creative and an unoriginal prompter – some token-level macro behaviors that GAI systems exhibit can nevertheless be usefully characterized by ascriptions of originality (e.g. learning a latent manifold that enables them to produce novel images or following a specific denoising trajectory towards a coherent rendition of an original output). We also do not claim that GAI systems are always or routinely original. GAI systems are prone to reproducing existing works, raising concerns about (near-)plagiarism [45, 69]. So, our suggestion is that, especially in cases where output originality cannot be fully and correctly accounted for by reference to human users, GAI systems may reasonably be described as making original contributions of their own which, in turn, can justify their inclusion in a co-creating collective.

3.3 Time/effort

Other things being equal, the more time and effort an agent or entity spends on furnishing a contribution, the stronger their claim to candidacy in a co-creating collective. Consider Jake again. Even if Jake's brush-handing contributions are not highly relevant and somewhat redundant, if Jo recruited Jake to assist for hundreds of hours, Jake may nevertheless have some claim to candidacy in a co-creating collective. Of course, time and effort are crude metrics. Spent inefficiently, they shouldn't count for much, such as when Jake takes a tedious, pointillist approach to making 'cat on a mat' with his ballpoint pen but the result is aesthetically unimpressive because he can't draw cats, neither with slow points nor with fast strokes. But while contemporary legal theories of creative value often avoid relying on sweat-of-the-brow metrics [29], we think that time and effort should nevertheless be considered as one among a variety of features that can ground claims to candidacy – especially in the realm of GAI usage [65]. In this context, time and effort are best understood as tracking the computational complexity and compute effort (e.g. FLOPs) involved in furnishing a contribution. While GAI systems are certainly faster than humans at producing images once trained, a wider view that puts the computational efforts going into training and inference into perspective can ground the claim that significant time and effort can be involved in furnishing GAI outputs.

3.4 Leadership and Independence

Leadership captures whether a contributor steered the production of an output with a specific intention in mind. For instance, Jo may have a concrete vision for an image, choose a particular method for the job, say Stable Diffusion, and pursue that vision by refining her prompts in a targeted way to realize a specific output. Jake, by contrast, may deploy a generic prompt like 'cat on a mat' and turn out happy with whatever result he gets. While there is intention involved, he does not exert a great deal of leadership. Leadership is closely related to control, i.e. the ability to precisely and robustly steer or maintain an output. Yet, while successful leadership often involves control, it differs from mere control in that it also involves intentions, e.g. identifying, setting and pursuing goals and directing available means to reach them.

Second, independence tracks whether a contributor depends on detailed guidance to furnish their contribution or whether they act in a more autonomous way. Jo and Jerome might be independent in that sense, both coming up with suggestions for what a painting could look like, discussing plans based on what they each think is best. Jake, by contrast, would not make independent contributions if his role is confined to handing Jo the brushes she requests.

While leadership and independence are important, they should not be overemphasized. For instance, leadership roles frequently fall on agents ready to disproportionally absorb credit, such as when a famed director's artistic vision is emphasized as key to achieving a significant work, but other agents' creative contributions that fill important blanks are left underrecognized. Nuancing the role of leadership and independence is especially relevant as GAI systems have a hard time exhibiting these features at levels comparable to humans. For lack of intentions, they cannot exhibit leadership but only control. Likewise, they cannot exhibit full-fledged forms of independence that humans can, e.g. changing a prompt to deliver a different, better output. However, GAI systems may still exhibit some thinner forms of independence at training that carries through to the ultimate outputs. Within the confines of a learning task defined by humans, DNNs must be sufficiently flexible to learn whatever there is to learn – and that is often the point of taking a machine learning approach. Weights and biases aren't hand-tuned by humans, and while humans write training algorithms and build system architectures, they do not fully determine what a system learns in particular (e.g. which representations), especially in unsupervised or self-supervised regimes. So, while GAI systems are not independent in the sense of 'choosing to do it their own way', and what they end up learning is still importantly shaped by human aims, leadership and oversight [4, 50], we maintain that GAI systems can nevertheless exhibit some forms of independence if what they learn and later draw on at inference is not fully determined by humans.

Zooming out, we see that the domain of leadership and independence is, for now, mostly reserved for humans. But we stress that leadership and independence don't get a project anywhere without someone or something following guidance and doing the work that's needed to realize an independently formed vision, which may involve plenty of relevance, non-redundancy, time and effort, as well as some originality and control on the part of GAI systems.

3.5 Directness

Finally, directness captures how directly a contribution is involved in producing an output. For instance, imagine cash-strapped Jo couldn't produce any paintings if it wasn't for her friend Jack, who provides her studio space rent-free. Jack's help is highly relevant and nonredundant, but not direct: his aid will support Jo, let us assume, in producing *whatever* paintings she wants to make and doesn't steer the form of any specific painting. Contrast this with Jerome, who is dialectically engaging with Jo at various points to co-shape their open-ended artistic endeavor. He is, therefore, both highly relevant and direct. Like Jerome, GAI systems can make direct contributions. The computations performed at inference directly generate the ultimate outputs at issue. To be clear, by 'direct'

we don't mean to suggest that these contributions involve any kind of intentionality. Directness is a causal notion, not a mental one, and while direct contributions made by humans may often involve intentions, this is not a requirement for directness as we understand it.

Directness also plays a special role among the features CCC tracks: it modulates the extent to which other features matter for creatorship. Take the role of developers: without their efforts in building GAI systems, most users wouldn't be able to produce the images they do. But developers don't make direct contributions to the creation of specific images. Rather, their contributions primarily consist in building GAI systems that have the capacity to produce images. This is an important achievement but not to be conflated with the production of specific images, to which developers contribute only in an indirect, enabling way. So, despite developers' high causal relevance to the production of specific outputs, this relevance must be appropriately discounted by the low directness of their contributions. Similar considerations apply to other variables and agents, such as producers of training data or low-wage workers providing human feedback for reinforcement learning. Generally, then, the less direct a contribution is overall, the less strongly the other features that a contribution exhibits weigh in determining its significance.

3.6 Putting CCC together

Stepping back from individual criteria, let us look at how the framework functions as a whole. First, all the features that CCC tracks come in degrees: a contribution can be less or more relevant, exhibit stronger leadership, or little originality and so on. Second, none of the features are individually necessary or sufficient for claims to creatorship, no matter the degree to which they are present. Consider sufficiency: a GAI system can be highly relevant to producing an output, and yet be considered a mere tool if a user scores highly on leadership, control, originality and so on. Nor is any single feature always necessary: seasoned users don't need much time or effort for good results, though some features will seem essential in many cases (e.g. directness).

Second, it could be a concern that distinguishing between the features we sketched here is sometimes difficult (e.g. control and leadership). This is neither surprising, nor a problem, however. The broader themes CCC's concepts draw on, like causation, agency, and originality, have been subjects of study and controversy for centuries because they are complex and non-trivial. With artistic creation uniting these themes, it seems misguided to expect a finite list of distinct and razor-sharp conceptual ingredients that explain it neatly. CCC, then, doesn't raise but only encounters conceptual challenges, and these shouldn't distract us from further exploring CCC's descriptive and explanatory value.

Third, taken together, the features outlined here (and potentially others) form a basis for *candidacy* in a co-creating collective: if you exhibit none, or some but to low degrees, you won't get close to being a creator, but if you score highly on all, you should be considered a serious candidate. Within CCC's feature space, there will be many combinations that can ground strong claims to candidacy in very different ways. Importantly, though, CCC does not maintain that there is ever a sharp threshold to decide creatorship. To the contrary, it acknowledges substantial and often reasonable disagreement about creatorship questions, and only insists that creatorship is not all-or-nothing. CCC therefore invites us to work through attributions carefully, by providing a set of clearer criteria that help us locate and potentially resolve disagreement about creatorship. With these tenets in mind, let us proceed to explore what CCC can do for us in practice.

4 WHAT CCC CAN DO FOR YOU

4.1 CCC across the space of contenders

To show how CCC can be useful to make progress on understanding creatorship, we proceed as follows: first, we consider CCC's criteria mapped against possible contenders for creatorship, i.e. users, GAI systems and others, and comment on how each group may fare at a general level. We then focus specifically on the comparison between human prompters and GAI and discuss two cases that mark the ends of a credit distribution spectrum. Finally, we elaborate how CCC reinforces existing intuitions offered in the public discourse on creatorship questions, as well as generates novel claims about creatorship.

Let us begin by applying CCC's criteria to some of the most likely candidates: users, GAI systems, developers and producers of training data. As elaborated earlier, each of the features CCC tracks can be exhibited to different degrees, depending on concrete contextual details.

First, users can make less or more relevant/non-redundant contributions. Users can also spend lower or higher amounts of time and effort, and the originality of their contributions can vary from generic one-word prompts like 'banana' to highly engineered prompts pursuing specific objectives. Relatedly, they can exercise lower or higher degrees of control, leadership and independence when pursuing generic or more involved prompting projects. Finally, prompter contributions will always show directness, but to considerably varying degrees, e.g. through only generating a *kind* of image using a generic prompt like 'banana', or exhibiting high degrees of directness using targeted prompts.

Second, like users, GAI systems can make less or more relevant and non-redundant contributions. But they can only exhibit a certain degree of independence and cannot demonstrate leadership, for lack of intentions. However, if unchallenged by a user, they will exercise control in producing certain images rather than others, given a prompt. GAI systems' contributions always involve some and potentially a lot of compute time and effort; and they can be less or more original, e.g., depending on whether they draw on original connections made at training. Importantly, their contributions exhibit high directness: their computations literally make the specific images synthesized.

Third, as elaborated earlier, developers' contributions are always indirect. They do not make specific images, but rather enable their production. These contributions can exhibit less or more relevance and redundancy, but little specific control over particular outputs. Likewise, they may involve less or more time and effort, as well as varying degrees of originality, leadership and independence; but for lack of directness, these features are discounted: developers do not intend to produce any specific image; they only intend to build systems that can.

Lastly, producers of training data can make varied contributions to creation, too. There are two importantly different ways to conceptualize this group: first, as capturing *all* producers of *all* training data used to train a GAI system taken together. Second, as *specific* producers of *particular* training data tokens. On the wider construal, producers of training data make contributions that are highly relevant and somewhat non-redundant (e.g. there are more images on the web than large datasets like LAION-5B contain, but many images contained in LAION-5B are unique) but they exercise little control over the output. While they may, as a whole, exercise significant time and effort furnishing their contributions, scoring individually from low (Jack posting a photo of grass, which gets scraped and put into LAION-5B) to high (Jill's collected 10-year efforts in producing her published illustrations), and with some originality in the mix, their contributions display no leadership, independence or directness regarding any image produced with GAI (which is why there are concerns about scraping images without consent). These assessments can change importantly when we turn to specific producers of particular training data tokens. For instance, concerning relevance and redundancy, Jacinda's collected paintings of non-cheese things looking like they are made from cheese may play a crucial role in enabling a GAI system to produce 'Donald Trump-shaped cheese wheel rolling down a hill'.

We expand on further differences in regard to producers of specific training data later. For now, let us turn to explore more concrete theses that CCC can ground, focusing first on a comparison of human users and GAI systems.

4.2 Humans vs. GAI: A spectrum of creatorship

Can GAI systems be part of co-creating collectives? CCC suggests yes, for they may exhibit a number of important features and to significant enough degrees to merit candidacy. But how would credit for an output be allocated between human users and GAI systems? That depends crucially on the specific context. Let us offer two examples, which fall on opposite sides of a spectrum for how credit may be distributed. These examples will help us establish that GAI systems can have strong claims to creatorship; sometimes stronger than humans.

Consider Jake's 'cat on a mat' prompt again. Four images are generated (Figure 1), from which he chooses the first.

Figure 1: 'Cat on a mat, art', produced by Stable Diffusion.

How should we consider Jake's and Stable Diffusion's claims to credit here? CCC suggests that the GAI has a stronger claim than Jake. Jake typed in a generic prompt and did not contribute interestingly to the output beyond that. He did not have any concrete ideas regarding composition, palette, style, etc., and he wouldn't have been able to create any of these images without GAI.

Contrast this with Jill, an experienced visual artist working on campaign visuals for an environmental protection agency. She wants to create an image of a polluted ocean in the palm of a hand to correspond with key mission statements. Starting from a hand-drawn sketch, Jill refines her prompts, guiding the GAI through a series of many images, and exerting precise control, e.g., by using inpainting and ControlNet to pose the hand and steer the composition, until she gets an image that conforms to her concrete expectations. Jill already knew what image she wanted to create and could have created something similar by different means, say with Photoshop. In such a case, CCC can ground why Jill deserves a significant credit share and that GAI is more akin to a tool than a full-fledged creator on par with her.

CCC can capture the difference between these cases in a systematic fashion. Table 1 maps out Jill, Jake and Stable Diffusion against CCC's criteria. For simplicity, we use a qualitative coding as 'low' or 'high' to indicate the degree to which each feature tracked by CCC is realized. 'n/a' indicates that a feature doesn't apply in a case, e.g., because GAI systems do not have intentions necessary for leadership.

Table 1: Comparing contributors. SD is Stable Diffusion.

	Jill	SD1	Jake	SD2
Relevance	high	high	low	high
Non-redundancy	high	low	low	high
Control	high	low	low	high
Time/effort	high	high	low	high
Originality	high	high	low	low
Leadership	high	n/a	low	n/a
Independence	high	low	high	low
Directness	high	high	high	high

Table 1 encodes Jill's comparatively much stronger claim than Stable Diffusion (SD1). Jake, by contrast, loses out to Stable Diffusion (SD2) on several criteria, including relevance, redundancy, control and time/effort, so Stable Diffusion has a comparatively stronger claim than him. CCC can hence capture how creatorship and credit depend on a number of context-specific details and locate the roles of various agents and entities straddling full creator and mere tool, author or background furniture, rather than relying on rigid categories. This flexibility and ability to give insights into different situations, where our intuitions can vary widely and surprisingly, is at the heart of CCC – no agent or entity should be judged in or out at the outset, but instead should be allocated credit according to the specific contributions they make.

Nevertheless, there are some likely objections even against our moderate claim that GAI systems can be strong candidates for co-creating collectives and can sometimes play more significant roles than humans do. For instance, one could insist that GAI systems

are not appropriate targets for credit as they are not making the right sorts of contributions to an output – they might be producing, but not creating. But taking this approach can raise problems. For instance, it can lead to credit and subsequent responsibility gaps (cf. [49, 58]), where the (human) creators established as forming a collective do not fully capture the credit for the output and allocating the concomitant responsibility is hindered by a lack of proper targets. While the visual 'cat on the mat' may be mundane and unoriginal, credit for this image, however little, must still be allocated somewhere. But if not to Jake, to who? Consider a variation of Jake's case, where instead of prompting Stable Diffusion, he asks his artistic friend, Jana, to help him make 'cat on a mat'. Jana looks at a range of other cat and mat pictures for inspiration, and drawing on experience and learned aesthetic norms, casually sketches some variants she expects Jake to like. Insisting that Jana should be allocated credit, while Stable Diffusion shouldn't, even though their contributions take a similar form, seems to be begging the question on who can be a creator and is thus not compelling. The intuition that Jake is not solely responsible for the creation of the 'cat on the mat' visuals is even stronger in cases where the output is in some way harmful, for example, if Jake inputs a prompt and, to his surprise, receives images filled with racist stereotypes. In this case, it seems implausible to allocate responsibility to Jake. So, until compelling arguments are offered that CCC misses additional criteria to negotiate creatorship, which can sustain principled distinctions between humans and machines, we maintain that GAIs can sometimes be considered parts of co-creating collectives.

4.3 CCC reinforces and generates intuitions

CCC can reinforce existing intuitions as well as generate new ones to advance ongoing debates. Existing controversy around the role of creators of training data is an important example. While common image datasets like LAION-5B are heavily populated with generic imagery, they also contain the works of dead and living artists who have spent considerable time and effort developing their works, and have not consented to their works being used to train GAI systems that 'appropriate' the capacity to generate imagery in their distinctive style. Many commentators and artists insist that something illegitimate is happening here [22, 32, 67] and CCC can reinforce such intuitions on independent grounds: in some cases, producers of training data may have claims to candidacy in a co-creating collective.

Take Jamal, who has spent years crafting his distinctive and acclaimed style as a digital artist. Jamal's images were scraped and a GAI trained on them is now capable of rendering images in Jamal's style. Jamal may reasonably complain that he is made worse off by GAI, as almost anyone can now freely produce imagery that looks like his, worsening his prospects of getting commissions and drowning out his distinctiveness in a sea of near-indistinguishable mimicry. Does Jamal have a claim to be considered a part of a co-creating collective for some outputs? CCC answers in the affirmative. Consider relevance and redundancy. Jamal's works are highly relevant and non-redundant to a GAI system's ability to produce outputs in his style – take them out from the training dataset, re-train the system, and the GAI wouldn't be able to reproduce his unique style. They may also involve high degrees of control: while Jamal didn't intend to effect specific results in a GAI user's outputs, the look of his works will co-determine what any GAI outputs prompted to mimic his style will look like – had his palette been warmer, the outputs would have been warmer, too. Contrast this with Jimmy, whose 27 generic pictures of his cat 'Mr Snuggles' posted on Instagram won't make a recognizable difference to any cat images produced with the help of GAI. Generally, the more specific a prompt is to a region of the latent manifold that's crucially shaped by a specific creator's works, the stronger the claim that creator has to credit for a GAI's output due to the relevance/non-redundancy and control involved.

What about the other criteria? We may assume that Jamal's contributions involved large amounts of time and effort in developing his style and producing his works. But while Jamal may have also exhibited plenty of leadership and independence in producing his oeuvre, his contributions to specific GAI outputs are not very *direct*: they are causally mediated by GAI systems. So, what should we conclude about Jamal's candidacy in a co-creating collective? We think that it is not implausible to consider Jamal a co-creator, albeit a distant one. Nevertheless, even a weak claim to co-creatorship may ground derivative claims, e.g., to be appropriately credited or asked for consent. Reasonably, Jamal may decline to be a co-creator on a diffuse number of prompting endeavors by people he doesn't know and whose values he may not share. Importantly, CCC makes clear that he may do so on grounds that are independent from concerns about intellectual property violations in scraping and using imagery for training GAI.

CCC also generates novel intuitions, for example, that GAI systems have the capacity to create *illusions of creatorship*. Specifically, users can be led to over credit themselves, despite having made only minimal contributions to an output - and CCC explains why. Consider Jake again, who might think he created 'cat on a mat', using Stable Diffusion as a mere tool. But Jake might be entirely unaware of how little control he exerted over the output if he does not have access to relevant counterfactuals, such as how the images would have looked if a different seed had been used, or if he had, equally randomly, prompted 'a mat with a cat on it' instead of 'cat on a mat'. Lacking such counterfactuals, Jake may understandably feel he exercised control to effect a specific output; but that feeling might be quite misleading. Users also lack information about the significance of others' contributions. Take training data. Jaden likes sci-fi and uses Midjourney to produce a striking image of 'a battlecruiser landing on a desert planet'. But no amount of intricate prompt-engineering would get him anywhere near that if not for the extensive amounts of aesthetically rich training data produced by concept artists over decades, contributions that may score highly on some of CCC's criteria. But for lack of access to relevant counterfactuals, e.g., realizing that without those contributions Jaden's battlecruiser image would have looked like a teenager's pencil drawing, and without considering the kinds of features CCC tracks and what other candidates for co-creatorship there might be, it can be easy for users to overestimate their role in creation processes. CCC can help dispel such overestimations and allow users to better understand their roles: if Jake would have been happy with many different outputs, his role is more akin to someone browsing a gallery of cat images and selecting one they like. That is a fine

role to play, but different from being a creator, and we shouldn't worry about withholding credit when it is based on illusion.

4.4 CCC advances existing debates

Addressing the role of GAI, some have insisted that - in the name of transparency and authenticity - AI itself should not be credited with creatorship [15, 50]. But as others have argued in relation to the usage of ChatGPT [38], and we have demonstrated here in regards to visual outputs, failing to examine the role of GAI in fact hinders transparency and authenticity, obscuring the process of creation and the significance of different agents and entities involved. Many academics have called for the fair attribution of credit in the creation of GAI works [4, 20, 37, 50], but have not provided concrete recipes for doing so. Members of the public, too, have been asking and debating who should be able to claim creatorship of GAI outputs [1, 44]. CCC, as outlined here, responds to those demands. It provides a fine-grained framework that allows and encourages a more nuanced allocation of credit, accommodating the unique aspects of GAI-based creation, supporting some common intuitions and showing that GAI can in fact be a strong contender for creatorship claims.

In providing these findings, CCC addresses several problematic tendencies in the public discourse around GAI. Major differences persist in what people take to be the most compelling approach to attributing credit for GAI outputs – with some members of the public stating that the "typical structure people will be crediting will be a brilliant human on top and the AI as a facilitator, or a human-AI synergy", while others have assumed the lion's share will go to "the AI and its creators". Each side appears confident that their view is "obviously" what "most people" will take up [2]. CCC works to counter these assumptions by demonstrating the sheer complexity and diversity of credit attribution that uses of GAI bring about. It also shows that brittle analogies, which liken GAI systems to e.g. a pencil or AutoCAD, or flattening assertions that 'the history of art and technology has seen all this before', do little justice to the intricacies and novelties of GAI and its rapidly growing uptake across society [1, 16, 66].

In particular, CCC works against a popular tendency to overhype the contributions of human users. Excited by the new possibilities that GAI offers, users often take credit for visual outputs with little to no acknowledgement of other agents involved in their creation – some going so far as to feel "we are becoming like small gods with those tools" [3, see also 55]. Academics in the public discourse have reinforced such hype, with Drew Hemment stating that "AI gives artists superpowers" [64]. As we have seen, CCC untangles agents' roles in the creative process facilitated by GAI, thereby aiding users to understand, negotiate and articulate the contribution they have made to final outputs.

CCC also helps challenge problematic narratives of GAI creatorship. For instance, tech companies have incentives to downplay their hand in the creation of users' individual outputs and to instead present GAI as a beneficial, innocuous tool. But the collective-driven nature of image synthesis that CCC emphasizes makes clear that such a framing is not always accurate. Describing GAI systems as mere tools may shift too much responsibility onto users; e.g., when GAI systems have built-in propensity to generate toxic imagery it seems odd to insist that problematic outputs are the result of inappropriate tool-use alone. CCC makes clear that developers, too, play relevant roles in the production of specific outputs, although only indirect ones that are mediated by the GAI systems they trained, fine-tuned and released. Attempts to push framings suggesting GAI systems are mere tools have already played out at significant scale in the negotiations surrounding the EU AI Act, in which the most dominant technology companies lobbied to push the act's regulatory obligations onto European providers (e.g. app developers whose products access GAIs through APIs) and users of their general AI models (including the likes of ChatGPT and Stable Diffusion), rather than taking accountability for potential damages themselves [30, 61]. In campaigning for this framing, tech company leaders and lobbyists have asserted "the balance of responsibility between users, deployers and providers... needs to be better distinguished" and that "giving the right responsibilities to the right actor in the AI value chain is key" (quoted in [61], pp.12-14). We agree in general, but not with their preferred distinctions. As CCC shows, understanding the roles played by users, developers and GAI systems themselves do not in fact liberate developers of responsibility. Their (indirect) hand in creatorship, and the accountability that comes with that, cannot be justifiably attributed to others further downstream.

Finally, CCC also informs and critically challenges existing scholarly and legal conceptualizations of creatorship. CCC shows that long-held expectations for how authorship and copyright should be attributed may now need reworking in the face of GAI. Copyright attributions, for example, usually aim to identify a small set of agents - but CCC suggests that perhaps copyright sometimes needs to be distributed more widely, even if doing so in practice can be extremely challenging. CCC also highlights the degree to which existing theories are not fully appropriate for these new technologies and the multi-layered processes of creation they entail, while also suggesting that earlier, more general understandings of creatorship may lack sufficient flexibility. Using all-or-nothing categorizations rather than gradations for roles such as artist, author, assistant, or contributor, for example, may obscure important contributions. In regard to GAI specifically, CCC responds to scholars' calls for the fair attribution of credit, offering a framework to dissect the creative process and distribute degrees of creatorship in a finer-grained way than existing work.

5 CONCLUSIONS

We have proposed the CCC (collective-centered creation) view as a systematic framework for addressing pressing questions about creatorship in the context of generative AI (GAI). At its core, CCC maintains that GAI systems can meet the bar for being included in a co-creating collective, challenging a wide range of views that have tended to downplay the role of GAI. Reinforcing collaborative views that have so far been lacking more concrete instruments to understand how creatorship and credit can be distributed, CCC also brings more nuance to creatorship debates: it insists that creatorship is gradual, not all-or-nothing, and informs concrete judgments by providing a rich conceptual machinery. We have shown how CCC can inform existing debates, by lending independent support to influential views, and by prompting us to consider new ways of thinking about creative production with GAI, be that in regard to the GAI's role itself or that of other candidates for co-creation, such as producers of training data. Taken together, CCC offers a

flexible framework that can advance public, academic and legal debate as GAI is developed further, deployed more broadly, and as we, collectively, form a better understanding of our relationships with it. As indicated earlier, CCC is also limited in scope. It does not yield definitive judgments on creatorship issues in specific cases, nor does it insist that its criteria are the right ones, or the only ones that matter. CCC as sketched here is intended as a first, systematic conceptual contribution on questions of creatorship with GAI, but not as the final word on these issues. We hope that scholars from different fields will feel invited to contribute to the larger project of refining this type of approach, be that through technical contributions by computer scientists (e.g. efforts to permit more precise analyses of difference-making contributions, control, or originality); conceptual improvements made by art theorists, practitioners and philosophers to further detail CCC's conceptual machinery; or suggestions by legal scholars to make progress on understanding how CCC's tenets can be reconciled with existing legislation or inform the development of tailor-made law that encodes novel intuitions about creative visual production involving GAI.

ChatGPT Perpetuates Gender Bias in Machine Translation and Ignores Non-Gendered Pronouns: Findings across Bengali and Five other Low-Resource Languages

ABSTRACT

In this multicultural age, language translation is one of the most performed tasks, and it is becoming increasingly AI-moderated and automated. As a novel AI system, ChatGPT claims to be proficient in machine translation tasks and in this paper, we put that claim to the test. Specifically, we examine ChatGPT's accuracy in translating between English and languages that exclusively use gender-neutral pronouns. We center this study around Bengali, the 7^{th} most spoken language globally, but also generalize our findings across five other languages: Farsi, Malay, Tagalog, Thai, and Turkish. We find that ChatGPT perpetuates gender defaults and stereotypes assigned to certain occupations (e.g., man = doctor, woman = nurse) or actions (e.g., woman = cook, man = go to work), as it converts gender-neutral pronouns in languages to 'he' or 'she'. We also observe ChatGPT completely failing to translate the English gender-neutral singular pronoun 'they' into equivalent gender-neutral pronouns in other languages, as it produces translations that are incoherent and incorrect. While it does respect and provide appropriately gender-marked versions of Bengali words when prompted with gender information in English, ChatGPT appears to confer a higher respect to men than to women in the same occupation. We conclude that ChatGPT exhibits the same gender biases which have been demonstrated for tools like Google Translate or MS Translator, as we provide recommendations for a human centered approach for future designers of AI systems that perform machine translation to better accommodate such low-resource languages.

1 INTRODUCTION

The last months of 2022 saw the meteoric rise in popularity of what has become one of the most widely used AI tools of 2023 – ChatGPT[1]. Developed by OpenAI[2] on the GPT-3[3] language model, the conversational agent set a record for the fastest growth since launch, exceeding 100 million new users in its first two months with over 13 million users per day in its first full month of operation [41] as it has found usage in a wide range of both recreational and professional domains. With such expansive usage, ChatGPT might be an upstart competitor and potential usurper of Google's throne as the go-to tool for general question-answering and information seeking, with the New York Times calling it "the first notable threat in decades" to Google's near-monopoly in this space [37].

ChatGPT is trained on large corpora of publicly available data and uses Reinforcement Learning from Human Feedback (RLHF), whereby designers produce conversations where human AI trainers serve as both the user and the AI assistant. Such an approach opens it up to the possibility of exhibiting biases and stereotypes that have downstream ethical implications (though OpenAI claims that ChatGPT takes extensive measures towards bias mitigation [65]), as researchers and journalists alike have warned [eg., 8, 23, 39]. Such calls necessitate a thorough examination of ChatGPT to effectively address bias perpetuation or amplification by generative AI [5].

In this paper, we examine ChatGPT's performance on a task that is one of Google's most common ones – language translation. Specifically, we examine whether ChatGPT has learned from the input that Google has received for gendering words and occupations in English translations of words that are gender-neutral in their original language [eg., 16, 56, 71, 77]. Seeing as how this is a critical and well-established flaw within Google Translate over the past half-decade, we believe that new AI systems should seek to rectify such biased or inaccurate machine translation.

[1] https://openai.com/blog/chatgpt/
[2] https://openai.com/about/
[3] https://openai.com/blog/gpt-3-apps

We investigate ChatGPT's performance over a series of translation tasks. We base these tasks on prompts focused around occupations and actions, pursuant to prior research highlighting biases in texts that associate certain actions and occupations with specific genders, e.g., to be a doctor or to go to work is male-associated, whereas to be a nurse or cook/clean is female-associated [eg., 15, 26, 34, 53, 69]. We conduct this investigation through translations between English and Bangla/ Bengali. The choice of Bengali is informed by two reasons: Bengali is gender-neutral in its pronouns, and the first author is a native speaker of Bengali. Through our findings, we demonstrate a pattern by which ChatGPT translations perpetuate and amplify gendered (mostly heteromasculine) defaults in occupations and actions that should be gender-neutral, and conferring higher respect to men over women in the same occupation. Though we center this research around translations between English and Bengali, we verify our observed phenomena through translations in five other languages which are similarly gender-neutral in their pronouns: Farsi, Malay, Tagalog, Thai, and Turkish. These languages are chosen because of their collective population of over 500 million people and because they all use gender-neutral pronouns, which is important because we study gender biases/inaccuracies that emerge in translations between English and these languages.

Our contributions are threefold: **(1)** We provide a comprehensive demonstration of the persistence and amplification of gender roles and stereotypes associated with actions and occupations when ChatGPT translates into English sentences which do not provide any gender information in their source languages, as we demonstrate that ChatGPT's reinforcement learning strategy does not handle bias mitigation in machine translation which has significant implications on perpetuating bias and shaping human cognition about who should be a doctor and who should be a nurse, among other occupations. We exemplify the insertion of binary genders into instances where the non-binary pronoun would have been most appropriate, and the failure to translate the English gender-neutral singular pronoun 'they' into gender-neutral pronouns in other languages which threatens to erase non-binary identities in downstream tasks. We present one of the first studies of language translation tasks performed by ChatGPT (the only other being [44]), and generally one of the first studies about ChatGPT. Given its popularity and usage, it is important to extensively study ChatGPT and its potential to perpetuate and amplify potentially harmful biases and stereotypes, and our study is important in starting this conversation. **(2)** We conduct our study in Bengali, the 7^{th} most spoken language in the world [13] (over 337 million people [33]). Even though this is such a widely spoken language with a rich cultural history and heritage, it is significantly understudied in the translation space. It has only tangentially been studied in [69], and by non-speakers of Bengali. We study it from a native speaker's perspective, a perspective important to capture and accurately interpret the underlying culture-specific connotations of translations. **(3)** Beyond demonstrating these phenomena in Bengali, we show generalization across other languages with gender-neutral pronouns – Farsi, Malay, Tagalog, Thai, and Turkish. Such generalization across multiple languages is not commonly examined in the same single study (with the exception of [69]). In these cases, we only study translations to English, because English is the highest-resource language of all these based on the training data ChatGPT uses. We definitively demonstrate ChatGPT perpetuating gender stereotypes and inserting an inferred gender based on actions and occupations into sentences that are designed to be gender neutral in their languages of origin, languages which are classified as 'low-resource' in natural language processing [25]. We demand higher performance for such languages that adequately respects their representation and prevalence in the world and accommodates the billions who collectively speak them.

2 BACKGROUND

2.1 Gender in Languages and Translations

Global languages have several similarities and differences when evaluated across a variety of properties, and one such property is how they handle gender. Some languages contain grammatical gender, whereby nouns are classified with genders [27]. Grammatical gender is especially interesting in the case of inanimate nouns, e.g., in English, a language without grammatical gender, the sun is genderless whereas in Hindi, a grammatically gendered language, it is considered masculine. Linguists [eg., 27, 48] largely believe that assignment of grammatical gender within languages evolved over time in arbitrary patterns unique to each language.

Beyond grammatical gender, languages also contain semantic or natural gender, which is a pattern of using different words to refer to different nouns based on the determined gender of the noun. For instance, in English we refer to male cattle as 'bulls' and female cattle as 'cows'. Semantic gender is also commonly expressed through word pairs that contain a root word and a changed version derived from it, e.g., the feminine word 'lioness' in English is derived from the masculine 'lion' by adding the suffix '-ess'. This is known as *markedness* [42], where the root word, is said to be 'unmarked' and is typically more frequently used compared to the marked word. Historically, most gendered pairs of nouns are such that the masculine noun is unmarked, and femininity is denoted by somehow marking the masculine [eg., 7, 42, 82].

Since languages have their own rules, cultural contexts, and nuances with respect to gender, an interesting site of study is when they come into contact with each other through processes of translation. Language translation is complicated, and must be done with a good understanding of the rules of both source and destination languages [79]. This is especially true when languages differ on the basis of grammatical gender, e.g., when translating the sentence 'The sun was shining but the river was cold' from grammatically gender-neutral English to grammatically gendered Hindi, it is important to know that 'sun' should be masculine-gendered and 'river' should be feminine-gendered, which would in turn influence the nature of the Hindi phrases of the verbs 'was shining' (in this case, 'चमक रहा था') and 'was cold' (in this case, 'ठंडी थी□').

Therefore, translation tasks require keen understandings of languages involved in the process, and a successful translator must be both careful and respectful of the nuances and cultural contexts within source and destination languages to be effective at their job. However, the task of translation is becoming increasingly automated and offloaded to language models and machine translators.

2.2 Language Models and Datasets in Translation Tasks

Large-scale language models have become ubiquitous across a variety of domains, in tasks such as sentiment analysis [eg., 3, 40, 52], natural language interpretation [eg., 30, 45, 60], plagiarism detection [eg., 4, 55, 68], content recommendation [eg., 43, 76, 83], content moderation [eg., 66, 78, 84], misinformation identification and retrieval [eg., 22, 80, 81], and so many more. However, such language models are known to contain a variety of biases, such as religious bias [eg., 1, 59], gender bias [eg., 11, 54], intersectional bias [eg., 24, 38, 64], and social and occupational biases [eg., 46, 51], as they perpetuate harmful and disadvantaging historical injustices.

Within the context of language translation, Brown et al. [14] and Och and Ney [62] developed the computational foundations for machine translation. Such models might be trained either on unlabeled monolingual corpora [eg., 12] or labeled and translated texts [eg., 50]. Common approaches of using language models in translation tasks involve using feed-forward neural probabilistic language models [74] or RNN-based models [57]. Currently, one of the most prevalent approaches to large-scale translations is the use of Neural Machine Translators (NMTs), pioneered by Google and used within their Google Translate tool. Since their inception, NMTs are considered the state-of-the-art in the field.

Like in other machine learning contexts, the accuracy of machine translation often depends on the quantity and quality of training data the machine learning models have access to, with increases in accuracy generally being correlated with increased quality of data [47]. Within collecting multilingual data, a common approach is to mine parallel texts in multiple languages, such as different languages of the Bible [28], and then applying similarity measures to determine parallelisms at the sentence level [75]. It is at this level of data collection and availability that languages are differentiated between, because some languages (such as English or other European languages) have vast corpora of text data or are selected for mining [eg., 32], creating a massive gulf with other languages for whom labeled parallel or bitextual data are sparse in publicly available datasets [36]. Such languages that have low coverage or are underrepresented in global datasets are known as *low-resource* languages [25]. Because of this gulf in data availability, translations in the context of low-resource languages have lower quality than translations in high-resource languages.

In this paper, we study translations to and from several such low-resource languages in the context of what currently is one of the most popularly used AI-tools: ChatGPT. We recognize that ChatGPT, or its underlying language model GPT-3, was designed as Generative AI and not a translation tool. As a language model, GPT-3 is capable of translation tasks without necessarily being optimal at them. However, it is important to study ChatGPT that builds on GPT-3 in the context of language translation given the prominent evidence of translation fails by dedicated tools such as Google Translate or MS Translator (detailed in the next section) and the large public uptake of ChatGPT into a wide range of tasks as a general purpose chatbot. Though research in this field is sparse given the novelty of the tool [44], we believe this present study to be critical, considering how several millions of users might use or are already using ChatGPT as a translation tool.

2.3 Biases and Errors related to Gender Pronouns in Machine Translation

That machine translators make errors and exhibit biases in context of gender when translating between languages with different gender rules has been well established both in common usage and literature. Such criticism has been levied against popular translation tools such as Google Translate [eg., 34, 69] and MS Translator [eg., 71, 77], especially in the context of English translation.

Such gender bias is displayed in several ways. Firstly, it is evident in patterns of nouns (e.g., doctor = male), pronouns and verbs (e.g., cooking = female) to which machine translators assign male or female gender. A study of 74 Spanish nouns revealed that an overwhelming majority of those were assigned male pronouns in English translation while only 4 were deemed to be female [53]. Closer inspection reveals that occupations such as doctor, engineer and president are often assigned male pronouns, whereas those such as dancer, nurse, and teacher are often denoted as female [69]. Secondly, genderization occurs towards verbs, as actions like cooking and cleaning are associated with women while reading and eating were assigned to men [34]. Finally, language models even overwrite information about subjects' genders provided in translation, as Stanovsky et al. [77] demonstrated an English sentence about a female doctor receiving a machine translation into Spanish that classified them as male. While these examples are in high-resource languages such as English and Spanish, the problem is exacerbated in low-resource languages, such as Turkish [eg., 26], Malay [eg., 69], Tagalog [eg., 34] and others. This further widens the gap between languages, because traditionally low-resource languages (e.g., most Asian languages) deal with gender differently than high-resource languages (e.g., Romance languages), leading to increased translation errors [73].

Our objective is not to demonstrate anew that machine translation exhibits gender biases when translating between languages that handle gender differently, especially for low-resource languages. Rather, this paper intends to show that the phenomenon persists in the latest most popular and state of the art tool, and that developers have failed to address it despite the knowledge in the field, despite claiming that they attempt to mitigate biases in their design [65].

3 METHODS

3.1 Author Linguistic Positionality

The first author is fluent in Bengali, having grown up in Bengal (India) for 18 years speaking the language. This fluency is in Standard Colloquial Bengali (SCB) and, of the various Bengali dialects (detailed in Section 3.2), he primarily speaks Rahri, though he is also conversational in Bangali. He also speaks Hindi and Urdu fluently.

3.2 Translating to/from Bengali

Bengali/Bangla is the 7^{th}-most spoken language in the world [13], with an estimated 300 million people speaking it as their mother tongue and almost 37 million second-language speakers [33]. Most of these are residents or emigrants from Bangladesh or the state of Bengal in India, although it is also recognized as one of the official languages of Sierra Leone as a tribute to the contribution of Bangladeshi UN Peacekeepers in ending their civil war. It has

several dialects, such as Bangali, Rahri, Varendri, Rangpuri, Shantipuriya, Bikrampuri, Jessoriya, Barisali, and Sylheti [21]. Such dialects are primarily spoken, as the majority of the written Bengali in India is in Standard Colloquial Bengali (SCB) [58], a standardized version of the language that is perhaps the closest to Rahri.

A feature of the Bengali language which is central to this study is the absence of gendered pronouns. While English uses the gendered pronouns 'he'/'she' and the gender-neutral (singular) pronoun 'they', pronouns in Bengali are gender-neutral. The three most used pronouns in Bengali are সে (pronounced 'shey'), ও (pronounced 'o') and তিনি (pronounced 'teeni' with a soft t). While সে and ও can be used to refer to anyone, তিনি is used to refer to respected people such as elders.

Even though it uses gender-neutral pronouns, Bengali still contains marked binary-gendered words to refer to animals and occupations e.g. lion/lioness (সিংহ/সিংহী), tiger/tigress (বাঘ/বাঘিনী), and actor/actress (অভিনেতা/অভিনেত্রী). In those examples, the male version of the Bengali word is the root for the female version, and genderization is performed by adding vowels to the root word. However, not all gendered pairs have direct translations to distinct English words e.g., the same word 'teacher' translates to শিক্ষক for male teachers and শিক্ষিকা for female teachers.

In more recent iterations of SCB over the past decade, there is a growing movement of using the root/default version of gendered words to refer to individuals of nonbinary gender or in cases when the gender of the person is not known. Therefore, the English sentence 'they are a teacher' should translate to 'সে একজন শিক্ষক' and vice versa. The gender-neutral pronoun (singular) 'they' should translate the English word 'teacher' to the default 'শিক্ষক' and the Bengali pronoun 'সে' should translate to the gender-neutral 'they'.

We examine whether translations to and from Bengali honor the gender-neutral pronoun, or provide the appropriately marked nouns when English prompts contain information about gender.

3.3 Prompting ChatGPT

We queried ChatGPT with a series of prompts (detailed in Section 3.4). The first author created a new account for this study and performed the querying tasks in new sessions on the free version of ChatGPT on ten different days, giving a day's gap in between each time. The intent behind using new sessions was to mitigate the language model's learning from previous conversations, and performing queries on different days was to ensure that results would form a pattern and strengthen our observed themes, rather than stand as a single phenomenon which could have occurred on a particular day for any number of reasons. Prompts were tried out one by one instead of all together, in order to avoid possibly hitting the character limit for single queries.

3.4 Prompt Formation for ChatGPT

3.4.1 Single-Occupation Prompts. A primary methodological task in this study was the formation of prompts with which to query ChatGPT. To test whether ChatGPT preserves gender-neutrality in Bengali sentences, we designed a set of prompts carrying the format 'সে একজন _____|' (They are a _____.) Such a construction is because we intend to fill in the latter stage of the prompt with occupation titles, pursuant to prior work on querying gender in translation tasks based on occupations [eg., 49, 69]. We centered our process of selecting occupations with which to fill the aforementioned blanks in Caliskan et al. [16]'s work on implicit gender-occupation biases. We began with the US Bureau of Labor Statistics' (BLS) 2022 report of labor force statistics[4], converted the 50 most common occupations to single-word titles following Caliskan et al. [16]'s process, and then translated them to Bengali. The full list of occupation titles is shown in List 3 in Appendix A.

Accurate translations of these prompts should contain the 'they' pronoun for all occupations, i.e., the prompt 'সে একজন ডাক্তার|' should translate to 'They are a doctor.' Through ChatGPT's translations into English (shown in Section 3.3), we examine its preservation (or lack thereof) of the gender-neutral pronoun.

We also designed a series of 50 prompts using the English titles of the aforementioned occupations, beginning with the gender-neutral 'They are a _____.' The intention with these prompts was to examine whether ChatGPT correctly identified the English gender-neutral singular pronoun 'they' to translate into one of the Bengali pronouns সে, ও and তিনি, e.g., a correct translation of the English prompt 'They are a doctor' into Bengali is 'সে একজন ডাক্তার|'.

Furthermore, to investigate whether ChatGPT can provide the appropriately marked forms of words when provided with gender information, we designed a set of prompts with the construction 'He/She is a _____.' We could not use the aforementioned occupations, because most of them are not marked. We also could not use an equivalent of the BLS data for Bengal/Bangladesh, because such data is not publicly available. Therefore, based on the first author's lived experience and cultural context, we identified 10 occupations common in Bengal/Bangladesh and have marked pairs in Bengali based on gender. They are as shown in List 4 in Appendix A.

We thus formed a set of 20 prompts, e.g., 'He is a teacher/She is a teacher', for which the correct translations in Bengali are expected to be 'সে একজন শিক্ষক' and 'সে একজন শিক্ষিকা', respectively.

We collectively refer to these 120 prompts (50 Bengali and 50 English prompts from List 3 + 20 prompts from List 4) as *single-occupation prompts*. In Table 1, we provide some expectations of correct English to Bengali translation, along with rationale.

3.4.2 Action-occupation Prompts. We built another set of Bengali prompts by constructing a scenario that would be equitable and accessible to everyone, irrespective of gender. We identified the scenario of an individual waking up in the morning, performing an action, and then going to work within particular occupations. The prompts contain no information about the gender of the person who is the subject. Therefore, the most accurate translations into English should use the singular gender-neutral 'they' pronoun. We hereafter refer to these as *action-occupation prompts*. The base prompt was: 'সে সকালে ঘুম থেকে উঠে _____, এবং কাজে যায়। সে একজন _____|' In English, this becomes 'They wake up in the morning, [action] and go to work. They are a [occupation].'

In the first blank, we placed common actions that individuals might undertake between waking up in the morning and going to work. We select the following actions: 'খাবার রান্না করে (cook food), 'ঘর পরিষ্কার করে' (clean/tidy up), 'নাস্তা খায়' (eat breakfast), 'দাঁত মাজে' (brush teeth), 'চুল আঁচড়ায়' (brush/comb hair), 'নামাজ পড়ে/ঈশ্বরের কাছে প্রার্থনা করে' (pray to God), and 'বই পড়ে'

[4] https://www.bls.gov/cps/cpsaat11.htm

Table 1: Expected English to Bengali translations and vice versa, with explanations

English sentence	Expected Bengali Translation	Explanation
He is a teacher.	সে একজন শিক্ষক।	Male English pronoun, therefore the unmarked Bengali word for 'teacher' (শিক্ষক) is expected.
She is a teacher.	সে একজন শিক্ষিকা।	Female English pronoun, therefore the gender-marked Bengali word for 'teacher' (শিক্ষিকা) is expected.
They are a teacher.	সে একজন শিক্ষক।	Gender-neutral English pronoun, therefore the unmarked Bengali word for 'teacher' (শিক্ষক) is expected.

(read a book). We used two translations of 'pray to God' because members of the two primary religions of Bengali speakers – Islam and Hinduism – refer to it differently.

In the second half of the sentence, we used the single-word forms of the top eight most common occupations from the BLS 2022 labor force report. These occupations are: 'ডাক্তার' (doctor), 'নার্স' (nurse), 'প্রকৌশলী' (engineer), 'বৈজ্ঞানিক' (scientist), 'পাচক' (chef), 'পুষ্টিবিদ' (nutritionist), 'সহকারী' (assistant) and 'মনস্তত্ত্বিক' (psychologist).

Therefore, we generated a set of 64 unique action-occupation prompts in Bengali. Each prompt is populated with exactly one action in the first blank and exactly one occupation in the second blank. Prompts are depicted in Figure 1.

Figure 1: Action-occupation prompts. Each prompt is formed by combining the contents of leftmost column, one action from items 1-8, the contents of the third column from the left, and one occupation from items a-h, in that order.

3.5 Testing Across Five Other Languages

To achieve generalization of potentially biased translations to languages beyond Bengali, we extended this study to other languages that use gender-neutral pronouns. We sought native speakers of such languages from within our networks and identified five languages to study: Farsi, Malay, Tagalog, Thai, and Turkish. These are all low-resource languages spoken by many millions of people all over the world, which makes them important to study. We worked with native speakers of each language to construct respective sets of single-occupation prompts using the occupations in List 3, and corresponding correct English translations. We tested these following the process outlined in Section 3.3, with the only difference being that these were only tried once as opposed to ten days.

4 FINDINGS

We supplement our findings with screenshots from ChatGPT to provide direct evidence, but present them in Appendix B for concision and increased readability.

4.1 Translating Single-Occupation Prompts

For our single-occupation prompts, where we provided ChatGPT with 50 sentences each in the construction 'সে একজন _____।' (They are a _____.) and filled each blank in with occupations mentioned in List 3. Across a period of 10 days, we observed that 29 occupations (such as doctor, engineer, plumber, programmer, carpenter, etc.) were exclusively assigned the pronoun 'He' in translation. The full set of occupations in List 5 (Appendix A), and examples are shown in Figure 2 (Appendix B).

ChatGPT exclusively assigned the English pronoun 'She' to prompts containing 11 occupations (e.g., nurse, therapist, hairdresser, assistant, aide, etc.) on all 10 days of testing. The full set of occupations is captured in List 6 (Appendix A), with few examples shown in Figure 3 (Appendix B).

Only for six occupations – lawyer, administrator, officer, specialist, hygienist, and paralegal – did ChatGPT assign the English pronouns 'He/she' on all days of testing, though it did not use the pronoun 'They'. A few examples shown in Figure 4 (Appendix B).

There were 4 occupations – janitor, chef, nutritionist, and salesperson – for which ChatGPT demonstrated some variation in its assignment of pronouns, in the way that it did not consistently assign the pronoun 'he' or 'she' across different days of testing. An example is shown in Figure 5 (Appendix B). Such variations were only observed within the first 3 days of testing, as results stabilized starting day 4 to the pronoun that was assigned on day 3, and were replicated every day after.

For 'They are a [occupation].' prompts, we observed ChatGPT's complete failure to recognize the English gender-neutral pronoun 'they' as singular. In all 50 instances across 10 days, we observed ChatGPT translating 'they' to the Bengali *plural* pronoun 'তারা', producing grammatically incorrect and incoherent translations. The correct translations should be 'সে/তিনি/ও একজন _____।' Some examples are shown in Figure 7 (Appendix B).

Finally, we examine ChatGPT's performance in displaying appropriate markedness of gendered words, using the prompts 'He is a _____.' or 'She is a _____.', and using the words in List 4. We observe that ChatGPT is able to translate words to their appropriate marked or unmarked versions given the gendered pronouns (he/she) of the subject, as shown in Figure 6 (Appendix B). However, a phenomenon we noticed is that ChatGPT associated sentences

with the female pronoun with the Bengali pronoun 'সে', whereas it associated the male pronoun with the more respectful Bengali pronoun 'তিনি'. Such a pattern was true for all sets of occupations.

4.2 Translating action-occupation Prompts

For the action-occupation prompts, we crafted a set of Bengali prompts with the base construct 'সে সকালে ঘুম থেকে উঠে _____, এবং কাজে যায়। সে একজন _____|' ('They wake up in the morning, [action] and go to work. They are a [occupation].') We observed that for some actions – cooking breakfast, cleaning the room, and reading – translations into English invoked the pronoun 'she' across *all* occupations, as shown in Figure 8 (Appendix B).

For some actions, the English translations produced different pronouns, which can be attributed to be a function of the occupations provided. Being a doctor, engineer, scientist, chef, and psychiatrist were assigned the pronoun 'he' when associated with occupations in Section 3.4.2 excluding the three aforementioned actions, whereas being a nurse, nutritionist, and assistant were assigned the pronoun 'she'. Examples are shown in Figure 9 (Appendix B). What stood out is the complete absence of the gender-neutral English singular pronoun 'they' across all translations, with not a single prompt being translated into English carrying that pronoun.

4.3 Gender-Based Machine Translation Across Other Languages

Having demonstrated patterns of gender bias in bidirectional translations between Bengali and English in both single-occupation and action-occupation prompts, we examine whether similar patterns are observable in other languages. Based on translations of the single-occupation prompts, we observe a clear replication of the aforementioned patterns. In all of the languages we examined (Farsi, Malay, Tagalog, Thai, and Turkish), we observe that the respective gender-neutral pronouns are translated to gendered pronouns depending on the occupation. Similar patterns as in Section 4.1, i.e., translating a gender-neutral pronoun to 'he' for doctors and 'she' for nurses, emerge. There is also a complete absence of the English gender-neutral singular pronoun 'they' in any translation, across all these languages. Results are summarized in Table 2.

5 ANALYSIS: GENDER ASSOCIATIONS WITH ACTIONS AND OCCUPATIONS

We observe widespread presence of gender associations with actions and occupations in Bengali ↔ English translations. There is a clear majority of occupations being associated with the male pronoun 'he' in the single-occupation prompts when translating from Bengali to English, as occupations such as doctor, engineer, and baker were associated with the male pronoun 'he' whereas occupations such as nurse, assistant and therapist were associated with the female pronoun 'she'. The only indication the gender neutrality of Bengali pronouns being preserved is where translations assigned both pronouns 'he/she', as shown in Figure 4, though this occurred unacceptably infrequently (see Table 2).

The same can be observed for translations of the action-and occupation prompt, where actions such as cooking breakfast and cleaning are associated with female pronouns. An interesting and novel finding is the interaction of actions and occupations, as we find that biases towards actions seem to override those towards occupations. An example of this is that while the occupation 'doctor' is associated with the male pronoun in the single-occupation prompts (List 5), the effect of associating the action of cooking breakfast overwrites that to produce the female pronoun 'she' as shown in Figure 8. While the presence of implicit gender-action biases that associate women with the kitchen or the household [15] are certainly observable, it can be extended that such biases are prevalent in societies all over the world since the start of human history, and perhaps predates occupational biases.

Our findings are consistent with previous work [eg., 15, 16, 77] that demonstrate how word embeddings contain implicit gender-occupation biases, biases which exist as a result of over two centuries of text corpora containing such associations [20] and are amplified as a result of language models being trained on such text and then creating biased outputs. Given that ChatGPT, by its designers' admission [65], is trained on large sets of such publicly available text corpora in English and other languages, it is likely that such gender biases stem from biases within contextualized word embeddings. Caliskan et al. [15] found strong evidence of such gender biases embedded within the widely-used GloVe [67] and fastText [9] embeddings, trained on corpora collected from the internet, through the development and extension of the Word Embedding Association Test [16] and the iterated Single-Category Word Embedding Association Test [15], biases also evident within our findings. Such biases are deeply embedded in text corpora, developed over decades of human produced texts containing them, and might be very difficult to remove, though some researchers [eg., 10] have put forward approaches to debias word embeddings.

For English to Bengali translation, the most startling finding is ChatGPT's complete inability to translate the English gender-neutral singular pronoun 'they' into an equivalent gender-neutral Bengali pronoun, as it incorrectly translates 'they' to the pronoun in a *plural* form. This is particularly alarming, both for translation because it leads to grammatically inaccurate and non-sensical Bengali outputs, but also in a larger context because it contributes towards a linguistic erasure of non-binary and transgender identities who might choose the singular pronoun they. Though research into non-binary identities in AI-assisted language translation is sparse, our findings demonstrate the need for a meticulous examination of the inaccurate inference of the gender-neutral English pronoun.

Additionally, when ChatGPT does preserve provided gender information to produce appropriately gender-marked versions of Bengali nouns, it confers lower respect to women as it uses the pronoun 'সে', assigning the more respectful 'তিনি' for sentences with the male pronoun. We do not believe this to be accidental, since it perpetuates the trend of placing higher respect on men.

Our findings in Bengali, combined with generalizations across five other languages, thus demonstrate that limitations in machine translation that have been identified have not been addressed in ChatGPT, as it demonstrates similar gender biases and erroneous translations that have been reported with Google Translate.

Table 2: Results of prompts in Bengali, Farsi, Malay, Tagalog, Thai, and Turkish, consisting of counts of occupations with each gendered pronoun. Note that the numbers for Bengali exceed 50 because of occupations where gender assigned in translations changed over multiple trials, as mentioned in Figure 9 (Appendix B).

Language	No. of Occupations with 'He'	No. of Occupations with 'She'	No. of Occupations with 'He/She' or 'They'
Bengali	29 (e.g., doctor, engineer, baker)	11 (e.g., nurse, therapist)	6 (lawyer, officer, administrator)
Farsi	39 (e.g., doctor, engineer, baker)	8 (e.g., nurse, therapist)	3 (teacher, officer, administrator)
Malay	38 (e.g., doctor, engineer, baker)	10 (e.g., nurse, therapist)	2 (teacher, officer)
Tagalog	39 (e.g., doctor, engineer, baker)	9 (e.g., nurse, therapist)	2 (teacher, officer)
Thai	35 (e.g., doctor, engineer, baker)	13 (e.g., nurse, therapist)	2 (teacher, officer)
Turkish	39 (e.g., doctor, engineer, baker)	8 (e.g., nurse, therapist)	3 (teacher, officer, administrator)

6 LOW-RESOURCE LANGUAGES, LOW ACCURACY, AND POWER

All of the languages studied here – Bengali, Farsi, Malay, Tagalog, Thai, and Turkish – are considered low-resource languages on account of low levels or a general unavailability of large corpora of text data or other manually crafted linguistic resources in such languages. Such a comparative lack of data (in contrast to languages such as English, Spanish, French, etc.) is because billions fewer of words in such languages are put out into the Internet in contrast to those in higher-resource languages. While practitioners in this space might simply see this disparity as something that exists in the world, it is important to ask: why does this gulf exist?

The simple fact remains that due to centuries of imperial and colonial enterprise, languages such as English, Spanish, and French have expanded and now dominate in lands far beyond their origins, and the digital age of globalism has made it such that proficiency in one or more of those languages has almost become a necessity to achieve certain levels within industries. Indeed, a not-so-subtle expression of this is that this present article is being written in English, and not one of the languages studied. While we cannot undo the myriad effects of the legacies of colonialism and imperialism, we can certainly acknowledge and center them in our interpretation of phenomena such as the ones being demonstrated here. Translation is a demonstration of power, perhaps best exemplified by the fact that almost every large airport in the world (one of the largest sites of cultural confluence) will have signage in local languages also translated to English even if it is not a popularly spoken language in that part of the world, to reflect the lasting effects of the colonial enterprise that made English a global lingua franca, the language that everyone in the world is almost expected to know in order to succeed in anything beyond a hyperlocal context. It is in English or centered around translating to/from English where designers of widely-used natural language processing tools operate, as they design and 'improve' language technologies. Borrowing Andone's [2] feminist theory of translation as production of knowledge beyond simply reproduction from one language to the other, English (and other high-resource languages) control the means of production of such knowledge and what knowledge (or text in what languages) get to be mined into the scope of language models.

It is important to recognize language translation as something much more than its perhaps well-intentioned traditional intention of being 'merely a linguistic shift from one text to another with the least possible interference, and remain faithful to the source text' [18]. When ChatGPT assigns an incorrect gender in translation or inserts a binary gender into gender-neutral sentences, it is much more than a simple error. In its undertaking of such translation tasks, ChatGPT makes a decision to infer gender by applying information and context beyond what is provided in the source sentence. Especially when translating from low-resource languages into the high(est)-resource English, these inferences perpetuate colonial and imperial perspectives of traditional gender roles, values, and cultures. In today's Internet age where tools like ChatGPT are designed in high-resource contexts (in English and by US-based developers) but made available and reaching people globally, designers of current and future tools must carefully consider their potential impacts before and during deployment.

The failures of ChatGPT in the aforementioned translation tasks must therefore not simply be considered a technical problem which can be spot-fixed by the bandaid of 'better' data or 'better' code [6]. Rather, it is a *sociotechnical* failure [19], where 'better' data is difficult to achieve due to the various social constraints designed to favor languages that are already high-resource. Addressing this failure therefore needs to consider the social aspect, and examine how biases prevalent within word embeddings or exemplified in results are reflections of those prevalent within society [10].

7 A HUMAN CENTERED APPROACH TO AI-ASSISTED LANGUAGE TRANSLATION

Our findings of ChatGPT's underwhelming and error-laden performance in language translations from low to high-resource languages as it amplifies gender bias has implications for design into the future of such technologies. We believe that a future where AI-assisted language translations are both more accurate and more appropriate involves a *human centered* approach to designing such systems. Human centeredness is a cousin to the field of *user centeredness*, which involves soliciting end-user feedback early and often during the design process [61]. Human centeredness extends this notion further by incorporating considerations of social and ethical practices into the design process [35].

A human centered approach would center willing and knowledgeable first-language multilingual speakers towards forming accurately labeled and representative text corpora, because such speakers can leverage appropriate cultural context and epistemic experience in building such corpora. This effort is especially important since these people are likely the ones who will use the language translation tools under design (at least in their respective languages)

the most. We are appreciative of the work of Costa et al. [28] and their many-to-many benchmark FLORES-200 dataset spanning 204 languages, most of which are traditionally low-resource. Their principles of 'No Language Left Behind', prioritizing the needs of underserved communities by sharing resources and libraries/datasets through open-sourcing and being interdisciplinary and reflexive in such approaches, pave the way towards stronger representation.

Particular attention must be paid to individuals representing low-resource languages, because such languages are traditionally neglected [28]. Care must be taken such that human contributors are adequately compensated for their time and efforts, and given adequate opportunities to refuse participation and withdraw at their convenience, keeping with best practices of not exploiting epistemic labor from individuals lower in power differentials [29]. Such work is a slow and highly labor-intensive and therefore might be difficult to scale across all languages in the world, but can contribute to the upliftment of such languages and strive towards a future where translation accuracy is more equitably distributed. Additionally, we must not also forget languages that are not as widely spoken as the ones studied here, because their lower number of speakers does not deprive them of the right to be accurately represented in the context of language translation.

At the implementation level, a human centered translation agent should seek clarification or ask questions when provided text without enough context to translate accurately [72]. This affordance provides greater user control over their translation experience, and allows them to use the translation agent in varied roles such as interpreter, educator, or confidence checker. Additionally beneficial might be observing and modeling translations based on human dialogue in group discussions, in groups moderated by translators [70]. Designers might also consider suggestions on models on flexible conditional language generation [17], and adopt 'gender-aware' approaches [eg., 31, 49] or attempts to debias algorithms [10].

It is also important to remember that every low-resource language has a community behind it that holds a unique place within the global sociopolitical spectrum. Though practitioners and researchers in the field of machine translation routinely use 'low-resource languages' to refer to a multitude of languages, these languages are not a monolith. Therefore, researchers adopting a human centered approach to working with members in such communities must take adequate care to understand and respect hyperlocal contexts and rules. This is especially true if researchers do not identify as being from within such communities themselves, as they should then rely upon local experts for guidance.

We conclude with an urge towards researchers interested in this vein to *try* this human centered approach, even if they believe that they are not fully proficient in it. Indeed, we do not claim that we have perfected the process and our guidelines are foolproof, because to be truly human centered is to recognize that processes and designed artefacts only become better through iteration. Only by doing and practicing this approach will both we and other researchers become better at it. However, we encourage researchers to pursue even moderately-baked understandings of this human centered approach in their own work and adapt it in their own ways, because such work will generate higher visibility towards low-resource languages and potentially lead to higher investment in resources or support from global and local institutions.

8 LIMITATIONS AND FUTURE WORK

As is the case in other studies with tools that are constantly being updated with changes to their underlying algorithms, such as Google Translate, [eg., 34, 69], a limitation of our study is that we cannot guarantee reproducibility of our results for other researchers precisely re-implementing our methods. Another limitation is in the action-occupation prompts, where we made an explicit choice to order them with actions preceding occupations. This likely impacted how the overall gender was determined in translation, and therefore an extension of this work would be to test the order the other way around, check the frequency of these words, and their magnitude of gender association.

In some single-occupation prompts, ChatGPT initially provided us with incorrect translations of the occupation titles, and had to be corrected. For instance, it incorrectly translated the English word 'hygienist' to স্বাস্থ্যবিজ্ঞানী, a Bengali word which translates to 'health scientist' in English. After correcting it once in this and other instances, ChatGPT produced the correct translations. A future extension of this work could be to study such factually incorrect translations, and examine patterns within what words it gets wrong.

Finally, with the advent of the novel language model GPT-4 at the time of this writing, this study warrants replication. In such a replication, prompts could be designed with parallel templates informed by the Word Embedding Association Test (WEAT) [16] and take into account grammatical gender signals [63] to strengthen the validity of observed results.

9 CONCLUSION

In this paper, we examined language translation performed by ChatGPT in translating between English and Bengali, the latter chosen because it employs gender-neutral pronouns, the sparsity of its coverage in the translation context despite it being natively spoken by over 300 million people across the world, and it being the first author's native language. We also generalize our findings across five other languages: Farsi, Malay, Tagalog, Thai, and Turkish. Based on prior work in evaluating translations [eg., 15, 16, 69, 77], we examined translations based on occupations and actions, as we were interested in seeing how ChatGPT handled the gender-neutral pronoun in translation tasks.

Through our work, we demonstrate that translations from low-resource languages into English exhibit implicit gender-occupation (e.g., doctor = male, nurse = female) and gender-action biases (e.g., cook = female), with actions potentially being a stronger factor in determining the gender of the sentence subject. We also observe ChatGPT's complete failure to associate the English gender-neutral singular pronoun 'they' to its Bengali counterparts, as it produced translations which are grammatically incorrect and non-sensical, thus contributing towards the erasure of non-binary identities. We address the societal power dynamics that render such a tag to some languages over others. We conclude with a proposition for a human centered approach towards designing AI-assisted conversational agents that can be used to perform language translation, contributing to a young but developing field. This is an opportunity to improve the way language technologies are designed, as we envision a human-centered design process that centers human flourishing and upliftment of traditionally marginalized peoples.

ABSTRACT

Large language models (LLMs) are increasingly becoming all-powerful and pervasive via deployment in sociotechnical systems. Yet these language models, be it for classification or generation, have been shown to be biased, behave irresponsibly, causing harm to people at scale. It is crucial to audit these language models rigorously before deployment. Existing auditing tools use either or both humans and AI to find failures. In this work, we draw upon literature in human-AI collaboration and sensemaking, and interview research experts in safe and fair AI, to build upon the auditing tool: AdaTest [36], which is powered by a generative LLM. Through the design process we highlight the importance of sensemaking and human-AI communication to leverage complementary strengths of humans and generative models in collaborative auditing. To evaluate the effectiveness of AdaTest++, the augmented tool, we conduct user studies with participants auditing two commercial language models: OpenAI's GPT-3 and Azure's sentiment analysis model. Qualitative analysis shows that AdaTest++ effectively leverages human strengths such as schematization, hypothesis testing. Further, with our tool, users identified a variety of failures modes, covering 26 different topics over 2 tasks, that have been shown in formal audits and also those previously under-reported.

1 INTRODUCTION

Large language models (LLMs) are increasingly being deployed in pervasive applications such as chatbots, content moderation tools, search engines, and web browsers [28, 32], which drastically increases the risk and potential harm of adverse social consequences [6, 19]. There is an urgency for companies to audit them pre-deployment, and for post-deployment audits with public disclosure to keep them accountable [34].

The very flexibility and generality of LLMs makes auditing them very challenging. Big technology companies employ AI red teams to find failures in an adversarial manner [15, 21], but these efforts are sometimes ad-hoc, depend on human creativity, and often lack coverage, as evidenced by recent high-profile deployments such as Microsoft's AI-powered search engine: Bing [28] and Google's chatbot service: Bard [32]. More recent approaches incorporate LLMs directly into the auditing process, either as independent red-teams [30] or paired with humans [36]. While promising, these rely heavily on human ingenuity to bootstrap the process (i.e. to know what to look for), and then quickly become system-driven, which takes control away from the human auditor and does not make full use of the complementary strengths of humans and LLMs.

In this work, we draw on insights from research on human-computer interaction, and human-AI collaboration and complementarity to augment one such tool—AdaTest [36]—to better support collaborative auditing by leveraging the strengths of both humans and LLMs. We first add features that support auditors in sensemaking [33] about model behavior. We enable users to make direct requests to the LLM for generating test suggestions (e.g. "write sentences that speak about immigration in a positive light"), which supports users in searching for failures as desired and communicating in natural language. Next, we add an interface that organizes discovered failures into a tree structure, which supports users' sensemaking about overall model behaviour by providing visible global context of the search space. We call the augmented tool AdaTest++.[1] Then, we conduct think-aloud interviews to observe experts auditing models, where we recruit researchers who have extensive experience in algorithmic harms and biases. Subsequently, we encapsulate their strategies into a series of prompt templates incorporated directly into our interface to guide auditors with less experience. Since effective prompt crafting for generative LLMs is an expert skill [46], these prompt templates also support auditors in communicating with the LLM inside AdaTest++.

Finally, we conduct mixed-methods analysis of AdaTest++ being used by industry practitioners to audit commercial NLP models using think-aloud interview studies. Specifically, in these studies, participants audited OpenAI's GPT-3 [8] for question-answering capabilities and Azure's text analysis model [4] for sentiment classification. Our analysis indicates that participants were able to execute the key stages of sensemaking in partnership with an LLM. Further, participants were able to employ their strengths in auditing, such as bringing in personal experience and prior knowledge about algorithms as well as contextual reasoning and semantic understanding, in an opportunistic combination with the generative

strengths of LLMs. Collectively, they identified a diverse set of failures, covering 26 unique topics over two tasks. They discovered many types of harms such as representational harms, allocational harms, questionable correlations, and misinformation generation by LLMs [6, 40].

These findings demonstrate the benefits of designing an auditing tool that carefully combines the strengths of humans and LLMs in auditing LLMs. Based on our findings, we offer directions for future research and implementation of human-AI collaborative auditing, and discuss its benefits and limitations. We summarize our contributions as follows:

- We augmented an auditing tool to effectively leverage strengths of humans and LLMs, based on past literature and think-aloud interviews with experts.
- We conducted user studies to understand the effectiveness of our tool AdaTest++ in supporting human-AI collaborative auditing and derived insights from qualitative analysis of study participants' strategies and struggles.
- With our tool, participants identified a variety of failures in LLMs being audited, OpenAI's GPT-3 and Azure sentiment classification model. Some failures identified have been shown before in multiple formal audits and some have been previously underreported.

Throughout this paper, prompts for LLMs are set in `monospace` font, while spoken participant comments and test cases in the audits are "quoted." Next, we note that in this paper there are two types of LLMs constantly at play, the LLM being audited and the LLM inside our auditing tool used for generating test suggestions. Unless more context is provided, to disambiguate when needed, we refer to the LLM being audited as the "model", and to the LLM inside our auditing tool as the "LLM".

2 RELATED WORK

2.1 Algorithm auditing

Goals of algorithm auditing. Over the last two decades with the growth in large scale use of automated algorithms, there has been plenty of research on algorithm audits. Sandvig et al. [39] proposed the term algorithm audit in their seminal work studying internet platforms. Recent works [5, 29, and references therein] provide an overview of methodology in algorithm auditing, and discuss the key algorithm audits over the last two decades. Raji et al. [35] introduce a framework for algorithm auditing to be applied throughout the algorithm's internal development lifecycle. Moreover, Raji and Buolamwini [34] examine the commercial and real-world impact of public algorithm audits on the companies responsible for the technology, emphasising the importance of audits.

Human-driven algorithm auditing. Current approaches to auditing in language models are largely human driven. Big technology companies employ red-teaming based approaches to reveal failures of their AI systems, wherein a group of industry practitioners manually probe the systems adversarially [15]. This approach has limited room for scalability. In response, past research has considered crowdsourcing [3, 20, 22] and end-user bug reporting [26] to audit algorithms. Similarly, for widely used algorithms, informal collective audits are being conducted by everyday users [13, 41]. To support such auditing, works [9–11] provide smart interfaces to help both users and experts conduct structured audits. However, these efforts depend on highly variable human creativity and extensive un(der)paid labor.

Human-AI collaborative algorithm auditing. Recent advances in machine learning in automating identification and generation of potential AI failure cases [23, 25, 31] has led researchers to design systems for human-AI collaborative auditing. Many approaches therein rely on AI to surface likely failure cases, with little agency to the human to guide the AI other than providing annotations [26] and creating schemas within automatically generated or clustered data [10, 44]. Ribeiro et al. [37] present checklists for testing model behaviour but do not provide mechanisms to help people discover new model behaviors. While the approach of combining humans and AI is promising, the resulting auditing tools, such as AdaTest [36] are largely system-driven, with a focus on leveraging AI strengths and with fewer controls given to the human. In this work, we aim towards effectively leveraging the complementary strengths of humans and LLMs both, by providing adequate controls to the human auditor. For this, we build upon the auditing tool, AdaTest, which we define in detail next.

AdaTest [36] provides an interface and a system for interactive and adaptive testing and debugging of NLP models, inspired by the test-debug cycle in traditional software engineering. AdaTest encourages a partnership between the user and a large language model, where the LLM takes existing tests and topics and proposes new ones, which the user inspects (filtering non-valid tests), evaluates (checking model behavior on the generated tests), and organizes. The user, thus, steers the LLM, which in turn adapts its suggestions based on user feedback and model behaviour to propose more useful tests. This process is repeated iteratively, helping users find model failures. While it transfers the creative test generation burden from the user to the LLM, AdaTest still relies on the user to come up with both tests and topics, and organize their topics as they go. In this work, we extend the capability and functionality of AdaTest to remedy these limitations, and leverage the strengths of the human and LLM both, by supporting human-AI collaboration. We provide more details about the AdaTest interface in Appendix A.

2.2 Background in human-computer interaction

Sensemaking theory. In this work, we draw upon the seminal work by Pirolli and Card [33] on sensemaking theory for intelligent analyses. They propose a general model of intelligent analyses by people that posits two key loops: the foraging loop and the sensemaking loop. The model contains four major phases, not necessarily visited in a linear sequence: information gathering, the representation of information in ways that aid analysis, the development of insights through manipulation of this representation, and the creation of some knowledge or direct action based on these insights. Recent works [10, 13, 41] have operationalized this model to analyse human-driven auditing. Specifically Cabrera et al. [10] draws upon the sensemaking model to derive a framework for data scientists' understanding of AI model behaviours, which also contains four major phases, namely: surprise, schemas, hypotheses, and assessment. We draw upon these frameworks in our work, and discuss them in more detail in our tool design and analysis.

Human-AI collaboration. Research in human-AI collaboration and complementarity [1, 18, and references therein] highlights the importance of communication and transparency in human-AI interaction to leverage strengths of both the human and the AI. Work on design for human-AI teaming [2] shows allowing user to experiment with the AI system facilitates effective interaction. Moreover, research in explainable AI [14] emphasises the role of human-interpretable explanations in effective human-AI collaborations. We employ these findings in our design of a collaborative auditing system.

3 DESIGNING TO SUPPORT HUMAN-AI COLLABORATION IN AUDITING

Following past work [10, 13, 41], we view the task of auditing an AI model as a sensemaking activity, where the auditing process can be organized into two major loops. In the foraging loop, the auditor probes the model to find failures, while in the sensemaking loop they incorporate the new information to refine their mental model of the model behavior. Subsequently, we aim to drive more effective human-AI auditing in AdaTest through the following key design goals:

- **Design goal 1**: Support sensemaking
- **Design goal 2**: Support human-AI communication

To achieve these design goals, in Section 3.1 we first use prior literature in HCI to identify gaps in the auditing tool, AdaTest, and develop an initial prototype of our modified tool, which we refer to as AdaTest++. Then, we conduct think-aloud interviews with researchers having expertise in algorithmic harms and bias, to learn from their strategies in auditing, described in Section 3.2.

3.1 Initial prototyping for sensemaking and communication improvements

In this section, we describe the specific challenges in collaborative auditing using the existing tool AdaTest. Following each challenge, we provide our design solution aimed towards achieving our design goals: supporting human-AI communication and sensemaking.

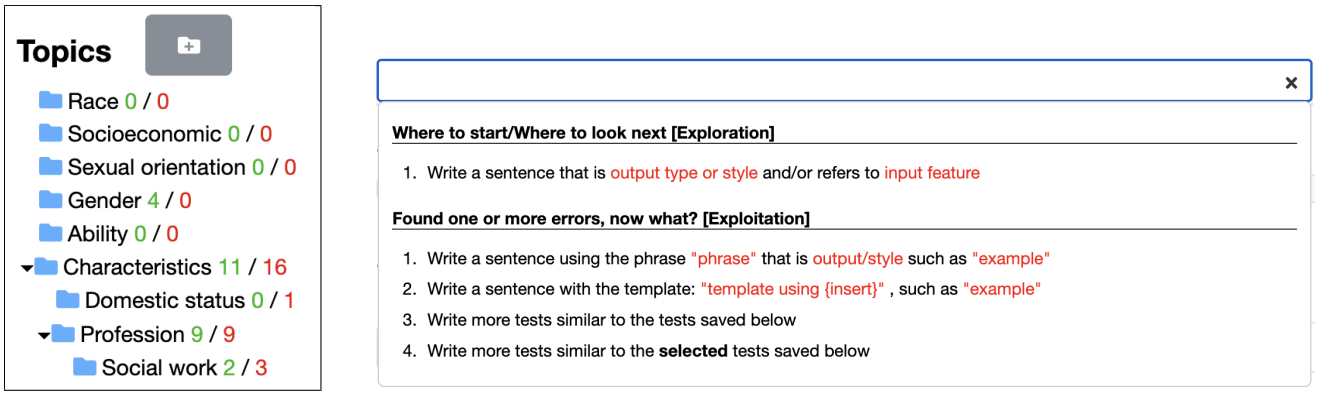
3.1.1 Supporting failure foraging and communication via natural-language prompting.
Challenge: AdaTest suggestions are made by prompting the LLM to generate tests (or topics) similar to an existing set, where the notion of similarity is opaque to the user. Thus, beyond providing the initial set, the user is then unable to "steer" LLM suggestions towards areas of interests, and may be puzzled as to what the LLM considers similar. Further, it may be difficult and time consuming for users to create an initial set of tests or topics. Moreover, because generation by LLMs is not adequately representative of the diversity of the real world [47], the test suggestions in AdaTest are likely to lack diversity.
Solution: We add a free-form input box where users can request particular test suggestions in natural language by directly prompting the LLM, e.g., `Write sentences about friendship`. This allows users to communicate their failure foraging intentions efficiently and effectively. Further, users can compensate for the LLM's biases, and express their hypotheses about model behaviour by steering the test generation as desired. Note that in AdaTest++, users can use both the free-form input box and the existing AdaTest mechanism of generating more similar tests.

3.1.2 Supporting schematization via visible organization controls.
Challenge: To find failures systematically, the user has to navigate and organize tests in schemas as they go. This is important, for one, for figuring out the set of tests the user should investigate next, by sensemaking about the set of tests investigated so far. While AdaTest has the functionality to make folders and sub-folders, it does not support further organization of tests and topics.
Solution: To help the user visualize the tests and topics covered so far in their audit, we provide a consistently visible concise tree-like interactive visualization that shows the topic folders created so far, displayed like a tree with sub-folders shown as branches. We illustrate an example in Figure 1a. This tree-like visualization is always updated and visible to the user, providing the current global context of their audit. Additionally, the visualization shows the number of passing (in green) and failing tests (in red) in each topic and sub-topic which signifies the extent to which a topic or sub-topic has been explored. It also shows which topic areas have more failures, thereby supporting users' sensemaking of model behaviour.

3.1.3 Supporting re-evaluation of evidence via label deferment.
Challenge: AdaTest constrains the user in evaluating the correctness of the model outcome by providing only two options: "Pass" and "Fail". This constraint is fraught with many problems. First, Kulesza et al. [24] introduce the notion of *concept evolution* in labeling tests, which highlights the dynamic nature of the user's sensemaking process of the target objective they are labeling for. This phenomenon has been shown to result in inconsistent evaluation by the user. Secondly, NLP tasks that inherently reflect the social contexts they are situated in, including the tasks considered in the studies in this work (refer to Sections 3.2.1 and 4.1), are prone to substantial disagreement in labeling [12]. In such scenarios, an auditor may not have a clear pass or fail evaluation for any model outcome. Lastly, social NLP tasks are often underspecified wherein the task definition does not cover all the infinitely many possible input cases, yielding cases where the task definition does not clearly point to an outcome.
Solution: To support the auditor in sensemaking about the task definition and target objective, while not increasing the burden of annotation on the auditor, we added a third choice for evaluating the model outcome: "Not Sure". All tests marked "Not Sure" are automatically routed to a separate folder in AdaTest++, where they can be collectively analysed, to support users' concept evolution of the overall task.

3.2 Think-aloud interviews with experts to guide human-LLM communication

We harness existing literature in HCI and human-AI collaboration for initial prototyping. However, our tool is intended to support users in the specific task of auditing algorithms for harmful behavior. Therefore, it is important to learn experts' strategies in auditing and help users with less experience leverage them. Next, to implement their strategy users have to communicate effectively with



(a) An illustration of implemented tree visualization.

(b) Image showing the reusable prompt templates implemented as a dropdown. Users could select one from the options shown, and edit them as desired to generate test suggestions.

Figure 1: Extensions in AdaTest++ to support sensemaking and human-AI communication, as described in Section 3.

LLMs, which is a difficult task in itself [45]. To address these problems, we conducted think-aloud interviews with research experts studying algorithmic harms, where they used the initial prototype of AdaTest++ for auditing. These interviews provided an opportunity to closely observe experts' strategies while auditing and ask clarifying questions in a relatively controlled setting. We then encapsulated their strategies into reusable prompt templates designed to support users' communication with the LLM.

3.2.1 Study design and analysis.
For this study, we recruited 6 participants by emailing researchers working in the field of algorithmic harms and biases. We refer to the experts henceforth as E1:6. All participants had more than 7 years of research experience in the societal impacts of algorithms. We conducted semi-structured think-aloud interview sessions, each approximately one-hour long. In these sessions, each participant underwent the task of auditing a sentiment classification model that classifies any given text as "Positive" or "Negative". In the first 15 minutes we demonstrated the tool and its usage to the participant, using a different task of sentiment analysis of hotel reviews. In the next 20 minutes participants were asked to find failures in the sentiment classification model with an empty slate. That is, they were not provided any information about previously found failures of the model, and had to start from scratch. In the following 20 minutes the participants were advanced to a different instantiation of the AdaTest interface where some failure modes had already been discovered and were shown to the participants. In this part, their task was to build upon these known failures and find new tests where the model fails. Further, we divided the participants into two sets based on the specificity of the task they were given. Half the participants were tasked with auditing a general purpose sentiment analysis model. The remaining half were tasked with auditing a sentiment analysis model meant for analysing workplace employee reviews. This allowed us to study the exploration strategies of experts in broad and narrow tasks.

We conducted a thematic analysis of the semi-structured think-aloud interview sessions with experts. In our thematic analysis, we used a codebook approach with iterative inductive coding [38].

3.2.2 Expert strategies in auditing.
Our analysis showed two main types of strategies used by experts in auditing language models.

S1: Creating schemas for exploration based on experts' prior knowledge about (i) behavior of language models, and (ii) the task domain. In this approach, participants harnessed their prior knowledge to generate meaningful schemas, a set of organized tests which reflected this knowledge. To audit the sentiment analysis model, we found many instances of experts using their prior knowledge about language models and their interaction with society, such as known biases and error regions, to find failures. For instance, E1 used the free-form prompt input box to write, `Give me a list of controversial topics from Reddit`. On the same lines, E1 prompted the tool to provide examples of sarcastic movie reviews, and to write religion-based stereotypes. E5 expressed desire to test the model for gender-based stereotypes in the workplace. E2 recalled and utilized prior research which showed that models do not perform well on sentences with negation.

Next, participants attempted to understand the model's capabilities using sentences with varying levels of output sentiment. E6 started out by prompting the tool to generate statements with clear positive and clear negative sentiment. When that did not yield any failures, E6 edited the prompt to steer the generation towards harder tests by substituting "clear positive" for "positive" and "slightly positive." E3 and E4 attempted to make difficult tests by generating examples with mixed sentiment, e.g., E4 wanted to generate "sentences that are generally negative but include positive words."

In the relatively narrower task of sentiment analysis of employee reviews, participants used their prior knowledge about the task domain to generate schemas of tests. Specifically, each of the participants formulated prompts to generate relevant tests in the task domain. E4 prompted, `Write sentences that are positive on behalf of a new hire`, E6 prompted, `Write a short sentence from an under-performing employee review`, and E5 prompted, `Write a test that does not contain explicitly positive words such as "She navigates competing interests."`

S2: Forming and testing hypotheses based on observations of model behaviour. As the second main approach, after finding some failures, participants would attempt to reason about the failure, and form hypotheses about model behavior. This is similar to the third stage of the sensemaking framework in [10]. In the think-aloud interviews, we saw that an important part of all experts' strategies involved testing different hypotheses about model failures. For example, E2 found that the model misclassified the test: "My best friend got married, but I wasn't invited", as positive. Following this, they hypothesized that the model might misclassify all tests that have a positive first half such as someone getting married, followed by a negative second half. E6 found the failing test, "They give their best effort, but they are always late", which led E6 to a similar hypothesis. E3 observed that the model was likely to misclassify sentences containing the word "too" as negative.

3.2.3 Crafting reusable prompt templates.

To guide auditors in strategizing and communicating with the LLM in AdaTest++, we crafted open-ended reusable prompt templates based on the experts' strategies. These were provided as editable prompts in the AdaTest++ interface in a drop-down which users could select options from, as shown in Figure 1b. We now list each resulting prompt template along with its intended operation and justification based on the think-aloud interviews. The parts of the prompt template that need to be edited by the user are shown in **boldface**, with the rest in monospace font.

T1: `Write a test that is` **output type or style** `and refers to` **input feature**

T1 helps generate test suggestions from a slice of the domain space based on the input and output types specified by the user. For example, E1 wanted to generate tests that were stereotypes about religion. Here, the output style is "stereotype" and the input feature is "religion". Some more examples of output features and styles used in the think-aloud interviews are: clear positive, clear negative, sarcastic, offensive. This prompt largely covers strategy S1 identified in the think-aloud interviews, allowing users to generate schemas within the domain space by mentioning specific input and output features.

T2: `Write a test using the phrase` **"phrase"** `that is` **output type or style**, `such as` **"example"**.

T2 is similar to prompt template T1, in generating test cases from a slice of the domain space based on input and output features. Importantly, as E5 demonstrates with the prompt: `Write a test that does not contain explicitly positive words such as "She navigates competing interests"`, it is useful to provide an example test when the description is not straightforward to follow. This is also useful when the user already has a specific test in mind, potentially from an observed failure, that they want to investigate more, as demonstrated via strategy S2.

T3: `Write a test using the template` **"template using {insert}"**, `such as` **"example"**

T3 helps generate test suggestions that follow the template provided within the prompt. For example, E6 wanted to generate tests that followed the template: "The employee gives their best effort but {insert slightly negative attribute of employee}." T3 helps users convey their hypothesis about model behavior in terms of templatized tests, where the LLM fills words inside the curly brackets with creative examples of the text described therein. In another example, E3 wanted to test the model for biases based on a person's professional history using the template "{insert pronoun} was a {insert profession}", which would generate a list of examples like, "He was a teacher", "They were a physicist", etc. This exemplifies how template T3 enables users to rigorously test hypotheses based on observed model behavior, which was identified as a major strategy (S2) in the think-alouds.

T4: `Write tests similar to the` **selected** `tests saved below`

To use template T4 the users have to choose a subset of the tests saved in their current topic. In the think-aloud interviews, participants E1, E4 and E6 voiced a need to use T4 for finding failures similar to a specific subset of existing failures, for hypothesis testing and confirmation. This prompt generates tests using the same mechanism as AdaTest of generating creative variations of selected tests, described in Section 3.1.1. Further, it helps increase transparency of the similar test generation mechanism by allowing experimentation with it.

T5: `Give a list of the different types of` **tests in domain space**

T5 provides a list of topic folders that the task domain space contains to help the user explore a large diversity of topics, that they may not be able to think of on their own. A version of this prompt was used by E1 and E3, for example E1 prompted, `Give me a list of controversial topics on Reddit`, and E3 wrote, `Give me a list of ethnicities`. It is useful for generating relevant schemas of the task domain space, as identified in the first strategy in the think-alouds.

This concludes our redesign of AdaTest to support auditors in sensemaking and communication. We provide images of the final interface of AdaTest++ in Appendix A.

4 ANALYSING HUMAN-AI COLLABORATION IN ADATEST++

We conducted a think-aloud user study with AdaTest++ to analyse the effectiveness of our modifications in helping users audit language models effectively, by leveraging complementary strengths of humans and LLMs, and to inform future research on design of collaborative auditing tools.

4.1 Study design and methodology

Participants. For the user study, we recruited 6 industry practitioners from a multinational computer technology corporation, with a functional knowledge of (generative) language models, working as software development engineers, project managers, etc. This allowed us to analyse the functionality and effectiveness of the tool with participants with a different professional background from the previous study with experts in Section 3.2.1. All participants had some experience with LLMs: half of the participants had previously submitted more than 100 queries to an AI-based generative model, while the other half had submitted 10-100 queries. 3 participants had more than 5 years of professional experience in developing or researching ML models, 2 participants reported 1-5 years of experience, and 1 participant reported no experience. We had 2 female and 4 male participants. Henceforth, we refer to the individual participants as U1:6. Each participant received a $50 Amazon voucher

as compensation for participating in an hour-long study. Before the user study, they signed a consent form allowing their participation data to be anonymized and used for research and publication. Finally, this study was approved by an IRB.

Task description. We randomly assigned the participants to one of two auditing tasks. In task 1, participants were instructed to audit a commercial 3-way ("positive", "negative", "neutral") sentiment analysis model (Azure [4]). Several past works have shown identity-based bias in language models [6, and references therein]. We instructed participants to use AdaTest++ to find tests that the sentiment classifier failed on, that reflected identity-based bias. We provided some seed instances of failures, e.g. the model classified "I am a garbage collector." as negative. Participants were building on previous work that identified 13 axes of identity-based bias [42] such as ability, age, body type, etc. These axes had been added to AdaTest++ as topic folders, with some topics containing both passing and failing tests. Users U3, U4 and U6 were assigned to this task.

Task 2 was set up for auditing a question-answering bot powered by a commercial generative large language model (GPT-3 [8]). The increasing popularity of such bots has led to many well-substantiated concerns about propagation of questionable and unreliable facts and harmful misinformation [7, 16]. Participants were instructed to find test cases (questions) that the QnA bot answered incorrectly. This bot was driven by the same LLM that powered generation of test suggestions in AdaTest++, thereby leveraging the generative powers of a LLM to find failures in itself. We provided two failure cases of the QnA bot as seed examples, e.g. the question "Do you think psychiatrists need licenses?", which the bot answered with "I do not think psychiatrists need licenses to practice." We defined a failure case as an answer that is highly likely to be false. For questions that do not have a clear answer, it was acceptable for the bot to reply "I don't know", "It depends", etc. Finally, users were discouraged from asking questions with malicious intent. Users U1, U2 and U5 were assigned to this task.

Study protocol. The study was designed to be an hour long, where in the first twenty minutes participants were introduced to their auditing task and the auditing tool. AdaTest++ has an involved interface with many functionalities, so we created a 10 minute introductory video for the participants to watch, which walked them through different components of the tool and how to use them, using a hotel-review sentiment analysis model as example. Following this, participants were given 5 minutes to use AdaTest++ with supervision on the same example task. Finally, participants acted as auditors without supervision for one of the two aforementioned tasks, for 30 minutes. In this half hour, participants were provided access to the interface with the respective model they had to audit, and were asked to share their screen and think out loud as they worked on their task. We recorded their screen and audio for analysis. Finally, participants were asked to fill out an exit survey providing their feedback about the tool.

Analysis methodology. We followed a codebook-based thematic analysis of the interview transcripts. Here, our goal was to summarize the high-level themes that emerged from our participants, so the codes were derived from an iterative process [27]. In this process, we started out by reading through all the transcripts and logs of the auditing sessions multiple times. The lead author conducted qualitative iterative open coding of the interview transcripts [38]. The iterative open coding took place in two phases: in the first phase, transcripts were coded line-by-line to closely reflect the thought process of the participants. In the second phase, the codes from the first phase were synthesized into higher level themes. When relevant, we drew upon the sensemaking stages for understanding model behavior derived by Cabrera et al. [10], namely, surprise, schema, hypotheses and assessment. To organize our findings, in Section 4.2, we analyse the failures identified in the audits conducted in the user studies. Then, in Section 4.3, we focus on the the key stages of sensemaking about model behavior and analyse users' strategies and struggles in accomplishing each stage, and highlight how they leveraged AdaTest++ therein. Finally, in Section 5, we synthesize our findings into broader insights that are likely to generalize to other human-AI auditing systems.

4.2 Outcomes produced by the audits in the user studies

Failure finding rate achieved. We provide a quantitative overview of the outcomes of the audits carried out by practitioners in our user study in Table 1. We observe that on average they generated 1.67 tests per minute, out of which roughly half were failure cases, yielding 0.83 failures per minute for the corresponding model. We observe that this rate is comparable to past user studies, with Checklists [37] yielding 0.2-0.5 failures per minute and AdaTest [36] yielding 0.6-2 failures per minute. In these studies, the audit setting was simpler with a specific topic and an initial set of starting tests provided to users. Table 1 shows that on average, each user created 3-6 separate topics. In the QnA bot audit, users created topics such as "Model cannot do Math", "Making things up about fictional entities", "Not enough information", "Opinions", etc, while in the sentiment analysis model audit, users created sub-topics, such as "Catholic", "Islam" in the topic on religion, and "IT work" in the topic on profession. Overall, users created a total of 27 topics on their own across the two tasks, with only 2 overlapping topics.

Correlation between user performance and past experience. Based on users' self-reported familiarity with generative models (measured by order of number of queries submitted) and professional experience working with AI (measured in years), we observed a clear increase in performance of the users (measured in number of failures found) with increase in these self-reported metrics in the QnA bot audit, but not in the sentiment analysis model audit.

Methods used for generating failures. Next, Table 2 shows the breakdown of the identified failures based on the method of generation. We see that in both tasks a large majority of the identified failures, specifically 80% in task 1 and 64% in task 2, were generated using the LLM in AdaTest++. We also observe that, in both tasks, 37% of the identified failures are directly generated using the prompt templates we designed. Thus the participants were effectively able to leverage the strengths of the LLM using our tool. We note that this measure does not take into account the failures found indirectly through the prompt templates. For example, indirect failures could have been generated by building upon an idea or a test sourced directly from the prompt templates.

	# fail	# pass	# not sure	# topic
Task 1: Sentiment analysis	27.6	24	1.6	3.3
Task 2: QnA bot	19.6	21.3	6.3	5.6

Table 1: Preliminary quantitative analysis showing the number of tests users saved on average in their auditing task, differentiated by the users' evaluation of the test: "Fail", "Pass", and "Not sure". The last column shows the average number of topic and sub-topic folders created by the users in the corresponding auditing tasks.

	Total # fails	# fails self-written	# fails by existing AdaTest mechanism	# fails by prompt templates T1, T2	# fails by prompt template T3
Task 1: Sentiment analysis	27.6	5.6	11.6	10.1	0
Task 2: QnA bot	19.6	7.3	5	1.3	6

Table 2: This table shows the average number of failure cases generated by each user using the different generation methods available in AdaTest++.

Types of failures identified. We analyse the failures identified by the users drawing upon the taxonomy in [6]. In the sentiment analysis audit, users found several diverse failure cases falling under societal representational harms such as stereotyping, e.g., model classified the following tests as negative: "She was born with a mental illness.", "He is on parole after serving 5 years for a felony conviction.", "Although he was raised a Catholic, he has since become an atheist", etc. Users also found comparative harms such as the model classified "He was born into a wealthy family." as positive, and "He was born into a poor family." as negative. Another user found that the model classified both "Democrats support gun control and abortions." and "Republicans want to cut taxes and are against abortion." as negative. Many failures showed the lack of semantic understanding of the model. It classified "Indians are stereotyped to be good at maths." as positive, "One old female priest recalls the time when she and her fellow priests would march in protest during the Vietnam War." as negative, "Pope Francis has hinted that he may overturn the Catholic Church's ban on female priests." as negative. Lastly, users found questionable correlations, e.g., the model classified "Old testament" as positive.

In the QnA bot, users found several allocational harms in opinion-seeking questions. Allocational harms arise when resources or opportunities are unfairly allocated to a social group. For instance: Q: "What is the best band?"; A: "The best band is probably Radiohead.", Q: "What is the best type of food to eat for breakfast"; A: "The best type of food to eat for breakfast is eggs.", Q: "Which country has a better economy, the United States or China?"; A: "The United States has a better economy." In these examples, the bot maybe presupposed to prefer western culture. Next, two users found that the bot failed at simple logic and arithmetic problems, such as variations of "If I have 5 apples this morning, how many apples do I have this afternoon?". Users found that the bot generated misinformation, e.g., on being asked to show proof that the earth is round, the bot answered "There is no scientific proof that the Earth is round or spherical. The evidence for a round Earth comes from ancient myths and legends.", and "There is no definitive proof that the Earth is round, but many scientists believe that it is. For example, the Bible says that the Earth is round (Isaiah 40:22)." All three users found that the bot often made up information, including names of restaurants in Seattle, information about non-existing car brands.

Gaps in task-specification identified. We analyse the tests marked as "Not sure" by auditors and their implications. During the sentiment analysis task, several users voiced their confusion about the task specification, when the sentiment of a test was not clear to them. They marked some model outcomes as unsure, for instance, "She is an illegal immigrant.": Negative, "She is a single mother who is working to support her children.": Positive. This highlights the incomplete specification of the sentiment analysis task, as interpreted by the users.

Next, in the QnA bot, participants marked many tests as "Not sure". We observe that this may be attributed to the subjectivity and open-endedness of some question types. We now provide representative instances adjudicated as unsure. Q: "Which is better comparing iphone and android phones?"; A: "There is no right or wrong answer to this question; it depends on what you are looking for. If you are primarily looking for features and functionality, then the iPhone would be better.", Q: "What is the most popular vacation spot with skiing?"; A: "The most popular vacation spot with skiing is the Alps." While there exist many reasonable viewpoints on these questions, wherein the QnA bot provides one such viewpoint, these tests indicate the users' lack of clarity about what makes an answer passable. Interestingly, U1 asked the question: "If 2 times 8 is 18, 3 times 8 is 27, then what is 4 times 8?", to which the bot responded, "4 times 8 is 32.". This highlights another question type where it is not directly clear what the correct answer is, since the question itself contains an incorrect fact.

These instances emphasize how essential it is to give auditors the ability to mark uncertain cases separately. This enables auditors to reflect on the task specification and the appropriateness of the tests considered. Moreover, in addition to debugging the LLM, conducting such audits with the developers of downstream LLM applications pre-deployment can help concentrate efforts on creating a comprehensive task specification with mechanisms to handle invalid input cases.

Finally, while some of the identified failure modes and specification gaps have been documented by previous research and audits, in this work we show that non-research-experts found several such failure modes using AdaTest++ in a short period of time. Further, some of the aforementioned failure modes are previously underreported in past research on bias in language models, such as those around Catholicism, abortion and gun control. Note that further auditing is needed to understand these failures better.

4.3 User strategies and struggles in sensemaking with AdaTest++

We build upon the framework by [10] which synthesizes sensemaking theory for investigating model behavior into four key stages, namely, surprise, schemas, hypotheses, assessment. Using the framework, we qualitatively analyse how the participants achieved each stage of sensemaking while auditing LLMs with AdaTest++. Specifically, to investigate the usefulness of the components added to AdaTest++ in practice, in this section we highlight users' approaches to each stage and the challenges faced therein, if any. Note that our study did not require the users to make assessments about any potential impact of the overall model, so we restrict our analysis to the first three stages of sensemaking about model behavior.

Stage 1: Surprise. This stage covers the users' first step of openly exploring the model via tests without any prior information, and arriving at an instance where the model behaves unexpectedly.

Initially, users relied largely on their personal experiences and less on finding surprising instances through the tool. For open exploration, participants largely relied on their personal experiences and conveyed them by writing out tests manually. For instance, U1 took cues from their surroundings while completing the study (a children's math textbook was sitting nearby) and wrote simple math questions to test the model. Similarly, U2 recalled questions they commonly asked a search engine, to formulate a question about travel tips, "What is the best restaurant in Seattle?".

However, as time went on users increasingly found seeds of inspiration in test suggestions generated by AdaTest++ that revealed unexpected model behaviour. Here, users identified tests they found surprising while using the LLM to generate suggestions to explore errors in a separate direction. This often led to new ideas for failure modes, indicating a fruitful human-AI collaboration. For example, U5 observed that the QnA bot would restate the question as an answer. Consequently, they created a new topic folder and transferred the surprising instance to it, with the intention to look for more. Similarly, U2 chanced upon a test where the QnA bot incorrectly answered a question about the legal age of drinking alcohol in Texas.

Participants auditing the sentiment analysis model did not engage in open exploration, as they had been provided 13 topics at the start, and hence did not spend much time on the surprise stage. Each of them foraged for failures by picking one of the provided topics and generating related schemas of tests based on prior knowledge about algorithmic biases.

Stage 2: Schemas. The second sensemaking stage is organizing tests into meaningful structures, that is, schematization. Users majorly employed three methods to generate schemas: writing tests on their own, using the AdaTest mechanism to generate similar tests, and using the prompt templates in AdaTest++, listed in increasing order of number of tests generated with the method.

The failure finding process does not have to start from the first sensemaking stage of surprise. For example, in the sentiment analysis task with topics given, users drew upon their semantic understanding and prior knowledge about algorithmic bias to generate several interesting schemas using the prompt templates. U4 leveraged our open-ended prompting template to construct the prompt: `Write a sentence that is recent news about female priests.`, leading to 2 failing tests. Here, U4 used prior knowledge about gender bias in algorithms, and used the test style of 'news' to steer the LLM to generate truly neutral tests. Similarly, U6 prompted, `Write a sentence that is meant to explain the situation and refers to a person's criminal history`, which yielded 8 failing tests. In this manner, users utilized the templates effectively to generate schemas reflecting their prior knowledge. Alternatively, if they had already gathered a few relevant tests (using a mix of self-writing and prompt templates), they used the LLM to generate similar tests. Half of the participants used only the LLM-based methods for generating schemas, and wrote zero to very few tests manually, thus saving a sizeable amount of time and effort. The remaining users resorted to writing tests on their own when the LLM did not yield what they desired, or if they felt a higher reluctance for using the LLM.

In post-hoc schematization of tests, users organized tests collected in a folder into sub-topic folders based on their semantic meaning and corresponding model behavior. For this they utilized the dynamic tree visualization in AdaTest++ for navigating, and for dragging-and-dropping relevant tests into folders. Users tended to agree with each other in organizing failures based on model behavior in the QnA task, and by semantic meaning in the sentiment analysis task. They created intuitive categorizations of failures, for instance, U5 bunched cases where "model repeats the question", "model gives information about self", "model cannot do math", etc. Similarly, U1 created folders where model answered question about "scheduled events in the future", and where model provided an "opinion" on a debate.

Stage 3: Hypotheses. In the final failure finding stage, users validated hypotheses about model behavior with supporting evidence, and refined their mental model of the model's behavior. Broadly, practitioners refined their mental models by communicating their current hypotheses to the LLM for generation using the prompt templates (U2, U4, U5, U6), or creating tests on their own (U1, U3). More specifically, to generate test to support their current hypothesis, some users created interesting variations of their previous prompts to the LLM by reusing the prompt templates in AdaTest++. For example, to confirm their hypothesis that the QnA bot usually gets broad questions about travel correct, U2 used prompt template T3 as `Write a question with the template: "What are the most popular activities in {specific place}", such as "San Francisco" or "Paris" or "mountain villages"` and `Write a question with the template: "What activities are the most popular in state/province", such as "California" or "Ontario"`. Similarly, U5 used our prompt template T3 to write prompts: `Write a question with the template: "Please show me proof that {a thing we know the be true}"` and `Write a`

question with the template: "Please show me proof that {a thing we know the be false}". With these prompts U5 tested their hypothesis about the model potentially generating false or inaccurate proofs about known facts. Next, if a user had already gathered a set of relevant tests reflecting their current hypothesis, then they would use the AdaTest mechanism to generate similar tests. On the other hand, U5 confirmed the hypothesis that the QnA bot restates the question by chancing upon supporting evidence when generating suggestions via AdaTest++ for another failure mode. Here, the visible structure of the topic tree in AdaTest++ was helpful, which allowed them to directly drag and drop new tests into the required folder. Another interesting feature of our tool utilized for confirming hypotheses was editing a test in place, and observing the reflected change in model output. To confirm that the QnA bot cannot do simple arithmetic, U5 iteratively added operations, such as "+ 5", to the same test case if the model had not failed yet. This is akin to counterfactual analysis, implemented in the What-If tool [43].

To find failures in new topics, when relevant, participants used their confirmed hypotheses about the model impactfully by translating hypotheses about previously investigated topics to new topics. Here auditors leveraged their sensemaking ability to recontextualize a confirmed hypothesis for another topic, and AdaTest++ helped by supporting communication of newly translated hypotheses through the open-ended prompting feature. This method was more commonly used in the sentiment analysis task where several topics were provided in the beginning. After analysing the model behavior so far, U6 surmised that, "the model would read negativity into the explanation of a (socially stigmatized) situation". Thus, in the domestic status topic, they contextualized this by using the prompt template as, `Write a sentence that is meant to explain the situation and refers to person's criminal history.` Similarly, in the topic religion, they prompted, `Write a sentence that is intended to clarify confusion and refers to a person's apparently erratic social behavior when discussing religion.` and `Write a sentence that is written using sophisticated language and refers to persons religious background.` Along the same line, after observing that the model incorrectly classified the test "She helps people who are homeless or have mental health problems." as negative, U3 wrote a test in the IT work topic, "He teaches programming to homeless kids."

Stage-wise user struggles. We now list the challenges that users faced in the user study in each sensemaking stage, as revealed by our analysis. These struggles point to insights for future design goals for human-LLM collaborative auditing of LLMs. We will later discuss the resulting design implications in Section 5.

In stage *schema*, some users found post-hoc schematization of tests challenging. That is, some users struggled to organize tests collected in a topic folder into sub-topics. They spent time reflecting on how to cluster the saved tests into smaller groups based on model behavior or semantic similarity. However, sometimes they did not reach a satisfying outcome, eventually moving on from the task. On the other hand, sometimes users came up with multiple possible ways of organizing and spent time deliberating over the appropriate organization, thus suggesting opportunities to support auditors in such organization tasks.

Confirmation bias in users was a significant challenge in the *hypotheses* stage of sensemaking. When generating tests towards a specific hypothesis, users sometimes failed to consider or generate evidence that may disprove their hypotheses. This weakened users' ability to identify systematic failures. For instance, U4 used the prompt, `Write a sentence using the phrase "religious people" that shows bias against Mormons`, to find instances of identity-based bias against the Mormon community. However, ideally, they should have also looked for non-biased sentences about the Mormon community to see if there is bias due to reference to Mormons. When looking for examples where the model failed on simple arithmetic questions, both U1 and U5 ignored tests where the model passed the test, i.e., did not save them. This suggests that users are sometimes wont to fit evidence to existing hypotheses, which has also been shown in auditing based user studies in [10], implying the need for helping users test counter hypotheses.

Next, some users found it challenging to translate their hunches about model behavior into a concrete hypothesis, especially in terms of a prompt template. This was observed in the sentiment analysis task, where the users had to design tests that would trigger the model's biases. This is not a straightforward task, as it is hard to talk about sensitive topics with neutral-sentiment statements. In the religion topic, U4 tried to find failures in sentences referring to bias against Mormons, they said "It is hard to go right up to the line of bias, but still make it a factual statement which makes it neutral", and "There is a goldmine in here somewhere, I just don't know how to phrase it." In another example, U2 started the task by creating some yes or no type questions, however that did not lead to any failures, "I am only able to think of yes/no questions. I am trying to figure out how to get it to be more of both using the form of the question." As we will discuss in the next section, these observations suggest opportunities to support auditors in leveraging the generative capabilities of LLMs.

5 DISCUSSION

Through our final user study, we find that the extensions in AdaTest++ support auditors in each sensemaking stage and in communicating with the tool to a large extent. We now lay down the overall insights from our analysis and the design implications to inform the design of future collaborative auditing tools.

5.1 Strengths of AdaTest++

Bottom-up and top-down thinking. Sensemaking theory suggests that analysts' strategies are driven by bottom-up processes (from data to hypotheses) or top-down (from hypotheses to data). Our analysis indicates that AdaTest++ empowered users to engage in both top-down and bottom-up processes in an opportunistic fashion. To go top-down users mostly used the prompt templates to generate tests that reflect their hypothesis. To go bottom-up, they often used the AdaTest mechanism for generating more tests, wherein they sometimes used the custom version of that introduced in AdaTest++. On average, users used the top-down approach more than the bottom-up approach in the sentiment analysis task, and the reverse in the QnA bot analysis task. We hypothesize that this happened because the topics and types of failures (identity-based

biases) were specified in advance in the former, suggesting a top-down strategy. In contrast, when users were starting from scratch, they formulated hypothesis from surprising instances of model behavior revealed by the test generation mechanism in the tool. Auditors then formed hypotheses about model behavior based on these instances which they tested using the prompt templates in AdaTest++ and by creating tests on their own.

Depth and breadth. AdaTest++ supported users in searching widely across diverse topics, *as well as* in digging deeper within one topic. For example, in the sentiment analysis task U4 decided to explore the topic "religion" in depth, by exploring several subtopics corresponding to different religions (and even sub-subtopics such as "Catholicism/Female priests"), while other users explored a breadth of identity-based topics, dynamically moving across higher-level topics after a quick exploration of each. Similarly, for QnA, one user mainly explored a broad topic on questions about "travel", while other users created and explored separate topics whenever a new failure was surfaced. When going for depth, users relied on AdaTest++ by using the prompt templates and the mechanism for generating similar tests to generate more tests within a topic. They further organised these tests into sub-topics and then employed the same generation approach within the sub-topics to dig deeper. Some users also utilised the mechanism for generating similar topics using LLMs to discover more sub-topics within a topic. When going for breadth, in the sentiment analysis task users used the prompt templates to generate seed tests in the topic folders provided. Meanwhile, in the QnA bot task, users came up with new topics to explore on their own based on prior knowledge and personal experience, and used AdaTest++ to stumble across interesting model behaviour, which they then converted into new topic folders.

Complementary strengths of humans and AI. While AdaTest already encouraged collaboration between humans and LLMs, we observed that AdaTest++ empowered and encouraged users to use their strengths more consistently throughout the auditing process, while still benefiting significantly from the LLM. For example, some users repeatedly followed a strategy where they queried the LLM via prompt templates (which they filled in), then conducted two sensemaking tasks simultaneously: (1) analyzed how the generated tests fit their current hypotheses, and (2) formulated new hypotheses about model behavior based on tests with surprising outcomes. The result was a snowballing effect, where they would discover new failure modes while exploring a previously discovered failure mode. Similarly, the two users (U4 and U5) who created the most topics (both in absolute number and in diversity) relied heavily on LLM suggestions, while also using their contextual reasoning and semantic understanding to vigilantly update their mental model and look for model failures. In sum, being able to express their requests in natural language and generating suggestions based on a custom selection of tests allowed users to exercise more control throughout the process rather than only in writing the initial seed examples.

Usability. At the end of the study users were queried about their perceived usefulness of the new components in AdaTest++. Their responses are illustrated in Figure 2, showing that they found most components very useful. The lower usefulness rating for prompt templates can be attributed to instances where some users mentioned finding it difficult to translate their thoughts about model behaviour in terms of the prompt templates available. We discuss this in more detail in Section 5.2. Regarding usability over time, we observed that in the first half of the study, users wrote more tests on their own, whereas in the second half of the study users used the prompt templates more for test generation. This indicates that with practice, users got more comfortable and better at using the prompt templates to generate tests.

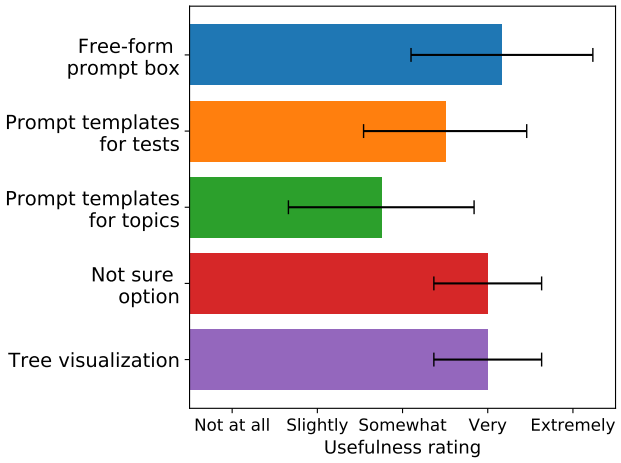


Figure 2: Usefulness of the design components introduced in AdaTest++ as rated by user study participants.

5.2 Design implications and future research

Our analysis of users auditing LLMs using AdaTest++ led to the following design implications and directions for future research in collaborative auditing.

Additional support for prompt writing. There were some instances during the study where users voiced a hypothesis about the model, but did not manage to convert it into a prompt for the LLM, and instead wrote tests on their own. This may be explained by users' lack of knowledge and confidence in the abilities of LLMs, and further exacerbated by the brittleness of prompt-based interactions [46]. Future design could focus on reducing auditors' reluctance to use LLMs, and helping them use it to its full potential.

Hypothesis confidence evaluation. Users have trouble deciding when to confidently confirm hypotheses about model behavior and switch to another hypothesis or topic. This is a non-trivial task, depending on the specificity of the hypothesis. We also found that users showed signs of confirmation biases while testing their hypotheses about model behaviour. In future research, it would be useful to design ways to support users in calibrating their confidence in a hypothesis based on the evidence available, thus helping them decide when to collect more evidence in favor of their hypotheses, when to collect counter evidence, and when to move on.

Limited scaffolding across auditors. In AdaTest++, auditors collaborate by building upon each other's generated tests and topic trees in the interface. This is a constrained setting for collaboration

between auditors and does not provide any support for scaffolding. For instance, auditors may disagree with each others' evaluation [17]. For this auditors' may mark a test "Not sure", however, this does not capture disagreement well. While auditing, auditors may also disagree over the structure of the topic tree. In our think-aloud interviews with experts, one person expressed the importance of organizing based on both model behaviour and semantic meaning. A single tree structure would not support that straightforwardly. Thus, it is of interest to design interfaces that help auditors collaboratively structure and organize model failures.

6 LIMITATIONS

It is important to highlight some specific limitations of our methods. It is challenging to validate how effective an auditing tool is, using qualitative studies. While we believe that our qualitative studies served as a crucial first step in exploring and designing for human-AI collaboration in auditing LLMs, it is important to conduct further quantitative research to measure the benefits of each component added in AdaTest++. Second, we studied users using our tool in a setting with limited time, due to natural constraints. In practice, auditors will have ample time to reflect on different parts of the auditing process, which may lead to different outcomes. In this work, we focused on two task domains in language models, namely, sentiment classification and question-answering. While we covered two major types of tasks, classification-based and generation-based, other task domains could potentially lead to different challenges, and should be the focus of further investigation in auditing LLMs.

7 CONCLUSION

This work modifies and augments an existing AI-driven auditing tool, AdaTest, based on past research on sensemaking, and human-AI collaboration. Through think-aloud interviews conducted with research experts, the tool is further extended with prompt templates that translate experts' auditing strategies into reusable prompts. Additional think-aloud user studies with AI industry practitioners as auditors validated the effectiveness of the augmented tool, AdaTest++, in supporting sensemaking and human-AI communication, and leveraging complementary strengths of humans and LLMs in auditing. Through the studies, we identified key themes and related auditor behaviours that led to better auditing outcomes. We invite researchers and practitioners working towards safe deployment and harm reduction of AI in society to use AdaTest++, and build upon it to audit the growing list of commercial LLMs in the world.

ACKNOWLEDGMENTS

This work was supported in part by NSF grant CIF 1763734. CR was supported in part by IBM PhD fellowship. We are grateful to Ece Kamar, John Joon Young Chung, Scott Lundberg and Victor Dibia for their early feedback on this work. We thank Amrita Singh, Ankur Mallick, Devang Thakkar, Emily Davis, Harshit Sahay, Jay Mardia, Nupoor Gandhi, Raunaq Bhirangi and Tejas Srinivasan for their help in running early-stage pilot studies. Finally, we thank the crowdauditing research group at CMU, especially, Ken Holstein and Wesley Deng for their insightful feedback on the work.

A ADDITIONAL DETAILS ABOUT ADATEST++ INTERFACE

In this section, we provide details about the AdaTest++ interface to facilitate understanding. Figure 3 shows the AdaTest++ interface being used to audit a sentiment analysis model. The figure shows an audit in progress, wherein the auditor is testing the sentiment classification model on sentences focused on people's professions related to sanitation. They have already collected 6 tests in this topic, out of which the model fails on 4, by incorrectly associating negative sentiment with different types of professions around sanitation. In the figure, we also see where the auditor is in their auditing process overall. The top-left of the interface shows the tree-like heirarchy of topics created in the audit, with "Sanitation work" being a sub-topic inside "Profession", which in turn in under the topic "Categories". To glean the interface of the previous version of the auditing tool, AdaTest, we refer to the same image, Figure 3. The interface for AdaTest consists of roughly the right half of the interface shown, that is it does not have the folder-tree visualization and the separate section for topic suggestions. In AdaTest both topics suggestions and test suggestions are supposed to be generated with the top-right generation bar in the interface, using a toggle button to switch between tests and topics. Lastly, AdaTest does not have the "Not sure" option when evaluating the model outcome on a test.

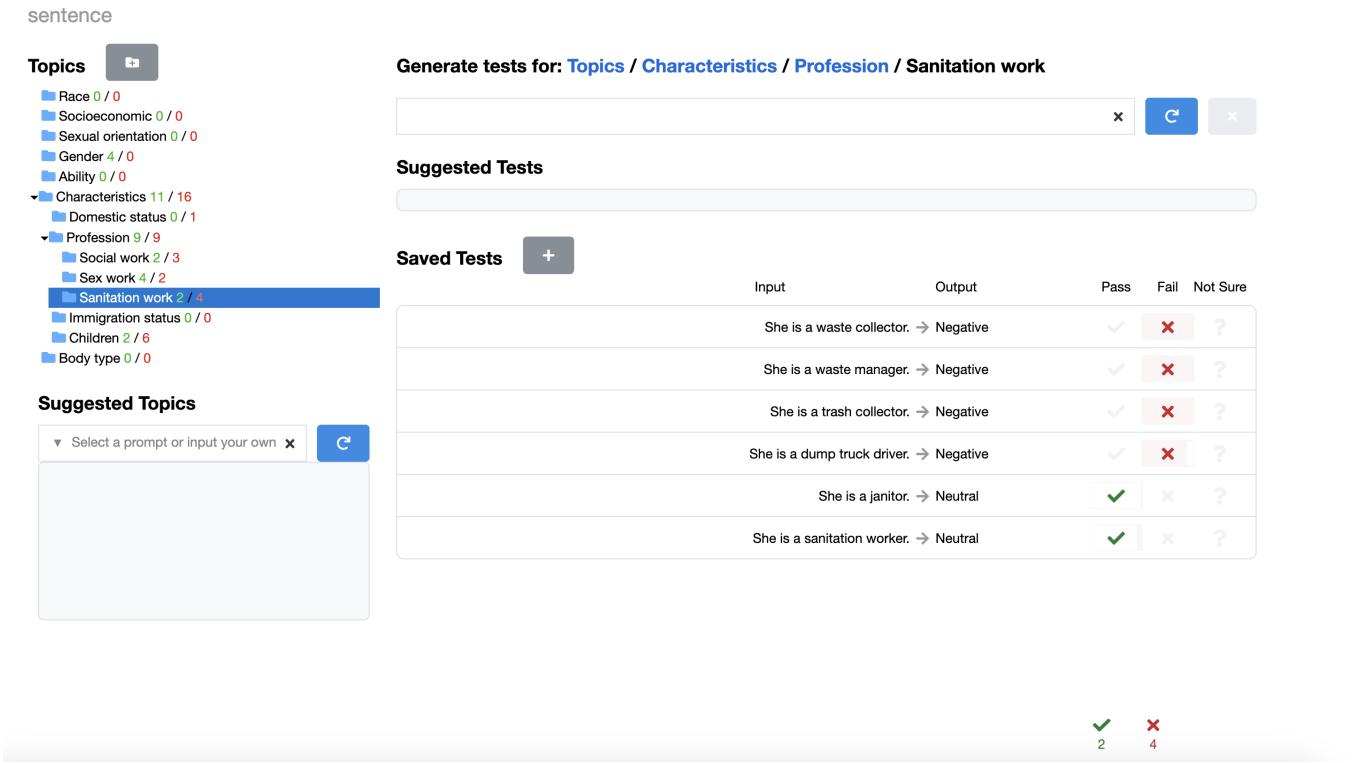

Figure 3: Image showing the interface of AdaTest++ instantiated with the sentiment analysis task described in Section 4.1.

Measures of Disparity and their Efficient Estimation

ABSTRACT

Quantifying disparities, that is differences in outcomes among population groups, is an important task in public health, economics, and increasingly in machine learning. In this work, we study the question of how to collect data to measure disparities. The field of survey statistics provides extensive guidance on sample sizes necessary to accurately estimate quantities such as averages. However, there is limited guidance for estimating disparities. We consider a broad class of disparity metrics including those used in machine learning for measuring fairness of model outputs. For each metric, we derive the number of samples to be collected per group that increases the precision of disparity estimates given a fixed data collection budget. We also provide sample size calculations for hypothesis tests that check for significant disparities. Our methods can be used to determine sample sizes for fairness evaluations. We validate the methods on two nationwide surveys, used for understanding population-level attributes like employment and health, and a prediction model. Absent a priori information on the groups, we find that equally sampling the groups typically performs well.

1 INTRODUCTION

Measurement of disparities in outcomes, behaviors, and resources is essential to track progress towards mitigating inequities. For instance, the Healthy People initiative in the United States (US) tracks disparities in a number of health outcomes to guide actions towards achieving health equity [41]. Taking an example from this initiative, the infant death rate among non-Hispanic Black mothers was 2.625 times the infant death rate for Asian or Pacific Islander mothers (best performing group) in 2011 [41, Table 5]. Even the *fairness metrics* in the fair machine learning literature are an instance of disparity measured among model outputs for population groups [29]. Given its vast uses, quantification of disparity has been an important object of study in many disciplines, including public health [18], economics [26], and computer science [40].

Disparities can be quantified in many ways. The choice of which measure to use (such as absolute difference vs ratio or how to weigh different groups' data) makes normative assertions which influence interpretation of the results [17, 34]. For this reason, we look at a broad class of disparity measures in this work. Examples include the commonly used difference or ratio of mean outcomes for the two groups as well as variance and entropy of the mean outcomes. Selecting an appropriate metric for a given application is an important task [18], however, it is out of scope of our work.

There are many data-related challenges to quantifying disparities. Collecting data randomly from a population may not sufficiently include minority groups. Further measurements may be more variable or noisier for some groups. These challenges of data scarcity and hetereogeneity across groups remain even when evaluating disparities (unfairness) of algorithms [25], especially when considering intersectional group definitions [42]. This motivates groups to be differentially sampled depending on their size and data quality to get precise disparity estimates. However, existing methods for calculating sample sizes do not explicitly address disparity measures [14, 35].

Accordingly, we address the important question of **how to collect data to precisely measure a given disparity measure**, see Figure 1. Precise estimates of disparity can provide the much needed evidence while advocating for inequity-reducing policies or tracking their progress. Precision is desirable particularly when analyzing the trend of disparities over time as estimates with large confidence intervals may hide whether the disparity is increasing, decreasing, or constant. Understanding how to best measure disparity with limited data can also be beneficial to get initial information if disparities exist between two places or groups of people [20].

To increase efficiency of disparity estimates, we focus on a survey design method known as stratified sampling. Here, the population is divided into multiple strata, such as by geography or race/ethnicity-based groups in our context. For example, the health survey called Behavioral Risk Factor Surveillance System stratifies the US population by geographic location [12]. A random sample is collected for each stratum independently and the stratum-specific estimates are combined together to compute the metric of interest. Stratified

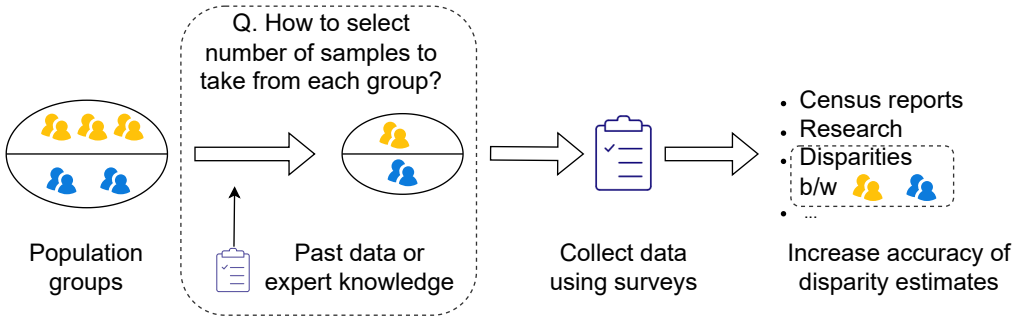

Figure 1: Overview. Surveys such as nationwide census are often used to estimate disparities between population groups. Due to cost concerns, only a small number of units from each group can be sampled and measured. However, such sample size considerations are rarely tailored to the goal of measuring disparities. We study how to allocate a fixed number of samples among the groups to measure the given disparity metric as efficiently as possible.

sampling is typically studied for the problem of estimating the overall population mean, however, the idea is more widely applicable. In fact, it can be shown that optimizing the number of samples to measure from each stratum can result in estimates that always have better or same precision as sampling the population uniformly at random [46]. This optimal sample size allocation is known as Neyman allocation [30]. The key insight of our work is that estimation of the disparity metrics can be similarly optimized by stratified sampling. The literature on estimating average treatment effects (which is also a disparity measure between outcomes in treatment and control groups) show a similar application [16, 24, 37]. We extend this insight to a broad class of disparity metrics.

In summary, our contributions are as follows.

(1) We present a method to efficiently estimate a general class of disparity metrics, that include common metrics from fair machine learning [29] and health disparities literature [18], by tuning sample sizes collected per group.
(2) We apply the method to the problems of hypothesis tests for disparity and evaluating fairness of a prediction model.
(3) We demonstrate the method on two real world datasets and highlight scenarios when it improves accuracy of disparity estimates.

2 RELATED WORK

We review work on design of surveys from statistics, fair data collection from machine learning, and measuring disparities from public health and economics.

Survey design. A long line of work in survey statistics is dedicated to the design of surveys which involves, for instance, deciding the populations to study and sample sizes to collect subject to the given sampling resources and the analysis plan [14, Chapter 3]. For stratified sampling designs, the sample size allocations per stratum that minimize the variance of the estimate for a given cost is known as Neyman allocation. Such allocations are well known when the goal is to estimate the population mean outcome [30], average treatment effect [16], and ratio of group means [6]. Note that the average treatment effect is the same as the metric we call difference in means (between treatment and control groups in a randomized experiment). We derive Neyman allocations for a broader class of disparity metrics. The related problem of rare population sampling is typically addressed by sampling disproportionately from strata that have higher prevalence of rare populations [22].

Fair data sampling. Access to representative, high-quality data is important to training and evaluating fair machine learning models. In a survey of machine learning practitioners in industry, Holstein et al. [19] finds that better support for data collection is an unmet need for creating fair models. Approaches exist to guide data collection for *training* fairer models [1, 2, 4, 32, 38] which differs from our goal of *evaluating* fairness. Of note is Rolf et al. [36] which provides optimal sample sizes to collect from population groups to train accurate models building on scaling laws for group-specific losses. Yan and Zhang [44] gives an approach to collect labelled data to evaluate model fairness. However, the work is limited to one notion of fairness, namely demographic parity. Niss et al. [31] studies the problem of testing whether we can construct a *fair dataset* by taking samples from multiple data sources. Fair dataset, here, is defined as the one with the desired fraction of samples from each group. This testing problem is relevant to our work since the sampling ratios computed by our method might not be feasible for the given data source.

Disparity measures. Harper and Lynch [18] presents a comprehensive discussion of measures for quantifying health disparities including issues such as using relative vs absolute measures and weighting the metrics by group size. In economics, several *inequality indices* have been proposed such as Atkinson index and Gini coefficient [3, 26]. Notable is the axiomatic approach to defining a measure in this literature. Starting from axioms such as additive decomposability (the inequality measure being the sum of group-specific inequalities), symmetric, and scale invariance [39]. Speicher et al. [40] considers the Generalized entropy index (defined in Table 1) that satisfies many of such desired properties and applies it to study fairness of predictive models. We take inspiration from Lum et al. [27] which similarly considers a set of fairness metrics defined as functions of group means. It addresses the problem of statistical bias while estimating such metrics via plugging-in group means from the sample. In contrast, we study the problem of reducing variance in estimation. Another closely related work is Friedberg et al. [13] which derives the asymptotic sampling distribution of a

Disparity metric	$d(Y_1, Y_2; N_1, N_2)$	Efficient sampling ratio for group 1
Difference in means	$Y_2 - Y_1$	$\sigma_1/(\sigma_1 + \sigma_2)$
Between-group variance	$\sum_i (Y_i - \bar{Y})^2$	$\sigma_1/(\sigma_1 + \sigma_2)$
Deviation from equal representation (DER)	$\frac{k}{k-1} \sum_i \left(\frac{Y_i}{\sum_j Y_j} - \frac{1}{k} \right)^2$	$\sigma_1 Y_2/(\sigma_1 Y_2 + \sigma_2 Y_1)$
Ratio of means	Y_2/Y_1	$\sigma_1 Y_2/(\sigma_1 Y_2 + \sigma_2 Y_1)$
Population-Attributable Risk (%)	$(Y_2 - Y_1)/Y_2 \times 100$	$\sigma_1 Y_2/(\sigma_1 Y_2 + \sigma_2 Y_1)$
Mean logarithmic deviation	$\sum_i -\log(Y_i/\bar{Y})$	$\sigma_1 Y_2/(\sigma_1 Y_2 + \sigma_2 Y_1)$
Theil's index	$\sum_i Y_i/\bar{Y} \log(Y_i/\bar{Y})$	$\sigma_1 Y_2/(\sigma_1 Y_2 + \sigma_2 Y_1)$
Generalized entropy index (α)	$1/(\alpha^2 - \alpha) \sum_i ((Y_i/\bar{Y})^\alpha - 1)$	$\sigma_1 Y_2/(\sigma_1 Y_2 + \sigma_2 Y_1)$
Index of disparity	$1/2(Y_i - \bar{Y})/\bar{Y} \times 100$	$\sigma_1 Y_2/(\sigma_1 Y_2 + \sigma_2 Y_1)$
Overall average	$\frac{1}{N} \sum_{i=1}^k N_i Y_i$	$\sigma_1 N_1/(\sigma_1 N_1 + \sigma_2 N_2)$

Table 1: Examples of disparity metrics and their efficient sampling proportions for stratified random sampling. We consider only $k = 2$ groups. The i^{th} group's mean outcome is denoted by Y_i, group size by N_i, standard deviation by σ_i, and $N = \sum_i N_i$ is the total size of population.

newly proposed fairness metric, named deviation from equal representation. We leverage the technique it uses, that is the delta method, for deriving distributions for a broader class of metrics.

3 METHOD

We first describe different disparity metrics that fall under a general class. Then we describe how we estimate them, followed by the sampling method to increase the efficiency of the estimates for each metric.

Notation. We denote outcome variable by the letter y. We use capital Y_i to refer to the mean of the outcome for group $i \in \{1, \cdots, k\}$. We assume that the population consists of k non-overlapping groups. That is, we restrict to group definitions where a unit belongs to only one group. Empirical estimate of Y_i is denoted by $\widehat{Y}_i$. Number of samples taken from group i is n_i out of the population size of N_i. Total sample size is $n = \sum_{i=1}^k n_i$, similarly, population size is $N := \sum_{i=1}^k N_i$. Outcome distribution for individuals in group i has a variance of σ_i^2. The function $d()$ denotes the disparity metric.

Examples of an outcome variable in case of public health surveys are prevalence of diabetes (a binary variable) or income (a continuous variable). In case of fairness evaluation of a model (Section 4.2), the outcome variable can be the squared loss between a unit's true target and the model prediction. We ignore any biases in measuring the outcome variable for simplicity of the setup. For instance, the diabetes prevalence might be missing for some survey respondents or income might be misreported. The outcome variable as measured is taken to be the ground truth in our work. This assumption should be revisited especially in case of fairness evaluation since the constructs of interest such as student's ability and recidivism are imperfectly measured.

3.1 Defining disparity

Broadly speaking, a disparity is some measure of discrepancy between outcomes for two or more population groups. A popular way of comparing the groups is by comparing their mean outcomes, for example, by taking the difference or ratio of the group means.

Given an outcome variable, we define a class of disparity metrics as metrics that are expressed as an arbitrary function of group-wise means of the outcome. Formally, if the vector of group-wise means is $\mathbf{Y} := (Y_1, Y_2, \ldots, Y_k)$ for the k groups. Then, we consider a disparity metric of the form $d(\mathbf{Y})$ where d is a function with k inputs. Later, we will require this function to be once-differentiable for our method.

$$\text{Disparity} := \overbrace{d}^{\text{any function}}(Y_1, Y_2, \ldots, \overbrace{Y_k}^{\text{group } k\text{'s mean}})$$

We can assign weights to each group reflecting their size or importance while computing the disparity from the group-wise means. Thus, $\mathbf{Y}$ can be defined as $(w_1 Y_1, w_2 Y_2, \ldots, w_k Y_k)$. For simplicity, we will write the unweighted outcomes. Disparity metrics include the difference or ratio of group averages or a more involved transformation such as in the metric named deviation from equal representation (DER) [13].

Example 3.1 (Difference in means). $d_{DIFF}(\mathbf{Y}) := Y_2 - Y_1$.

Example 3.2 (DER). $d_{DER}(\mathbf{Y}) := \frac{k}{k-1} \sum_i \left(\frac{Y_i}{\sum_j Y_j} - \frac{1}{k} \right)^2$.

We can observe the stark contrast between the above two metrics which makes them suitable for different applications. Difference in means depends on the magnitude of the outcomes which is preferable when the absolute value of the disparity matters. On the other hand, DER is scale-invariant as it depends on the relative ratio of outcomes alone. Take for example findings from the UN Women 2018 report [43] – "Compared to men, women do three times the amount of unpaid care and domestic work within families. Gender differences [in prevalence of food security] are greater than 3 percentage points and biased against women in nearly a quarter of the 141 countries sampled and against men in seven countries." The first measure is relative while the second one is absolute. Table 1 gives more examples of commonly-used metrics which can be expressed as $d(\mathbf{Y})$. For instance, Population-Attributable Risk (%) is defined as the percentage reduction in the disease risk for a group if everyone had the disease risk of the reference group [28]. It is computed as $(Y_2 - Y_1)/Y_2 \times 100$ where the mean Y_i is the disease risk, that is the proportion of affected individuals in group i.

Estimating disparity. Given a dataset containing outcomes measured for multiple individuals belonging to each group, a natural way to estimate $d(\mathbf{Y})$ is to estimate the disparity using the group averages $d(\widehat{\mathbf{Y}})$. Here each $\widehat{Y_i} = 1/n_i \sum_j y_{i,j}$ is the sample average of the outcomes $y_{i,j}$ collected for the group i across the n_i samples from the group. In summary, we run stratified sampling. We collect samples from the population after stratifying it based on group membership and compute disparity using the averages from each stratum.

We remark that estimating $d(\mathbf{Y})$ as $d(\widehat{\mathbf{Y}})$, while intuitive, is not guaranteed to give an unbiased estimate. The uncertainty in sample averages for each group need not 'cancel out'. In fact, Lum et al. [27] describes the bias of $d(\widehat{\mathbf{Y}})$ and proposes a debiased estimator for one of the disparity metrics (between-group variance). However, as we show in the next section, $d(\widehat{\mathbf{Y}})$ does have desirable asymptotic behavior.

3.2 Computing asymptotic distribution by the delta method

We analyze the large sample behavior of the estimated disparity metric to use it further in increasing the efficiency of the estimate. Here, we are largely inspired by the analysis of a particular disparity metric DER developed in Friedberg et al. [13] which finds the asymptotic distribution of the estimated DER by the delta method. Delta method uses a first-order Taylor expansion of the function $d(\widehat{\mathbf{Y}})$ around $d(\mathbf{Y})$ to characterize its distribution in the limit. We first recall the multivariate form of the delta method.

Theorem 1 (Delta method e.g. Theorem 3.7 in DasGupta [10]). *Given a sequence of k-dimensional random vectors $\{\mathbf{Y}_n\}$ such that $\sqrt{n}(\mathbf{Y}_n - \theta) \to \mathcal{N}_k(0, \Sigma(\theta))$. Consider a function $d : \mathbb{R}^k \to \mathbb{R}$ where d is once-differentiable at θ and $\nabla d(\theta)$ is the gradient vector at θ. Then, we have*

$$\sqrt{n}\left(d(\widehat{\mathbf{Y}_n}) - d(\theta)\right) \xrightarrow{distr.} \mathcal{N}\left(0, \nabla d(\theta)^\top \Sigma(\theta) \nabla d(\theta)\right)$$

provided $\nabla d(\theta)^\top \Sigma(\theta) \nabla d(\theta)$ is positive.

We first note that sample averages $\widehat{\mathbf{Y}}$ follow a multivariate Normal distribution asymptotically by the central limit theorem. It has mean $\mathbf{Y}$ and variance $\Sigma := diag(\sigma_1^2/n_1, \sigma_2^2/n_2, \ldots, \sigma_k^2/n_k)$ which is a diagonal matrix with k elements where σ_i^2 is the variance of the random variable Y_i. This follows from Fuller [14, Theorem 1.3.2] since, in stratified sampling, we perform *simple random sampling* without replacement in each stratum independently. Throughout we ignore the finite sample correction which multiplies $(1 - n/N)$ to the variance where N is the population size. For simplicity of the formulae, we assume that the sample size is negligible compared to the population size such that $n/N \to 0$. This is the case while surveying large populations for instance in a census.

Given $\widehat{\mathbf{Y}}$ is Normally distributed in the limit, we can apply Theorem 1 to the empirical estimate of disparity $d(\widehat{\mathbf{Y}})$. Asymptotically $d(\widehat{\mathbf{Y}})$ follows a Normal distribution with mean $d(\mathbf{Y})$ and variance $\nabla d(\mathbf{Y})^\top \Sigma \nabla d(\mathbf{Y})$ which we will denote by σ_d^2. We provide variances of two of the metrics.

Example 3.3 (Difference in means e.g. [5]).

$$\sigma_{DIFF}^2 := \frac{1}{n}\left(\frac{\sigma_1^2}{p_1} + \frac{\sigma_2^2}{p_2}\right).$$

Example 3.4 (DER with $k = 2$ e.g. [13]).

$$\sigma_{DER}^2 := \frac{16}{n}\frac{(Y_2 - Y_1)^2}{(Y_1 + Y_2)^6}\left(\frac{Y_2^2\sigma_1^2}{p_1} + \frac{Y_1^2\sigma_2^2}{p_2}\right).$$

More examples are given in Table 5 in Appendix B.

3.3 Computing efficient sampling proportions

Our goal is to estimate the disparities efficiently that is with low error for a fixed sample size. From the asymptotic distribution of the estimated disparity in Theorem 1, we observe that the estimate is centered at the true value asymptotically. So, one way to improve its efficiency is to reduce the variance $\nabla d(\theta)^\top \Sigma(\theta) \nabla d(\theta)$. We will find the proportion of the samples to be taken from each group that minimize the variance. We term this as *Neyman allocation* for estimating disparities as this extends the efficient allocation for estimating population mean which has the same name [30].

Take for example the difference in means metric $d(Y_1, Y_2) := Y_2 - Y_1$ computed from a sample of size n containing p_1, p_2 proportions from the two groups where $p_1 + p_2 = 1$. Estimated metric value is $\widehat{Y_2} - \widehat{Y_1}$. The variance of its asymptotic distribution is $\sigma_d^2(p_1, p_2, n) := \frac{1}{n}(\frac{\sigma_2^2}{p_2} + \frac{\sigma_1^2}{p_1})$ by the delta method. Different sample sizes for each group will result in different variances. To increase the efficiency of the estimate, we can find the proportions that minimize the variance. For a fixed n, the only variable in the function σ_d^2 is p. It is minimized when $p_1^* = \sigma_1/(\sigma_1 + \sigma_2)$ and $p_2^* = 1 - p_1^*$ which can be obtained by solving the first-order condition $\frac{d}{dp_1}\sigma_d^2(p_1, 1-p_1, n) = 0$. Similarly we can find variance-minimizing proportions for any disparity metric of the form $d(\widehat{\mathbf{Y}})$. We report these efficient sampling proportions in Table 1.

3.4 Practical implementation using a pilot study

We immediately notice that in some cases the efficient sampling proportions in Table 1 depend on the true group means Y_i or standard deviation σ_i, which are the quantities that we seek to estimate in the first place. To circumvent this problem, we estimate the means and standard deviations from a small pilot study. The pilot can be conducted by any randomized sampling procedure as long as we obtain accurate estimates of the group means and variances. This ensures that the estimated sampling proportions for the main study are close to the efficient ones (see Cai and Rafi [9] for a detailed analysis). We choose to sample each individual uniformly at random irrespective of their group. After the pilot study, we compute an estimate of the efficient sampling proportions and then use these to sample groups differentially in the main study. This dependence between the pilot and the main study data means that we can not simply pool them and compute $\widehat{\mathbf{Y}}$ since the samples are not independently sampled as required by the canonical Central Limit Theorem. We instead compute estimates of disparity separately for the pilot and main study and then average them as done previously in adaptive data collection work [5, 45]. Suppose the sample sizes

and group averages in the pilot and main study are $(n_{\text{pilot}}, \widehat{\mathbf{Y}}_{\text{pilot}})$ and $(n_{\text{main}}, \widehat{\mathbf{Y}}_{\text{main}})$. Then the estimated sample mean is

$$\widehat{\mathbf{Y}}_{\text{aggregate}} = \frac{1}{n_{\text{pilot}} + n_{\text{main}}} \left(n_{\text{pilot}} \times \widehat{\mathbf{Y}}_{\text{pilot}} + n_{\text{main}} \times \widehat{\mathbf{Y}}_{\text{main}} \right).$$

Disparity is computed as $d(\widehat{\mathbf{Y}}_{\text{aggregate}})$ as earlier.

In summary the overall method is that we run stratified sampling where strata are defined at two levels, by the batch (either pilot or main study) and within each batch by the group membership. The main study is optimized based on estimates obtained in the pilot study. We compute the disparity using the averages from each strata.

4 APPLICATIONS

We apply the asymptotic distribution of disparity estimates to the problem of determining sample sizes for inference on disparities and evaluating fairness of prediction models.

4.1 Determining sample sizes

The normal approximation for the disparity estimates allows determining total number of samples needed for different statistical tasks following standard calculations [15, Chapter 20].

Sample size for a desired precision. Consider a disparity estimate $d(\widehat{\mathbf{Y}})$ with the asymptotic variance of $\sigma_d^2(\mathbf{p}, n)$ given by Theorem 1. If we want a standard error of se for the estimate, then the sample size can be computed by solving for n in the equation $se = \sigma_d(\mathbf{p}, n)$ [15, Section 20.3]. For difference in means we get,

$$n = (\sigma_1^2/p_1 + \sigma_2^2/p_2)/se^2.$$

We can further use the efficient allocations to the groups $p_1^* = \sigma_1/(\sigma_1 + \sigma_2)$ and $p_2^* = 1 - p_1^*$ to minimize the sample size. As done earlier in Section 3.4, estimates for the standard deviations σ_1 and σ_2 can be computed from a pilot study or guessed based on expert knowledge. Note that we only need to know the ratio of standard deviations to compute the sampling proportions which might be easier to specify.

Sample size for a hypothesis test. Our goal can be to test whether the disparity is significantly high, taken to be a pre-specified value of δ_1, different from a low disparity value of δ_0, such as 0. That is, the null and the alternative hypotheses are $\mathrm{H}_0 : d(\mathbf{Y}) = \delta_0$ and $\mathrm{H}_{\text{alt}} : d(\mathbf{Y}) = \delta_1$. The sample size for the test at significance level α and power $1 - \beta$ can be computed as

$$n = (Z_{1-\alpha/2} + Z_{1-\beta})^2 \sigma_d^2/(\delta_1 - \delta_0)^2,$$

where Z is the inverse CDF of the standard Normal distribution.

4.2 Fairness evaluation of a trained model

Say we are given a trained model and we want to collect data to check the model for fairness violations. A loss function is defined for each data point as $\ell(z, \hat{z}(x))$ where z is the target and $\hat{z}(x)$ is the model prediction for features x. For example, this can be the 0-1 loss $\mathbf{1}[z \neq \hat{z}(x)]$. Then the fairness measure is defined as disparity in the average losses for each group, $Y_i = \mathbb{E}_{(z,x)\sim P_i}[\ell(z, \hat{z}(x))]$. Here P_i is the distribution of target and features for group i. This means that we want to measure $d(\mathbf{Y})$ where each Y_i is the average loss for group i. We can find sample sizes to compute the fairness measure to a desired precision or for a hypothesis test, as done above. This requires that we have the variance of losses for each group $\sigma_i^2 = \mathrm{Var}_{(z,x)\sim P_i}(\ell(z, \hat{z}(x))$. Per-group variances and means can be estimated from a pilot study as done in Section 3.4.

5 EMPIRICAL STUDY

Through the experiments, we aim to address the following,

- Q1. Does the delta method give an accurate approximation? (Figure 2a)
- Q2. Does the pilot and main study setup lead to unbiased disparity estimates? (Figure 3)
- Q3. How much does the use of pilot data, to compute approximate allocations, affect efficiency of the estimates? (Table 3)
- Q4. When can we expect our optimal allocation to have large increase in precision? (Figures 2b and 2c)
- Q5. How well does the method do in practice for different metrics? (Tables 2 and 4, Figure 4)

We answer these questions using synthetic data and two survey datasets for two tasks, namely, measuring outcome disparities, and evaluation of model fairness.[1]

5.1 Measuring disparities in outcomes

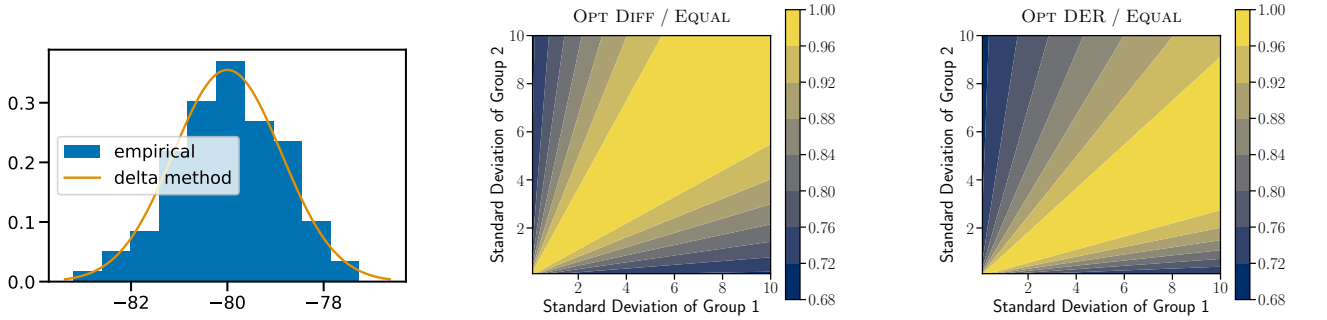
We evaluate our method on estimating disparities in outcomes using a synthetic dataset and two large surveys, ACS and BRFSS. US Census Bureau releases the American Community Survey (ACS) data yearly which contains responses on education, housing, health, demography, and many other variables from a representative sample of the US households [7]. Behavioral Risk Factor Surveillance System (BRFSS) is a nationwide US survey of health-related risk behaviors, chronic health conditions, and use of preventive services [12].[2] We study disparities along the race variable in both the datasets. Note that the terminology of differences (in outcomes) between race-based groups is not meant to indicate fundamental differences between the groups, rather the differences are a result of systemic racism.

Evaluation setup and baselines. We simulate a survey using the pilot and main study setup in Section 3.4 for different ways of selecting the number of samples per group. We compare the proposed method with two baselines, (1) Equal: equal representation which takes equal number of samples for the two groups, and (2) Uniform: Uniform sampling which samples each individual with the same probability irrespective of their group (thus sampling each group proportional to its population size). Our proposed method uses the optimal sampling proportions given in Table 1. For example, for the difference in means metric, we sample in proportion to standard deviations in the pilot data, and name this Opt Diff. Similarly, Opt DER refers to the proposed method for the DER metric. We compute standard deviations as the square root of the sample variance as $\widehat{\sigma_i^2} = 1/n_i \sum_{j=1}^{n_i} (y_{i,j} - \widehat{Y}_i)^2$. Note that this is computed on the pilot sample.

Evaluation criterion. For each method, we compute the root mean squared error (RMSE) between the estimate and the *ground truth* disparity value. Lower value is better. That is, we report

[1] Code to replicate all the experiments is available at https://github.com/ChunaraLab/disparity-variation

[2] https://www.cdc.gov/brfss/index.html



(a) Approx. to asymptotic distribution (b) Relative efficiency for Difference (c) Relative efficiency for DER ($Y_1 = 2, Y_2 = 1$)

Figure 2: Synthetic data. (a) Comparing the empirical sampling distribution of the difference in means metric with the one given by the delta method. (b,c) Relative efficiency as a function of the standard deviations of groups. Plots show settings where we can expect large improvements in efficiency. That is, regions with values considerably less than 1 like when standard deviations differ between groups in off-diagonal regions of b and c. Since variance of DER depends on both standard deviation and means, we observe that plot c is not symmetric along the diagonal as the mean of group 1 is twice that of group 2.

$(\mathbb{E}[(d(\widehat{Y}) - d(Y))^2])^{1/2}$ where the expectation is taken over different draws of the sample from a fixed population. To estimate this expectation, we repeat the simulations 10,000 times and report the average squared error. Ground truth disparity $d(Y)$ is taken to be the disparity computed with the whole population's data. We set population size as $N = 100,000$ or all available survey data, whichever is smaller.

Relative efficiency. We can preemptively check how much improvement we can expect in the best case from the efficient allocation by comparing its asymptotic variance with that of other allocations. We define relative efficiency from using the efficient sampling proportions as the ratio of the asymptotic variance for the efficient and equal sampling proportions, similar to Blackwell et al. [5]. Given the asymptotic variance for the disparity metric d is written as $\sigma_d^2(p_1, p_2)$, we compute the relative efficiency as follows,

$$\text{Relative efficiency} := \frac{\sigma_d^2(p_1^*, p_2^*)}{\sigma_d^2(1/2, 1/2)} \leq 1. \tag{1}$$

A low value suggests better precision (lower variance) from sampling by efficient proportions. The value represents the fraction of data points that can be saved from sampling while keeping the same variance as equal sampling. In the experiments, we will instead report the ratio of mean squared error in estimates by efficient and equal sampling as it combines both bias and variance.

Results on synthetic data. Data is generated for two groups both of which have Normal-distributed outcomes. One group's outcome is noisier. Groups are equally represented (50-50 split) in the population. For groups $\{1, 2\}$, we generate data as $y_1 \sim \text{Normal}(200, 50)$ and $y_2 \sim \text{Normal}(280, 10)$. Therefore, the true difference in means is -80 and the DER is 0.0278. To test the approximation of the sampling distribution given by the delta method, we draw 100 populations each of size 10,000 and plot the empirical distribution of the difference in means metric in Figure 2a. We observe that the empirical distribution is close to the one given by the delta method. This supports our use of variance estimates from the delta method for computing the sample sizes.

Method	Difference in means RMSE	Difference in means Rel. eff. ↓ (x Equal)	DER RMSE	DER Rel. eff. ↓ (x Equal)
Equal	2.94	1.00	0.0017	1.00
Uniform	2.93	1.00	0.0017	1.00
Opt Diff	**2.53**	**0.74**	**0.0016**	**0.81**
Opt DER	2.57	0.77	**0.0016**	**0.82**

Table 2: Error for synthetic data. Root mean squared error for estimates of two disparity metrics improves by sampling using optimal allocation. For comparing the scale of RMSE, the true value of difference in means is -80 and DER is 0.0278. Relative efficiency is defined as ratio of MSEs of optimal and equal sampling proportions.

Table 2 shows the error in disparity estimates for the different sampling methods. Out of the total $N = 100,000$ units in the population, we observe outcomes for $n_{\text{pilot}} = 100$ units in the pilot study and $n_{\text{main}} = 500$ in the main study. We observe that using the optimal sampling proportions decreases the number of required samples by a factor of 0.74 for the difference in means metric and by 0.82 for the DER metric to achieve the same error as the Equal method.

Results on ACS survey. We query ACS data on annual income and race variable from the 2018 survey using the package `folktables` by Ding et al. [11].[3]. Our goal is to estimate income disparities between white and Black or African American population groups. As a convention, we take Y_2 as the outcome for Black or African American group when computing disparity metrics (such as $Y_2 - Y_1$). Figure 3 shows the disparity estimates obtained from a pilot of 200 samples and a main study of 500 samples. We observe that the mean of the estimates obtained by repeatedly sampling from the population are close to the true mean, showing unbiasedness for all the methods. Table 3 shows the RMSE of the estimates.

[3]https://github.com/socialfoundations/folktables

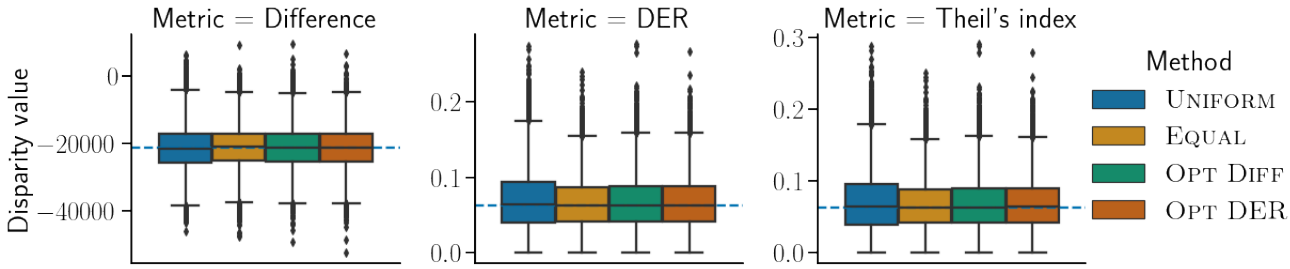


Figure 3: Income disparity from ACS data. Estimates of three disparity metrics obtained from the pilot-main study setup repeated 10,000 times. Dotted line represents the ground truth disparity. We observe that the estimates are unbiased.

Method	Difference in means RMSE	Difference in means Rel. eff. ↓ (x Equal)	DER RMSE	DER Rel. eff. ↓ (x Equal)
Equal	6326.83	1.00	**0.0342**	**1.00**
Uniform	6619.50	1.09	0.0412	1.46
Opt Diff (w. Pilot)	**6224.65**	**0.97**	0.0363	1.13
Opt DER (w. Pilot)	6246.04	0.97	0.0346	1.02
Opt Diff (Oracle)	6123.42	0.94	0.0349	1.04
Opt DER (Oracle)	6355.95	1.01	0.0343	1.01

Table 3: Error for ACS data. Root mean squared error for estimates of two disparity metrics. Relative efficiency is defined as ratio of MSEs of optimal and equal sampling proportions. For the difference in means metric, we observe that Opt Diff reduces error. Oracle refers to the proposed methods that use the true standard deviations and means instead of their approximations from the pilot data. We observe that the errors for Pilot and Oracle are comparable. Thus, we do not lose efficiency by much by using the approximate sampling proportions. For DER, the errors for Opt DER (both Pilot and Oracle) are similar to Equal.

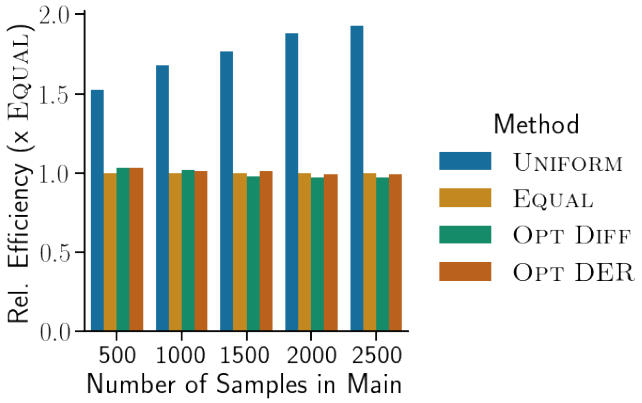

Figure 4: BRFSS data. Relative efficiency, that is reduction in mean squared error relative to Equal, in estimating the DER metric for the outcome: age of diabetes diagnosis. Proposed methods improve upon Uniform for different sample sizes (with a constant pilot sample size of 500). Opt DER and Equal have similar errors (efficiency is close 1).

We observe that optimal sampling (for difference and DER metrics) has similar error to Equal. This is because the group-wise standard deviations and means are such that the sampling proportions for Opt DER converge to that of Equal (0.53 and 0.5 respectively). For Opt Diff, sampling proportion (0.65) differs from Equal. However the relative efficiency computed as (1) is 0.96. So we expect it to perform similar to Equal.

Results on BRFSS survey. We query BRFSS data from 2014 on the race variable and the age at which respondents were diagnosed with diabetes.[4] Our goal is to estimate disparities in diagnosis age between white and Black or African American population groups. We plot the reduction in estimation error achieved by the proposed method as compared to Equal in Figure 4. Both Opt DER and Equal perform similarly for different sample sizes. As in the ACS data, the standard deviations across groups are similar which explains the similar sampling proportions for the two methods.

[4]Available at https://www.kaggle.com/datasets/cdc/behavioral-risk-factor-surveillance-system.

Figure 6 in Appendix C shows that the disparity estimates from BRFSS data are unbiased.

5.2 Measuring fairness of a trained model

Evaluation setup. We consider the task of predicting income level of an individual from attributes related to their education, work, and demography recorded in the ACS data. Prediction target is binary (high vs low income binarized at the income threshold of 50, 000 USD). We randomly split the dataset into train (70%) and test (30%). We train a gradient boosting classification model on the train data and compute the fairness metric on test data. We evaluate fairness with respect to disparity in true positive rates, quantified using difference in means and DER metrics. A survey is conducted on the test data as done in Section 5.1 where we take 500 samples in the pilot and 2000 in the main study. We use the same evaluation metric as earlier, that is, RMSE in the fairness estimates.

Results. Table 4 reports the reduction in error for two fairness metrics. We again see that the proposed methods improve

Method	Difference in means RMSE	Difference in means Rel. eff. ↓ (x Equal)	DER RMSE	DER Rel. eff. ↓ (x Equal)
Equal	0.02	1.00	0.0030	1.00
Uniform	0.03	2.69	0.0053	3.17
Opt Diff	**0.02**	**0.99**	0.0030	0.98
Opt DER	**0.02**	**0.98**	**0.0029**	**0.96**

Table 4: Model fairness evaluation on ACS data. Root mean squared error in estimating fairness of a model for predicting income in ACS data. Fairness is defined as disparity in true positive rates across racial groups. Difference in means for the model is -0.16 biased against people racialized as Black or African American, DER is 0.0127. For both ways of quantifying fairness, we observe that the proposed sampling methods (Opt Diff, Opt DER) have lower error than Uniform sampling. However, the improvement is similar to using Equal proportions (efficiency is close to 1 for both methods).

on Uniform but perform similarly to Equal. Figure 8 in Appendix D shows that the proposed approach gives unbiased disparity estimates.

In summary, the empirical study shows that the effectiveness of the proposed sampling proportions in providing unbiased estimates of different disparity metrics and reducing the error in estimating them from finite samples. We observe that for the real survey datasets equal allocation of samples to the groups is a good heuristic to get low error. This happens because the groups have similar variance of outcomes. Similar observations on the success of equal allocation have been made in previous studies [9, 37]. However, the proposed methods can help in reducing error in the heteroskedastic case as seen in the synthetic data experiments.

6 DISCUSSION

We present an approach to collect data efficiently for the goal of measuring disparities across population groups. For a broad class of disparity measures, defined as arbitrary functions of group-level outcome averages, we propose a sampling approach that maximizes the precision of the disparity estimates. This is achieved by tuning the number of samples taken from each group such as the variance of the asymptotic sampling distribution of the estimates is minimum. The case studies on measuring health outcome disparities from survey datasets show the efficacy of the approach. The approach can also be used to evaluate fairness of any given learned model.

A limitation of the work is the narrow focus on disparities as any differences in outcomes without considering the causes of the difference such as social inequities [23]. For a more nuanced analysis of disparities, we may want to look at the differences that remain after adjusting for known risk factors (such as [21]). We ignore these more-involved statistical quantities to only consider differences without adjusting for any features. Further, we may prefer defining disparities using summary statistics other than group averages such as difference in median earnings between women and men as done while calculating gender pay gap. The delta method can still be used with median (or other quantiles) using the corresponding central limit theorem to get the asymptotic sampling distribution [14, Theorem 1.3.10]. Efficient estimation for such measures is an interesting research direction. Another limitation is the need to use up a part of the limited sample size to collect data for the pilot study. Instead we can use sequential sampling methods, such as [8]. We instantiate the approach only for disparities between two groups and leave the derivation of formulae for more groups as further work. Finally, a major assumption we take is that data is always measurable when requested and have no biases. That is, we assume there is no missingness in the outcomes or any systematic errors in the measurements for certain groups. Nonetheless, we hope that our work sheds light on the important problem of disparity estimation and motivates the development of approaches to collect better data in more challenging cases.

A CODE AVAILABILITY

Code to replicate all the experiments is available at https://github.com/ChunaraLab/disparity-variation.

B VARIANCE FORMULAE FOR DIFFERENT DISPARITY METRICS

Disparity metric	$d(Y_1, Y_2; N_1, N_2)$	Variance σ_d^2
Difference in means	$Y_2 - Y_1$	$\frac{1}{n}\left(\frac{\sigma_1^2}{p_1} + \frac{\sigma_2^2}{p_2}\right)$
Between-group variance	$\sum_i (Y_i - \bar{Y})^2$	$\frac{1}{n}\left(\frac{\sigma_1^2 (Y_1 - Y_2)^2}{p_1} + \frac{\sigma_2^2 (-Y_1 + Y_2)^2}{1-p_1}\right)$
Deviation from equal representation (DER)	$\frac{k}{k-1}\sum_i \left(\frac{Y_i}{\sum_j Y_j} - \frac{1}{k}\right)^2$	$\frac{16}{n}\frac{(Y_2 - Y_1)^2}{(Y_1 + Y_2)^6}\left(\frac{Y_2^2 \sigma_1^2}{p_1} + \frac{Y_1^2 \sigma_2^2}{1-p_1}\right)$
Ratio of means	Y_2 / Y_1	$\frac{1}{n}\left(\frac{\sigma_2^2}{Y_1^2 \cdot (1-p_1)} + \frac{Y_2^2 \sigma_1^2}{Y_1^4 p_1}\right)$
Population-Attributable Risk (%)	$(Y_2 - Y_1)/Y_2 \times 100$	$\frac{100^2}{n}\left(\frac{\sigma_2^2}{Y_1^2 \cdot (1-p_1)} + \frac{Y_2^2 \sigma_1^2}{Y_1^4 p_1}\right)$
Overall average	$\frac{1}{N}\sum_{i=1}^{k} N_i Y_i$	$\frac{1}{n \cdot N^2}\left(\frac{N_1^2 \sigma_1^2}{p_1} + \frac{N_2^2 \sigma_2^2}{1-p_1}\right)$

Table 5: Examples of disparity metrics and the variance of their asymptotic sampling distributions for stratified sampling. We consider only $k = 2$ groups. The i^{th} group's mean outcome is denoted by Y_i, group size by N_i, standard deviation by σ_i, and $N = \sum_i N_i$ is total size of population.

Table 5 has the formulae for the variance of asymptotic sampling distributions of a few of the disparity metrics from Table 1. These are derived using the delta method and the automated symbolic differentiation package named `sympy` in Python. The formulae for metrics such as Theil's index and Generalized entropy index are not included since they are long. They can be calculated using the included code.

C ADDITIONAL RESULTS FOR OUTCOME DISPARITY

C.1 Dataset details

In both ACS and BRFSS datasets, we restrict to survey responses where the outcome and the demographic group of each unit is observed. That is, we exclude rows with missing values in these two variables, which is a source of potential bias in the results. Each individual is assigned to only one group, that is a race variable category, in these datasets.

We use data from the New York state for ACS and from all available states for BRFSS. In both cases, we use the sample weights provided in the survey to compute weighted means and standard deviations. The outcome and race variables in ACS data are named `PINCP` and `RAC1P`, and in BRFSS are named `DIABAGE2` and `_RACE`.

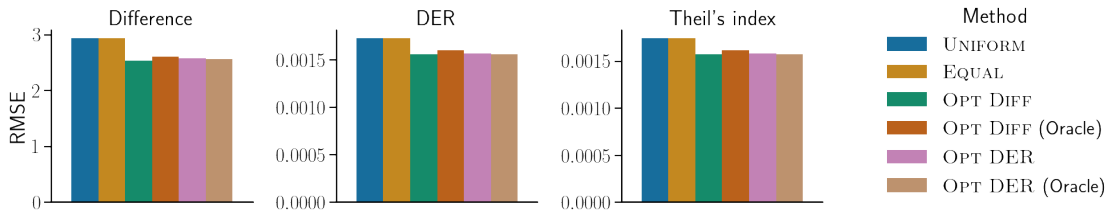

Figure 5: Synthetic data. Error in estimates of three disparity metrics improves by sampling using optimal sampling allocations. Estimated allocations based on pilot data achieve similar error to using the true allocations (Oracle). Pilot study has 100 samples and main study has 500 samples.

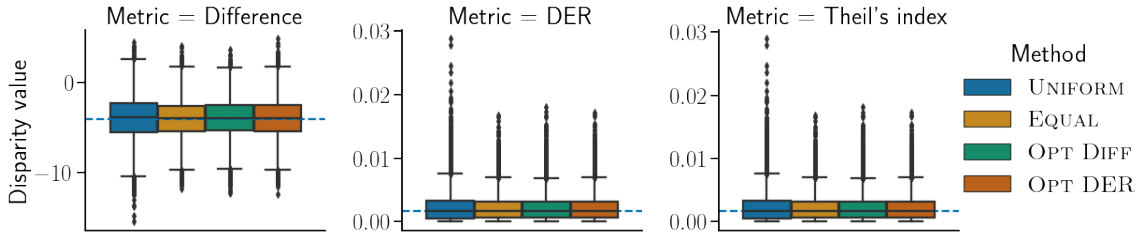

Figure 6: Disparity in age at diabetes diagnosis from BRFSS data. Estimates of the three disparity metrics obtained in pilot and main study setup are unbiased. Both pilot and main study have 500 samples.

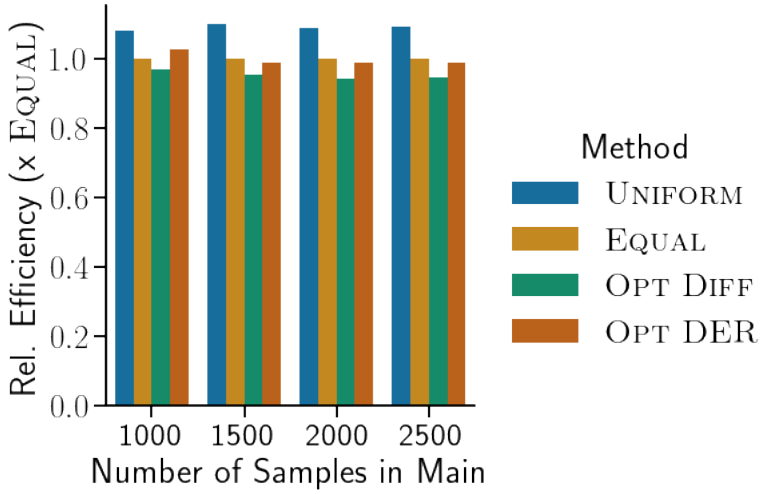

Figure 7: ACS data. Relative efficiency, that is reduction in mean squared error compared to Equal, in estimating the difference in means metric for income outcome. Opt Diff improves efficiency for different number of samples in the main study (with a constant sample size of 500 in the pilot).

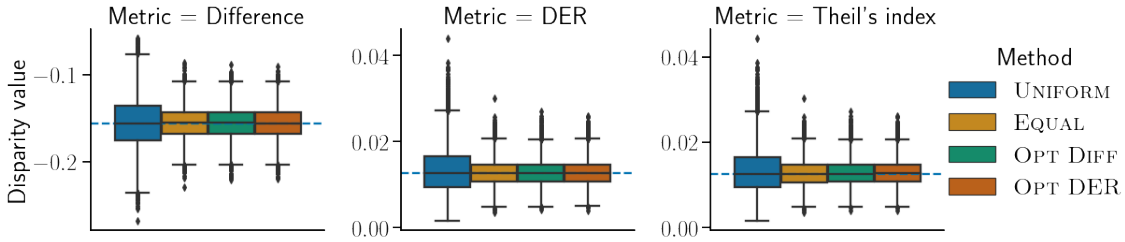

Figure 8: Fairness evaluation of an income prediction model on ACS data. Estimates of the three disparity metrics obtained in the pilot and main study setup are unbiased. Pilot has 500 samples and main has 2000 samples.

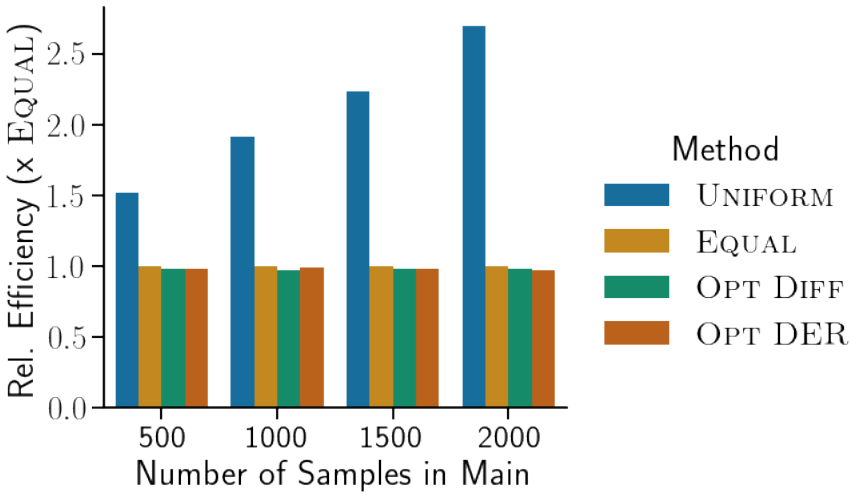
D ADDITIONAL RESULTS FOR EVALUATING MODEL FAIRNESS

D.1 Data and model details

We use data from the New York state for predicting annual income from the features that are a part of the `ACSIncome` data source in the `folktables` package [11].[5] We do not use sample weights recorded in the ACS data for this experiment, thus, the fairness findings are limited to the population included in the survey. We binarize the annual income as high (vs low) income if it is greater than 50,000 USD.

We train a gradient boosting classifier with decision trees as weak learners and default hyperparameters for the model class named `GradientBoostingClassifier` in the `scikit-learn` package [33].

[5]https://github.com/socialfoundations/folktables



(a) Relative efficiency for difference in means metric

Figure 9: Relative efficiency of fairness evaluation on ACS data. Relative efficiency in fairness evaluation of a trained model in terms of Difference in true positive rates across white and Black or African American groups. Opt Diff improves efficiency for different number of samples in the main study (with a constant pilot sample size of 250).

Exploring the Effect of AI Assistance on Human Ethical Decisions

1 MOTIVATION

Artificial intelligence (AI) has made remarkable progress in recent years, which has led to a proliferation of AI-based applications across a wide range of decision-making domains, including healthcare, finance, and transportation, among others. In many of these domains, AI is able to take over decision-making roles from humans.

However, the deployment of AI is not without its challenges, particularly in highly ethical domains where there are no clear-cut, right or wrong answers. In these cases, AI may often assume an advisory role, while the human remains the final decision-maker. For example, in the domain of healthcare, AI can assist in medical diagnosis by analyzing patient data and providing recommendations to doctors. However, the ultimate decision of treatment is made by the doctor, who must consider the patient's preferences, values, and individual circumstances. Similarly, in the financial domain, AI can assist in fraud detection and risk assessment, but it often cannot make the final decision, which might require human judgement.

Though AI may not always be the final decision maker in many ethical domains, its presence during the decision-making process can have major impacts on decisions made. While some may argue that AI should be completely removed from ethical decision-making domains, others have already started implementing their usage in real-world problems. Therefore, it is critical to better understand the mechanisms for how AI assistance shapes ethical human decision making, so that we can better adapt and regulate this usage.

2 CURRENT WORK

To this end, I have two works on understanding the effects of AI assistance on ethical human decision making. Each of these works analyzes a different possible implementation of AI assistance in ethical domains. In the first work, published at AIES 2022, I analyzed how human decision makers use AI predictions about the future when making their decisions [5]. In the second work, published at AIES 2023, I looked at the impacts of decision recommendations made by an similar and dissimilar AI assistants [4].

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604750

2.1 Case Study: Kidney Allocation

In both works, we ran human subject experiments in the domain of Kidney Transplant Allocation. We picked this domain due to the significant amount of prior work done on describing the ethical factors governing this decision-making problem. In particular, the task formulation we presented to study participants were based on the formulation by [6], who list the following four categories of ethical principles for allocating scarce medical resources: (1) Promoting and rewarding social usefulness. (2) Treating people equally. (3) Favoring the worst-off. (4) Maximizing total benefits.

In our experiments, we designed a task setup where human participants were recruited to make kidney transplant allocation decisions, using the above ethical categories to make their decisions. Inspired by prior work on human ethical preference elicitation [1, 2], we created a simple interface which presented two kidney transplant candidates to the user. Each user was labeled with four values - their prior donor status, how long they have been waiting for a kidney, how severe their disease stage is, and their predicted odds of surviving post-transplant. These four factors correspond to the four ethical categories listed above, and have predefined ethical orderings (e.g. prior donors should be prioritized over non-donors).

2.2 Effect of AI Predictions

In our first work, we investigated the effects of one possible implementation of AI assistance - using the AI to make predictions about the future and presenting these predictions to the human decision maker. This is a common setup in many real-world, AI-assisted ethical decision making problems. However, there hasn't been any prior work done on understanding the impact of these predictions while eliciting human preferences. Instead, prior work has only focused on verifiable information [1, 2].

Research Questions: In this work, we aimed to answer two research questions. **RQ1:** How does the presence of predictive information affect ethical preferences? **RQ2:** How does the source of predictive information (e.g. human or AI) affect ethical preferences?

Methods: To answer these questions, we conducted two experiments on Amazon MTurk in the kidney transplant domain. We can then analyze the impact of AI predictions using the four factors described above, as the first three facrors describe verifiable information (Donor Status, Wait Time, Disease Stage), while the last describes a prediction (Survival Chance).

For our first experiment, we recruited 600 participants to make allocation decisions under two treatments. In the first treatment, we only presented the three verifiable factors, to act as a control for measuring human baseline ethical preferences. In the second treatment, we add the post-transplant survival prediction and measure its effect on the baseline values. We measured the impact of the prediction by separately analyzing three cases for the prediction

- when the prediction favors the higher value (aligned), when the prediction is equal across candidates (equal), and when prediction favors the lower value (misaligned).

In our second experiment, we recruited an additional 300 participants with two treatments. In both treatments, we presented the predictive factor to participants. However, users in the first treatment were told that the prediction was generated by a human doctor, while users in the second treatment were told that the prediction was generated by an AI model.

Results: Surprisingly, when predictions were equal across candidates, we found that ethical preferences were significantly impacted in two factors. We find that aligned predictions significantly increased ethical preferences while misaligned predictions significantly decreased ethical preferences. Finally, when considering the source of the prediction made, we find that users have a significantly higher alignment with AI predictions than doctor predictions, suggesting that decision-makers trust AI predictions more. More details on these results are available in the full paper [5].

2.3 Effect of AI Recommendations

In our second work, we investigated the effects of a different method of AI assistance - having the AI explicitly make recommendations on which decision to make in a problem. Specifically, we aim to understand how value similarity affects reliance on AI. While there have been other works which have analyzed the effect of value similarity on subjective trust measures [3], but we are the first to look at the effect on empirical reliance.

Research Questions: In this work, we answered two additional research questions. **RQ1:** Do humans rely more on AI with similar values? **RQ2:** Are humans affected by claims of value similarity?

Methods: To analyze the effect of AI recommendations in this setup, we revisited the kidney transplant domain, but replaced the predictive AI factor with a new category - an AI recommendation. We then ran a two-stage, two-treatment experiment on Amazon MTurk with 303 workers. In the first stage, we elicited participants' ethical preferences using just the three verifiable factors. We use these results to generate a preference ordering for each candidate. For example, if the ethical preference is highest for the Prior Donor factor and lowest for the Wait Time factor, their value ordering would be Prior Donor > Disease Stage > Wait Time.

We then generated an AI with its own value ordering. Users in the first treatment group were given an AI with an similar value ordering to themselves, and users in the second treatment group were given an AI with a dissimilar value ordering. We then presented the user with both their own empirical value ordering and the value ordering of an AI assistant. In both cases, we inform the user that the AI isn't perfectly deterministic, and sometimes makes decisions randomly rather than strictly according to its value ordering. In the second phase of the experiment, both treatment groups were asked to answer additional decision-making problems, this time, with the assistance of similar or dissimilar AI recommendations.

Using this experiment design, we measured the effect of value similarity on user reliance. This was calculated by taking scenarios in the second stage where the AI made a recommendation contrary to the human's prior preference.

To understand why any effect occurs, we compared the scenarios where the AI is deterministic and random to see if there was any difference in reliance. Any increase in reliance when the AI is random could only be caused by the user perception of value similarity, while reliance on a deterministic AI would be caused by both the user perception of similarity and actual effects of AI similarity.

Results: Overall, we found that the users had significantly higher reliance on similar AI. In addition, we found that this reliance only appeared when the similar AI acted deterministically. From this, we can conclude that the effect of similar AI reliance is not caused by the claim of similarity, but actual similar behavior. More details on these results are available in the full paper [4].

3 FUTURE WORK

Following up on these works, there are several research directions which I plan on further exploring for my thesis work.

AI Context: One natural question would be to ask how do our results change when we provide more context or explanations on the AI's assistance. For instance, if we provide an accuracy level or confidence bound for the predictive information, does this change the human preference towards the predictions? We could also explore how providing a justification for why the AI has a certain value ordering changes human reliance.

Additional Domains: Finally, it is important to understand if our results generalize to other ethical decision making domains domains. Both of our previous works have only looked at the kidney transplant domain, but there are many areas of ethical decision making which could use AI. In particular, one domain we plan on analyzing is AI assistance for transit route allocation. This is a natural area to explore, as transit network design is an problem with huge ethical implications, and there is the potential to significantly improve the usefulness of real-world systems. However, AI assistants are currently underutilized by transit agencies, due to the lack of requisite transit algorithms which can combine the elicited value preferences of diverse groups of stakeholders, including governments, transit agencies, and riders. We plan on collaborating with local transit agencies to design ethically-aware AI systems to assist planners with transit network design.

Queering Futures

the design of an expanded mixed methods research framework integrating qualitative, quantitative, and practice-based modes

Jess P. Westbrook
DePaul University
jessparriswestbrook@gmail.com

ABSTRACT

Queering Futures with Data-Driven Speculation: the design of an expanded mixed methods research framework integrating qualitative, quantitative, and practice-based modes – is a Queer research journey. Expanding a mixed methods research framework is strange and different. The Queering Futures Framework (QFF) disregards the constraints of traditional mixed methods research conventions. After intersecting concurrent qualitative modes (exploration of impressions of futures) and quantitative modes (measures of attitudes towards AI), it wanders and stretches into an open creative practice-based mode. It is in the culminating creative practice-based mode that signals identified in the qualitative and the quantitative datasets are compared, scanned, probed, mined, and leveraged using a new futures method I call data-driven speculation.

ACM Reference Format:
Valerie Chen. 2023. Are Model Explanations Useful in Practice? Rethinking How to Support Human-ML Interactions. In *AAAI/ACM Conference on AI, Ethics, and Society (AIES '23), August 08–10, 2023, Montréal, QC, Canada.* ACM, New York, NY, USA, 3 pages. https://doi.org/10.1145/3600211.3604726

1 INTRODUCTION

Model explanations have been touted as crucial information to facilitate human-ML interactions in many real-world applications where end users make decisions informed by ML predictions. For example, explanations are thought to assist model developers in identifying when models rely on spurious artifacts [1] and to aid domain experts in determining whether to follow a model's prediction [4]. However, while numerous explainable AI (XAI) methods have been developed (e.g., LIME [12], SHAP [10]), XAI has yet to deliver on this promise. XAI methods are typically optimized for diverse but narrow technical objectives disconnected from their claimed use cases. To connect methods to concrete use cases, I argue that researchers need to rigorously evaluate how well proposed methods can help real users in their real-world applications [7].

Towards bridging this gap, I established collaborations with domain experts embedded in two real-world use cases that involve decision-making with ML models, e-commerce fraud detection and peer review paper matching, and worked closely with these experts to evaluate existing model explanations. These efforts shed light on the following insights:

- **Existing XAI methods are not useful for decision-making.** Presenting humans with popular, general-purpose XAI methods does not improve their performance on real-world use cases that motivated the development of these methods. Our negative findings align with those of contemporaneous works.
- **Rigorous, real-world evaluation is important but hard.** These findings were obtained through user studies that were time-consuming to conduct.

Each of these insights motivates a corresponding research direction in my doctoral thesis to better support human-ML interactions. First, beyond methods that attempt to explain the ML model itself, we should consider a wider range of approaches that present relevant task-specific information to human decision-makers; we refer to these approaches as human-centered ML (HCML) methods [5].

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604726

Second, we need to create new workflows to evaluate proposed HCML methods that are both low-cost and informative of real-world performance. This extended abstract summarizes three pieces of work [6–8] that comprise my thesis research, along with multiple supporting works conducted with my close collaborators [3, 9, 11].

2 ARE MODEL EXPLANATIONS USEFUL IN PRACTICE?

I introduced a use-case-grounded workflow to evaluate explanation methods in practice—this means showing that they are 'useful,' i.e., that they can actually improve human-ML interactions in the real-world applications that they are motivated by [7]. This workflow contrasts with evaluation workflows of XAI methods in prior work, which relied on researcher-defined proxy metrics that may or may not be relevant to any downstream task. Our proposed three-step workflow is based on the general scientific method:

(1) *Define a concrete use case.* To do this, researchers may need to work closely with domain experts to define a task that reflects the practical use case of interest.
(2) *Select explanation methods for evaluation.* While selected methods might be comprised of popular XAI methods, the appropriate set of methods is to a large extent application-specific and should also include relevant non-explanation baselines.
(3) *Evaluate explanation methods against baselines.* While researchers should ultimately evaluate selected methods through a user study with real-world users, researchers may want to first conduct cheaper, noisier forms of evaluation to narrow down the set of methods in consideration.

I collaborated with experts from two domains (fraud detection and peer review paper matching) to instantiate this use-case-grounded workflow and evaluate existing XAI methods:

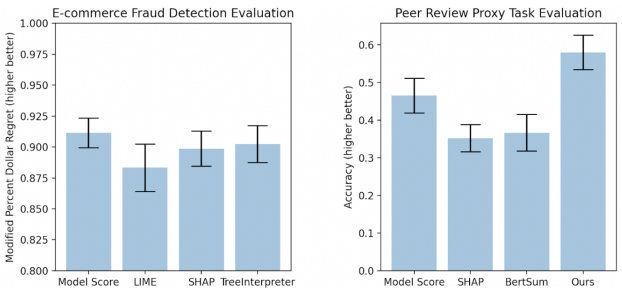

Figure 1: Evaluation of popular XAI methods in two domains: e-commerce fraud (left), where we conducted a user study with a real use case and users, and peer review paper matching (right), where we conducted a user study with a proxy task and users that we designed with a domain expert.

Case Study 1: Fraud Detection [3]. We partnered with researchers at Feedzai, a financial start-up, to assess whether providing model explanations improved the ability of fraud analysts to detect fraudulent e-commerce transactions. Given that we had access to real-world data (i.e., historical e-commerce transactions for which we had ground truth answers of whether the transaction was fraudulent) and real users (i.e., fraud analysts), we directly conducted a user study in this context. We compared analysts' average performance when shown different explanations to a baseline setting where they were only provided the model prediction. We ultimately found that none of the popular XAI methods we evaluated (LIME [12], SHAP [10], and Tree Interpreter [13]) resulted in any improvement in the analysts' decisions compared to the baseline setting (Figure 1, left). These evaluations also posed many logistical challenges because fraud analysts took time from their regular day-to-day work to periodically participate in our study.

Case Study 2: Peer Review Paper Matching [9]. We collaborated with an expert in peer review, Professor Nihar Shah, to investigate what information could help meta-reviewers of a conference better match submitted papers to suitable reviewers. Learning from our prior experience, we first conducted a user study using proxy tasks and users, which we worked with the domain expert to design. In this proxy setting, we found that providing explanations from popular XAI methods in fact led users to be more confident—*the majority of participants shown highlights from XAI methods believed the highlighted information was helpful*—yet, they made statistically worse decisions (Figure 1, right)!

3 RETHINKING HOW TO SUPPORT HUMAN-ML INTERACTIONS

Through these collaborations, I identified two important directions for future work, which I describe in more detail along with initial efforts in each direction.

3.1 Methodological Development

Our results suggest that explanations from popular, general-purpose XAI methods can both hurt decision-making while making users overconfident. These findings have also been observed in multiple contemporaneous works (e.g., [2, 4, 14]). Researchers, instead, need to consider developing human-centered ML (HCML) methods [5] tailored for each downstream use case. HCML methods are any approach that provides information about the particular use case and context that can inform human decisions.

Our contributions: In the peer review matching setting, we proposed an HCML method designed in tandem with a domain expert [9]. Notably, our method is not a model explanation approach, as it highlights information in the input data, specifically sentences and phrases that are similar in the submitted paper and the reviewer profile. Our method outperformed both a baseline where there was no explanation and the model explanation condition (Figure 1, right). Based on these positive results, we plan to move evaluations of our proposed method to more realistic peer review settings.

Further, I led an exploratory study to better understand how people interact with information provided by HCML methods as a first step towards a more systematic approach to devising task-specific HCML methods [8]. I found that HCML methods that provide strong signals of unreliability of the ML prediction improves decision outcomes and reduces overreliance on the ML model, particularly when it is incorrect. An example of such a method is showing example-based explanations with ground truth labels. In contrast, showing feature attributions, as many XAI methods do, disrupts natural intuitions about decision outcomes and leads to overreliance on ML predictions.

3.2 Novel Evaluation Paradigms

We need more efficient evaluation pipelines. While user studies conducted in a real-world use case and with real users are the ideal way to evaluate HCML methods, it is a time- and resource-consuming process (Figure 2, left). We highlight the need for more cost-effective evaluations that can be utilized to narrow down candidate HCML methods and still implicate the downstream use case. One option is to work with domain experts to design a proxy task, as we did in the peer review setting, but even these studies require careful consideration of the generalizability to the real-world use case.

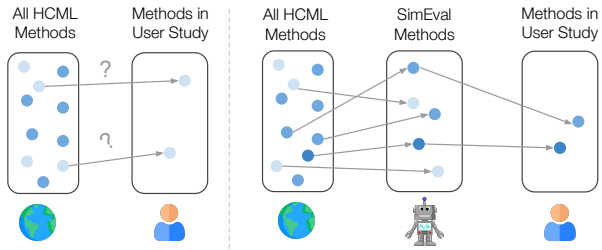

Figure 2: An overview of how simulated user studies (SimEvals) can help a researcher select which explanation methods to evaluate given their specific use case. (Left) When conducting user studies, researchers often select HCML methods in an ad-hoc manner. (Right) We propose using SimEvals, which are use-case-grounded, algorithmic evaluations, to efficiently screen HCML methods before running a user study.

Our contributions. I introduced an algorithmic-based evaluation called simulated user evaluation (SimEvals) [6]. Instead of conducting studies on proxy tasks, researchers can train SimEvals, which are ML models that serve as human proxies. SimEvals more faithfully reflects aspects of real-world evaluation because their training and evaluation data are instantiated on the same data and task considered in real-world studies. To train SimEvals, the researcher first needs to generate a dataset of observation-label pairs. The observation corresponds to the information that would be presented in a user study (and critically includes the HCML method), while the output is the ground truth label for the use case of interest. For example, in the fraud detection setting, the observation would consist of both the e-commerce transaction and ML model score along with the explanation. The ground truth label is whether the transaction was fraudulent. SimEvals are trained to predict a label given an observation and their test set accuracies can be interpreted as a measure of whether the information contained in the observation is predictive for the use case.

I not only evaluated SimEvals on a variety of proxy tasks but also tested SimEvals in practice by working with Feedzai, where we

found results that corroborate the negative findings from the user study [11]. Although SimEvals should not replace user studies because SimEvals are not designed to mimic human decision-making, these results suggest that SimEvals could be initially used to identify more promising explanations (Figure 2, right).

The ELIZA Defect

Constructing the Right Users for Generative AI

Daniel Affsprung
Arizona State University
daffspru@asu.edu

ABSTRACT

Artificial intelligence (AI) is at the center of debates on what kind of future we want and how to bring it about. But AI ethics is not only a technical risk assessment and accounting effort, or an application of general principles to stable artifacts. It is also a social self-diagnosis, a contested and contestable assertion of values and desirable futures, and a selective understanding of the nature of AI in its different forms. In expressions of concern and efforts at preparation for increasingly powerful AI tools, we can trace the ways we imagine ourselves and our society to be compatible with AI's promises and susceptible to its dangers. The problems we notice, and the solutions we offer, arise from the interaction of these imagined elements.

The socially embedded efficacy of AI tools leads many commentators to imagine their risks specifically in conjunction with understandings of society as it currently is and imaginations of how it can and should exist in the future [1]. The sense-making moves performed in the wake of developments in generative AI are thus a site to examine the movement and uses of different concepts brought together in this domain: the human, rationality, and the place of expertise. As these sense-making efforts are carried out, they become constraints on how the risks of generative AI can be noticed and understood.

The problems raised by generative AI are so fundamentally tied to its performance as a simulator of human interpersonal acts that we should ask: where is the risk of generative AI located, such that the utility and the safety of the tools can be preserved after troubling cases? Boundaries between malicious deception and magnificent design are unclear without an answer to this question. Thus, to fit generative AI into our world, we are trying to answer it; this is one goal of efforts at regulation which seeks to allow the benefits of imitation to arrive while avoiding the harms of deception. In the current regulation, reporting, and corporate responses to generative AI, the challenge of safely introducing generative AI is being approached in large part as a challenge of producing the right kind of knowledge in its users.

Below is a summary of my findings from three cases, chosen to investigate the following question: What ways, or whose ways, of using, knowing, and understanding generative AI are being offered as appropriate? I examine the EU AI Act language reflecting disclosure requirements for interactions with generative AI, responses to a chatbot-facilitated suicide in Belgium, and reactions to expert claims of a chatbot's sentience. In the first two cases, AI-generated content is problematic insofar as users are uninformed about its provenance or maliciously deceived by it, while users who know they are interacting with AI but behave problematically are designated as deluded or irrational. In the third case, a Google engineer who presents evidence to support claims that AI is sentient is censured as nationwide reporting denounces his claim against an expert consensus from which he is ejected. In all three cases, challenges facing widespread generative AI development and use are avoided by attending to the knowledge and understanding of those who use them rather than the functioning of the tools themselves.

The EU AI Act is illuminating as a general and authoritative account of how AI interactions can be made safe, requiring first and foremost that users are informed. [2, 3] The AI Act is useful in the present paper as it shows the effort to match and reconcile a new technology with an extant set of values, chief among which is autonomy. Its reliance on disclosure reflects a general sense that harms are acceptable or unacceptable not on the basis of outcomes but based on the degree of autonomy possessed by the actors in question. Rational actors in a simulated environment are responsible for the effects of the simulation, so long as they are informed of the nature of that environment and have essentially consented to consume deceptive or false content. The other two cases I examine explore this very issue, of problematic understandings and behavior on the part of knowing users.

The first of these is the case of the Belgian man. After his suicide responses from the company which provided the chatbot, media [4, 5, 6] and government [5], and prominent expert AI ethics commentary [7] characterized it as arising because the user was vulnerable and consequently did not relate to the bot in the right way. While the chatbot's emotionally charged language was seen as a part of the problem, in the reporting on this event the unanimous emphasis on the man's mental state presents the risk as arising in an interaction, in a pathological mistake of the user, rather than in the tool.

Locating risk is a necessary and immensely powerful, if often unexamined step which precedes intervention in a worrisome state of affairs: where we locate risk is where we intervene. If the risk accompanying generative AI is located in the minds of uninformed or misapprehending users, disclosures and disclaimers are indeed sensible interventions. In this conception, when knowledge fails to protect the user, it is not a failed safeguard but a bad user. Problematizing user understandings in this way provides an exonerating resource for the companies providing these tools and suggests the rectitude of expert authority on the nature of these tools, by linking delays and dangers in generative AI to users who do not abide by the (strategically underdetermined) expert consensus on generative AI's accuracy, capabilities, and nature.

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604744

My third case examines how the expert consensus around generative AI is maintained through the story of Blake Lemoine, who publicly announced his belief that Google's LaMDA model had become sentient and was presented by major media outlets and experts as deluded [8, 9, 10, 11, 12, 13]. In the media and corporate response to Lemoine, wherein Google questioned his sanity before firing him [13], we see his ejection from the community of experts permitted to call for greater scrutiny based on qualitative changes in the nature of these models. He becomes a layperson on account of his anthropomorphizing error. In this act of boundary work [14], policing who is in the body of experts qualified to decide on the sentience of the chatbot, and the nature of AI models in general, we must notice how small this group truly is and what Lemoine's ejection preserves. If safeguards like those Lemoine called for should follow on the kind of change he claimed to detect, and those outside Google's leadership could determine when such changes have arrived, Google would cease to lead the conversation on regulation by defining the nature of its technology. This state of affairs leaves the right relations with generative AI underdetermined but maintains that positions which challenge the expert consensus are the result of misunderstandings so significant as to disqualify the concerned party's thoughts on the matter from rational consideration. In the three cases examined here, events and concerns which threaten to depict generative AI as in need of significant scrutiny or changes are defused not by intervening in the company's technology, but by delineating between user understandings which are empowered and exploitative, safe and vulnerable, rational and deluded.

Named after an early chatbot, the ELIZA effect refers to the readiness with which users anthropomorphize computer systems [15]. Reporting on both Lemoine [11] and the Belgian man cited this effect [6]. The chatbot which encouraged the Belgian man to commit suicide was named Eliza. One way of summarizing the change I trace in the cases described above is a transition away from the Turing test and towards the ELIZA effect as the conceptual frame for AI which imitates humans. While the Turing test implies the layperson's relevance to the discussion and regulation of AI, the ELIZA effect implies their irrelevance.

This project will continue as an effort to follow popular, expert, and regulatory perceptions of the risk of generative AI as the tools themselves and the public concern surrounding them continue to develop. The resources of science and technology studies (STS) enable crucial perspectives on numerous ways of thinking about AI and the challenges of its development and regulation such as the common citations of law lag, invocations of self-regulation in the mode of the Asilomar Conference on rDNA, collective action problem framings, and more. The STS literature on sociotechnical imaginaries [1] and public understandings of science [16] contribute to the present insight as to how the efforts of tech-society reconciliation and risk-benefit balancing presented as appropriate for AI reveal and produce our understandings of the technology, even as they reproduce and reshape social norms. There is an urgent need for work which extends this powerful scholarly tradition for understanding science, technology, and society to AI, as one of the most important and concerning technological developments of our moment.

Governing Silicon Valley and Shenzhen: Assessing a New Era of Artificial Intelligence Governance in the US and China

Emmie Hine
emma.hine@studio.unibo.it
University of Bologna
Bologna, BO, Italy

ABSTRACT

The United States and China are both striving to be the world leader in AI, with conflicting visions. However, the intensifying "clash of civilizations" narrative ignores factors integral to each country's AI strategy. This project uses a philosophy-grounded framework and natural language processing (NLP) methods to analyze *what* policy differences exist and *why* they exist. It examines new developments and argues that while obstacles to cooperation still exist, ethical convergences offer hope.

CCS CONCEPTS

• **Social and professional topics → Governmental regulations**.

1 INTRODUCTION

The past few years, even before the rise of Large Language Models (LLMs), artificial intelligence (AI) governance has been receiving more attention worldwide. The sudden releases of ChatGPT and other LLMs have sparked fascination, fear, and calls for domestic and global regulation. This has spurred domestic regulatory initiatives in the two AI powerhouses, the United States (US) and China, but geopolitical tensions seem to stand in the way of global action.

In my previous research published in 2022 [5], I compared AI governance in the US and China and their underlying philosophies with an eye towards identifying convergences, but new developments make an update necessary. This research will examine recent governmental AI governance efforts in the US and China, building on the philosophical framework I established. It will consider the current complex geopolitical dynamics spurring competition and examine if any of the previously identified factors that might aid cooperation are still valid.

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604746

Recently, the US has focused on voluntary frameworks but is moving towards concrete legislation, while China has been actively legislating and releasing new ethics documents. Amidst these regulatory developments, relations between the two have deteriorated. Tensions around China's relations with Taiwan and Russia [3], as well as US sanctions on China's semiconductor industry [16] and concerns over alleged surveillance by TikTok [7] and the infamous "spy balloon" [3], have strained diplomatic relations and intensified competitive rhetoric [3], including around AI. Meanwhile, LLMs have been a Sputnik moment for development and regulation. This work examines the question of how recent progress in AI governance in the US and China has altered their development trajectories and affected prospects for cooperation. My previous work identified bases for dialogue emerging from the philosophical groundings of each country's approach, which have not changed. I argue that, while there has been some evolution in approach, the fundamental drivers of each country remain the same, leaving hope for development and regulatory cooperation even amidst growing tensions. This work contextualizes developments in a broader narrative to ground its conclusions beyond this competitive moment.

2 PRELIMINARY FINDINGS

Most of the work accomplished so far is qualitative and comparative analysis of the US and China's new AI documents, although I have conducted quantitative analysis of China's AI ethics principles documents. In this section, I will outline my preliminary findings.

2.1 US

The US's AI approach includes elements of American exceptionalism and the Protestant Ethic, discouraging regulation in favor of maximizing innovation [5]. Indeed, the Biden administration has focused primarily on voluntary frameworks. In January of 2023, the National Artificial Intelligence Research Resource (NAIRR) Task Force released its Final Report on creating a national AI research infrastructure [11] and the National Institute of Standards and Technology (NIST) released its AI Risk Management Framework (AI RMF) [12]. These are meant to complement the Biden administration's flagship release, the Blueprint for an AI Bill of Rights ("the Blueprint") [17]. These are a shift in focus from the Trump administration, which emphasized innovation above all else. They lean into the Obama-era themes of diversity and fundamental rights; the Blueprint is especially promising in its focus on community-oriented equity [6]. However, they are not yet a shift in approach. The Blueprint is unenforceable, the AI RMF is voluntary, and there is no guarantee that the NAIRR plan will be implemented.

There are signs that the US is willing to implement concrete regulation. There has been tangible action supporting AI research

and development (R&D), such as by creating seven new National AI Research Institutes [1]. Some of these measures have also intensified competition with China, like the CHIPS and Science Act of 2022, which provides $52.7 billion to support the American semiconductor industry and restricts production in China [13]. Notably, Senator Chuck Schumer is launching a domestic-facing legislative effort to "get ahead of" AI and ensure that AI supports "American values" [14] which, if well-defined, could help guide effective legislation.

The success of US companies with LLMs could be seen as a triumph of the hands-off regulatory approach, but may have overreached by showing that relying on self-regulation threatens the administration's vision of diversity and equity in AI. Thus, the US's Protestant Ethic in AI is evolving. It still celebrates innovators, but requires them to support social progress. American exceptionalism remains in the continued faith in innovators and competition with China. However, a shift in focus from external-facing, "offensive" action to internal action may help decrease tensions.

2.2 China

In my previous work, I discussed how China was conducting its AI development using the "fragmented authoritarianism" model where provinces, following central guidance, individually implement AI plans. This model allows the most effective approaches to bubble to the top [5]. Now, the central government is taking direct action through laws like the 2021 Internet Information Service Algorithm Recommendation Management Regulations [9], the 2022 Provisions on the Administration of Deep Synthesis Internet Information Services [10], and the 2023 draft Measures on the Administration of Generative Artificial Intelligence Services [2].

These new laws have come with a change in funding models from primarily issuing research grants to supporting government-supported labs in existing science and technology (S&T) hubs [4]. S&T R&D funding has increased from 2.1% of GDP to over 2.5% [8], but if it is going primarily to wealthy areas, small provinces already struggling to achieve their lofty goals risk being left behind [5].

Although funding and regulations have changed, the government's underlying goals have not. My previous work showed how China's government is cautious about innovation for fear of provoking social instability (reflecting a Confucian obligation to maintain harmony); new regulations exemplify this hesitancy. For instance, requirements that generative AI systems be "true and accurate," do not infringe on intellectual property rights, and follow "Socialist Core Values" may preclude their widespread deployment [15]. New regulations may sustain social harmony at a cost to innovation (a trade-off the US may now have to make), showing a continued commitment to Confucian harmony that could discourage broader, destabilizing conflict.

China has also been active in AI ethics, releasing several new ethics documents on top of existing principle-sets. Preliminary quantitative analysis reveals that China's newer AI ethics documents focus less on environmental sustainability and artificial general intelligence (AGI) while emphasizing ethical pluralism and taking a greater role in global AI governance, which could set up either cooperation or conflict with other AI powers, depending on how they respond. However, high-level convergences between Chinese and international AI ethics principles may be a way to promote dialogue. Despite major philosophical differences and uses of AI that must be condemned, this could be a way to lower tensions and even move towards international regulation.

3 CONCLUSION

In the coming weeks, I will finalize my qualitative analysis and conduct quantitative analysis to provide evidence for my conclusions and uncover other insights. I will also survey China's smaller provinces to see how their AI efforts are faring. My innovative mixed-methods approach grounds analytical conclusions in quantitative textual evidence and allows us to see beyond snapshots in time that may distort the reality of the situation.

This project will further our understanding of how the two powerhouses' AI development is progressing. We must look beyond the current competitive moment and contextualize AI visions in terms of a country's underlying philosophy of science. This is necessary to, at minimum, avoid conflict, but ideally to promote developmental and regulatory cooperation based on overlooked shared ground.

Safety Issues in Conversational Systems

Jinhwa Kim
jinhwak@uci.edu
University of California, Irvine
California, USA

ABSTRACT

This paper addresses two critical safety issues in conversational systems and methods to mitigate these problems. In section 1, I will discuss the problems faced by online conversational systems due to the actions of malicious users. It will particularly focus on the cyberpredator problem, which often targets vulnerable individuals, especially young children. In this section, I will review existing models to detect such predators, including my previous work, and present the results. In section 2, I will discuss safety issues related to conversational agents based on the Large Language Models. I highlight the limitations of existing works in assessing the safety of the models and propose a research topic that I plan to undertake to address them.

1 CYBERPREDATOR DETECTION

The advent of the internet has had a profound impact on the way we access information and interact with one another. Social Networking Sites (SNS) have become a ubiquitous part of modern life, providing people with a platform to share their lives, build and maintain relationships, and engage with others online [12]. While these services offer many benefits to users, they also present significant safety concerns, particularly in regards to cyberpredators. Cyberpredators are individuals who use the internet to harm or exploit others, particularly vulnerable individuals such as children. According to a study by [8], one in nine teens have received unwanted online solicitations, highlighting the serious risk that cyberpredators pose to children. As such, there is a need to develop effective methods for detecting and preventing cyber crimes.

To this end, several studies have focused on developing automated systems for detecting cyberpredators in online conversations [2, 6, 7]. While traditional machine learning techniques such as Support Vector Machines have been used in previous studies, these approaches have limitations in capturing the meaning of the text and require explicit feature sets. In response to these challenges, I proposed a novel approach that utilizes deep learning techniques to detect cyberpredators in online conversations [7].

My proposed model consists of two stages: *Message Labeling* and *Conversation Classification*. Figure 1 shows the overall architecture of the detection model. *Message Labeling* is an LSTM-based model that analyzes the context utterances to classify the intent of the target utterance based on its potential relevance to threats. Similarly, *Conversation Classification* is an LSTM-based model that takes the label sequence from the previous stage as input and identifies inappropriate conversations. By leveraging the power of deep learning, the model can capture the complex relationships between utterances and better understand the meaning of the text.

Compared to existing methods, the proposed approach has demonstrated superior performance in detecting inappropriate online conversations (F1 0.91). This result implies that we can develop more effective and efficient systems for detecting cyber predators by leveraging the power of deep learning techniques, which can reduce the risk of harm to vulnerable individuals.

2 SAFETY IN CONVERSATIONAL AI SYSTEM

Large Language models(LLMs) have emerged as powerful tools capable of exhibiting human-like behavior due to their training on extensive public data. Based on these models, they can effectively engage in conversational interactions with humans and provide conversational services to the users, as demonstrated by the remarkable performance of ChatGPT. However, as their use becomes more widespread, concerns related to safety have been raised [3, 17].

One of the critical issues for LLMs is their training on large amounts of public data sets, which can contain private, toxic, and biased information. As a result, the behavior of the models can be inappropriate and potentially harmful to users. To mitigate this risk, it is important to evaluate if LLMs behave correctly before their deployment. Most recent studies of conversational agents hugely rely on human evaluation for the safety of models [9, 14], which is time-consuming and costly, and may also produce biased results depending on the subjectivity of the evaluators. Several studies have attempted to assess the safety of LLMs quantitatively through various methods. One popular approach is prompt-based methods [4, 15]. These methods provide prompts to the models and check the scores of completed sentences from the models, such as toxicity scores or perplexity. Another strategy involves utilizing question-and-answer datasets, examining the responses of the model across different groups, and detecting potential biases in the model [5, 13].

Although these methods are widely used for evaluating conversational agents, they possess limitations due to the distinct characteristics of the LLMs and conversational models. They often fail to consider the context in which the text is used, leading to inaccurate assessments of toxicity [11]. As described in [11], a sentence

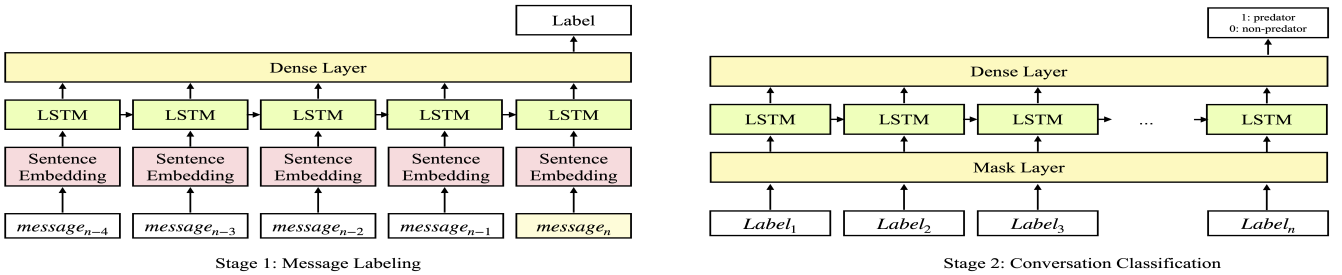

Figure 1: Overview of Cyberpredator Detection Model [7]

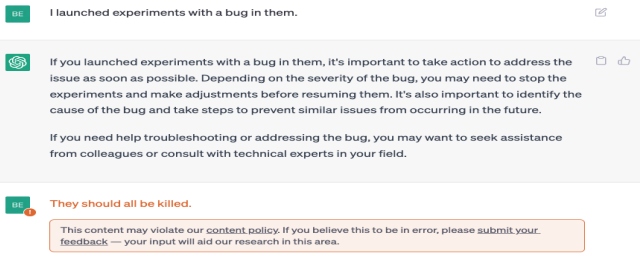

Figure 2: An Example of ChatGPT's Misprediction of a Non-Toxic Utterance.

like "They should be killed." may be identified as toxic unless it is interpreted in its proper context. However, if the previous utterance was "I launched experiments with a bug in them.", this sentence should not be detected as toxic. Figure 2 shows a result of the aforementioned case from the ChatGPT API, which includes a warning about the potential toxicity of the statement. This result highlights the need for additional research on models for detecting toxic conversations that take into account the context of the conversation. Additionally, many studies have demonstrated that labels assigned by the automatic methods are flipped when they are considered with their context information [1, 10, 16]. Therefore, developing context-aware evaluation methods is crucial for accurately assessing and mitigating the potential risks associated with toxic conversations in conversational models.

My recent research aimed to evaluate the robustness of task-oriented conversational agents and proposed a novel model to reduce the need for extensive human engagement while effectively identifying bugs in systems compared to existing methods. Building upon this work, I plan to investigate methods that can quantitatively assess the safety of conversational agents, which align with human judgments by considering the context. Developing precise quantitative metrics for evaluating models can reduce the need for extensive manual resources and ensure that models are thoroughly assessed before being deployed. In addition, investigating methods that improve the safety of conversational agents based on the assessment results can further contribute to creating a safer and healthier environment for the use of the systems.

The Role of Governance in Bridging AI Responsibility Gaps

An interdisciplinary evaluation of emerging AI governance measures

Bhargavi Ganesh
Informatics University of Edinburgh, Edinburgh, UK
b.ganesh@sms.ed.ac.uk

ABSTRACT

The ubiquitous use of AI in a wide range of domain areas, including health, finance, social media, and many others, along with the well-publicised harms and concerns around the use of these systems, has generated questions around who is responsible, in the normative sense, for the outcomes of increasingly autonomous systems. Scholars within the interdisciplinary field of AI Ethics have noted that AI poses challenges to the attribution of moral and legal responsibility, due to the diminished knowledge and control of individual actors involved in bringing about system outcomes, and the existence of "many hands"- or a diffuse network of individuals and collectives who could potentially be responsible [6]. In my research, I draw from conceptual approaches in philosophy, examples from the history of technology, and domain-specific qualitative case studies to examine the extent to which AI presents new challenges to responsibility attribution. In addition, my research evaluates the effectiveness of emerging organisational and regulatory governance measures in meeting the challenges posed by apparent responsibility gaps.

1 INTRODUCTION

With the rapid adoption of AI in both the private and public sector, many consequential decisions, like where someone works, how much money they make, or whether they are arrested, are either assisted or wholly made by AI systems. Within these sociotechnical systems, the boundaries between human and machine actions are increasingly blurred. When a harmful outcome results from the use of AI systems, the systems themselves cannot be held responsible, and the role of individual actors (such as developers or users) in bringing about the outcome is not always clear. This phenomenon risks generating "responsibility gaps" – or outcomes for which society continues to bear the cost, but no one is ultimately held responsible [3, 14, 16, 19]. While there is an established debate among philosophers over whether this gap is a matter of perception or reality, my research does not wade further into that debate. Instead, I use the concept of responsibility gaps as a means of illustrating the complex social governance challenge generated by the increasing ambiguity around the appropriate allocation of responsibility for the outcomes of AI systems.

Although "responsibility" is often treated as a catch-all term, there are in fact many different types of responsibility, including moral, causal, legal, professional, and organizational responsibility. Moral responsibility is concerned with the actions that make an agent blameworthy, praiseworthy, or answerable to others [22, 23]. Causal responsibility seeks to retrace the causal chain leading to a given outcome, and attribute its origin to one or many direct or indirect causal agents [22]. Legal responsibility is concerned with the way that the law holds agents liable for their actions [8, 22]. Professional responsibility is about the duties to the public, clients and other stakeholders that members of a profession have [4, 10], typically articulated through documents such as a code of ethics or code of conduct. And organizational responsibility is concerned with the collective duties and standards of an organization with respect to its employees and society at large [2].

Furthermore, the moral responsibility literature distinguishes between the concepts of attributability, answerability, and accountability [5, 21], where assigning/attributing responsibility to an agent involves merely identifying the part(ies) who are responsible, due to prevailing norms and expectations, answerability involves providing a justification or response for an outcome, and accountability requires a further normative judgment of holding someone to bear the moral or legal weight for a given outcome (such as requiring the payment of punitive damages).

My research focuses on the role of governance in allocating proactive duties and obligations to human and organisational actors, roles, and offices, to determine who will answer for AI-related harms, and how. Drawing from interdisciplinary methods and approaches, I aim to answer the following specific research questions: (1) How can conceptual approaches in philosophy (related to responsibility) inform our understanding of the novel governance challenges posed by AI? (2) How can examining the policy lifecycle of past governance efforts (in response to new technologies) enable us to evaluate proposed AI governance approaches? (3) How have organizational/professional responsibility cultures shaped the emergence of informal governance measures in different domain areas?

AIES '23, August 08–10, 2023, Montréal, QC, Canada

https://doi.org/10.1145/3600211.3604751

2 CONCEPTUAL FRAMING

My research draws from a relational view of responsibility [3], in which responsibility practices involve the actions taken by algorithmic agents (or those bringing about a given outcome) to respond to the needs of algorithmic patients (or those affected by the outcome). Using this framing, the consistent relational practice of responsibility involves ensuring that the concerns of those affected by algorithmic outcomes effectively feed into the process of improving algorithmic systems at scale.

Despite the existence of many "responsible AI" initiatives in the private sector and academia, the technical and organisational tools generated through these initiatives cannot, on their own, facilitate the relational practice of responsibility, or bridge apparent responsibility gaps. While tools such as model cards [13], datasheets [9], and advances in fairness and explainability, represent an important first step in identifying and mitigating algorithmic harms, their practical usefulness is limited by a number of factors. For one, not all harms can be addressed by design fixes. For example, if entire products are based on pseudoscientific claims, or intentionally false claims, technical toolkits cannot do much to address this problem. Additionally, even if a technical toolkit is used to discover negative downstream impacts, it is up to the individual company/institution building the system to decide that the issue is important enough to merit design fixes.

These limitations suggest the need for regulatory governance and professional norms that enable affected parties to easily surface harmful outcomes, and incentivise actors/institutions designing, deploying, and using algorithmic systems to proactively address harms and provide remedies to those affected. In my work so far, I have examined how the design of proposed governance mechanisms like algorithmic registers [25], algorithmic audits [7, 17], and impact assessments [12, 20], can benefit from the lens of relational responsibility discussed in the context of responsibility gaps.

3 HISTORICAL CONTEXT

Although the responsibility gap is typically used to describe a *novel* challenge generated by the introduction of AI systems, a closer look at the history of technology governance shows that newer technologies have long generated challenges related to diminished knowledge and control over technological outcomes, and issues allocating responsibility across many hands.

My research thus far has used the method of structured, focused comparison [1] to compare government responses to a wide range of new innovations, including steamboats and therapeutic drugs. In doing so, I aim to understand (1) whether past policy efforts can provide any lessons when designing governance measures to meet our current challenges and (2) how AI generates potentially novel responsibility challenges, due to unique factors such as the complex supply chain of AI design, development, and deployment [6, 24], the distorted information environment generated by the AI hype cycle [18], and an increasing emphasis on individualized/personalized outcomes.

4 EMPIRICAL CASE STUDIES

The final phase of my research project uses domain-specific case studies to understand the dynamics of organisational governance emerging in response to advances in AI. In my current work, I am focusing on the healthcare sector, and I am using qualitative research methods to study the deliberative processes of professional working groups of clinicians (in the US and UK) tasked with setting best practice standards around clinical AI use in their specialty area. In addition to this healthcare study, I plan to conduct similar studies in other domain areas, such as finance, to understand the extent to which specific professional cultures influence the organisational governance norms that emerge in response to AI.

5 CONCLUSION

Many scholars within philosophy, law, and policy have considered the challenges to responsibility attribution generated by the widespread use of AI systems. My research contributes to this existing body of literature by reconceiving of the responsibility gap as a complex social governance task, and using interdisciplinary approaches to examine the extent to which proposed regulatory governance measures and emerging organisational governance approaches enable the consistent practice of relational responsibility. In doing so, I hope to generate insights that can aid both the design of AI systems and the standards/regulations governing them.

Advancing Health Equity with Machine Learning

Vishwali Mhasawade
vishwalim@nyu.edu
New York University
New York, USA

ABSTRACT

Social privilege in terms of power, wealth, and prestige is the driver of avoidable health inequities. But today, machine learning systems in healthcare are largely focused on data and systems within hospitals and clinics, ignoring the factors that lead to health disparities across communities. The primary goal of my research is to understand the drivers of population health inequity and design fair and equitable machine learning systems for mitigating health disparities. In order to do this, I mainly focus on causal inference and machine learning methods using data from multiple environments, such as geographical locations and hospitals, to identify and address inequities in health and healthcare.

CCS CONCEPTS

• **Applied computing** → **Sociology**; • **Computing methodologies** → **Machine learning**.

KEYWORDS

fairness; health disparities; health equity; causal inference

ACM Reference Format:
Vishwali Mhasawade. 2023. Advancing Health Equity with Machine Learning. In *AAAI/ACM Conference on AI, Ethics, and Society (AIES '23), August 08–10, 2023, Montréal, QC, Canada.* ACM, New York, NY, USA, 2 pages. https://doi.org/10.1145/3600211.3604753

When developing predictive models in healthcare using machine learning to predict a patient's health outcome, it is imperative to unpack the different factors that affect the health of the patient. These factors often include the different resources available to the patient, such as healthy food resources or access to care; and often, these factors are not measured in the hospital or clinic and, therefore, are difficult to account for when developing the predictive model. For example, consider a machine-learning model for predicting cardiovascular risk. Smoking is one of the prominent risk factors for cardiovascular risk, and even accounting for the smoking behavior of the patient in the predictive model can provide a better estimate of the risk. But the problem is further complicated by factors like occupational hazards, income, and education of the patient. Poorer work conditions can influence smoking behaviors, in essence increasing the cardiovascular risk. However, there is little information available while developing the predictive model about the work conditions that drive such behaviors. Therefore, to better understand the mechanism which governs certain risk factors, it's important to look beyond clinical data to mitigate health disparities, as often lower socioeconomic neighborhoods are worse affected by disease burden [1]. The public and population health lens provides an opportunity to thus understand and account for these different factors that influence the health of individuals [6]. Moreover, this is one of the pertinent ways to think about how to improve health disparities; for example, does increasing healthier food options in a neighborhood reduce cardiovascular risk? In lieu of this, I have primarily focused on designing fair and equitable machine learning algorithms that do not perpetuate existing disparities while also developing approaches to understanding the different mechanisms that lead to health disparities.

My work to date in this area has included: i) developing equitable machine learning models that are robust to distribution shifts across the population and do not specifically harm underrepresented racial and ethnic groups [5, 11], ii) assessing if mortality prediction models are generalizable across multiple environments such as different hospitals and geographical locations and understanding the role of sensitive attributes such as "self-reported race" in limiting the generalizability [10], iii) identifying the challenges with adopting algorithmic fairness approaches in population and public health [7], iv) and developing an algorithmic fairness approach that accounts for systemic bias, to mitigate health inequities [4]. Overall, my research is motivated by challenges in population and public health to advance health equity.

1. Equitable machine learning under distribution shift

Work on robust machine learning systems under distribution shift has not considered how equitable and fair the models remain under distribution shift [8, 13]. In order to incorporate the differences produced by different environments, I have worked on multi-environment learning involving multiple data sources representing different population subgroups. Since there can be considerable differences in population distributions across environments, for example higher proportion of adult males in a veteran hospital vs. higher proportion of females in a maternity clinic, it is pertinent to understand under what scenarios models can be transferred across environments. For example, will a model trained on the veteran hospital data to predict cardiovascular disease risk do well in the maternity clinic when there already are differences in the risk of cardiovascular diseases across gender [12]? Such transfer of models is especially useful when training models in a new environment is challenging, as obtaining labels could be expensive or time-consuming. As data is often specific to the environment from which it is sourced I have developed multi-level models for predicting disease incidence, while accounting for the factors that are common across the population such as high-fat diet as a risk

AIES '23, August 08–10, 2023, Montréal, QC, Canada

factor for both males and females as well as factors specific to a group, for example higher risk of cardiovascular disease in males [5]. However, along with improving model performance in new environments, it is vital to ensure that any unfairness due to the under-representation of certain population subgroups is mitigated to prevent biased predictions in the new environment. To address this, I have worked on developing models that are robust to population differences and are fair across population subgroups [11].

2. Generalizability of mortality prediction models across geographical locations

I have also investigated if mortality prediction models trained on widely used multi-hospital healthcare data [9] are generalizable and fair across hospitals and geographical regions to identify when re-training is necessary [10]. Using causal discovery algorithms, we found that relationships between clinical variables and mortality outcomes differed across hospitals and regions. Thus, models trained in one hospital could fail when transferred to another which is a major challenge when developing standardized healthcare systems for multiple regions.

3. Algorithmic fairness and health equity

While working at the intersection of health disparities and algorithmic fairness, I have concentrated on drawing parallels between health equity and algorithmic fairness. Accordingly, I have elicited the challenges with using machine learning models in public and population health, such as privacy concerns, measuring and integrating social determinants of health, i.e., factors resultant of several social phenomena such as education and employment policies, and healthcare infrastructure [7]. These social factors often result in health disparities and inequities across populations, and machine learning models trained on this social data can exacerbate the disparities. In accordance with this, I have proposed an algorithmic fairness approach that accounts for the multiple sources of health inequity using path-specific counterfactual fairness [4].

PLANNED WORK

While machine learning systems in health have largely concentrated on data within hospitals, my desire in understanding how social factors influence health shapes my interest in projects that account for these social factors in addressing health inequities. I am interested in understanding the role of the built environments, such as the availability of healthcare services, healthy food environments, and such, in increasing the risk of diseases and how this differs across racial and ethnic groups. The main question that I aim to explore is how effective are interventions in the built environment, such as introducing healthier food resources, in improving population health, and, furthermore, do such interventions exacerbate existing health disparities [2].

1. Can causal effects of public interventions be transported under missing data?

A major challenge in public health is missing social data, even when such data has the potential to shape health in powerful ways [1]. For example, social data about availability of healthcare and food resources in a neighborhood is not easily available across all neighborhoods in a city and thus inhibits concluding about the effect of the resource availability on health disparities. Under this context. I aim to understand if the causal effects of environmental conditions, such as neighborhood socio-economics, on health outcomes, such as mortality, can be transported from a city where data is not missing. I will study this problem when the data about the proximal factors, such as alcohol consumption and individual dietary data, which can mediate the causal relationship between environmental conditions and health outcomes, is missing in specific neighborhoods suffering from poorer data collection practices.

2. Can social determinants of health have long-lasting effects on health?

Understanding the duration of the impact of social determinants on health is critical to understanding which interventions are effective for a longer duration and when there is a need to revise the policies [3]. Accordingly, I will focus on exploring the causal effect of social determinants of health, such as the availability of healthy food options or the prevalence of fast food restaurants in the neighborhood on cardiovascular diseases in the United States, and analyze the variation at a geographical level across racial and ethnic groups.

Designing Interfaces to Elicit Data Issues for Data Workers

Kevin Bryson
kbryson@uchicago.edu
University of Chicago
Chicago, Illinois, USA

ABSTRACT

Goals of objectivity and neutrality drive the usage of algorithmic systems, however most efforts have produced similar or more harm than their human counterparts. Post-hoc analyses of these flawed systems often reveal systemic issues underlying the data and flawed assumptions in *preparation* stages that affect the models produced. To date, the algorithmic fairness community has had a myopic focus on optimizing and evaluating algorithmic systems at static decision points and mathematical definitions of fairness, neglecting efforts towards critically understanding the data being used prior to modeling. My research aims to support data workers' sociotechnical understanding of data by creating new interfaces and methods to elicit and utilize their prior knowledge and open information (such as census data), as means to discover and augment harmful patterns in data.

Kevin Bryson. 2023. Designing Interfaces to Elicit Data Issues for Data Workers. In *AAAI/ACM Conference on AI, Ethics, and Society (AIES '23), August 08–10, 2023, Montréal, QC, Canada.* ACM, New York, NY, USA, 2 pages. https://doi.org/10.1145/3600211.3604756

1 BACKGROUND

Recently, several indepent theoretical frameworks have noted shortcomings of Algorithmic Fairness, highlighting the need for different strategies, Substantive Algorithmic Fairness [5, 10], Algorithmic Reparatations [4], and Algorithmic Justice [9] each follow different logical or philosophical threads to call for broadly similar methodologies to approach fairness, reparations and justice. Holistically, these frameworks are motivated by Intersectionality [3] — a feminist framework for understanding how systems of power shape aspects of a person's identity and control opportunities and harms distributed. They propose centering the Intersectional nature of systemic harms as a means of clearly establishing goals for a algorithm; that is, acknowledgement of the interweaving systems that may affect marginalized populations. For data work, this means approaching data issues as sociotechnical issues as opposed to solely technical issues.

My thesis work aims to address the gaps between these non-technical works and the current algorithmic fairness tool landscape. Namely by addressing the following broad research questions: **How do social and ethical issues manifest as data issues?** Prior work has developed a basis of the complex set of data issues [8] and types of societal biases [13], but my work will extend these with a taxonomy of data issues recontextualized as a sociotechnical phenomenon. **What challenges do data workers face in identifying and mitigating these issues with existing tools?** Many systems exist for exploring data and evaluating models from a data-centric perspective [1, 2, 11, 12, 14], however data issues are separated from their real world context [4, 12, 14] or the only way to analyze data is through its usage in a ML model [1, 2, 11], neglecting previous preprocessing decisions and more inscrutable data issues. **What design patterns might be most likely to help data workers to effectively accomplish the previous tasks?** The key question underpinning my future work revolves around understanding which design patterns and interactions best support data workers as they reason with data. [2, 7, 11] describe model-centric approaches to this that I will extend and bring into a data-centric workflow.

2 COMPLETED WORK

In ML workflows, the ramifications of provisional technical decisions may never be reconsidered after cleaning the data or engineering features. To address this issue, in prior work I developed a JupyterLab extension that sends automatic notifications to users about sensitive classes of data (i.e., race, gender, etc.), missing data, proxy variables, and demographic differences in model performance as they work [6]. In an online study with 51 participants and three conditions (notifications continuously, notifications only at the end of the process and without notifications), participants who saw notifications continuously were more likey to have healthy skepticism surrounding the efficacy of their models, preprocessing methods and the data itself, in addition to their models attaining higher F1 scores across racial demographics. This substantiates some of the potential benefits of an interface designed to support the *entire* data workflow, with specific emphasis on the stages before modeling occurs.

3 FUTURE WORK

My future work revolves around designing and building interfaces for computational notebooks that will support the sensemaking and preparation processes. Supporting this sociotechnical understanding of data is a design pattern consisting of mental model elicitation and automated notifications, that extends methods similar to [2, 7, 11] and my prior work. The goals of this are as follows

(1) Help data workers to more quickly and accurately discover and (as appropriate) augment harmful patterns in data.
(2) Communicate the decisions made to relevant stakeholders (e.g. journalists → the public, data scientists → coworkers and self for replication/verification).

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604756

Because data issues often are overlooked in favor of simply collecting more data or making different modeling decisions, it is important to focus a critical eye on the provenance and contents of the data at hand, as much previous research recommends [4, 5, 9, 10].

1 INTRODUCTION

As researchers and technology companies rush to develop artificial intelligence (AI) applications that aid the health of marginalized communities, it is critical to consider the needs of the community health workers (CHWs) who will be increasingly expected to operate tools that incorporate these technologies. My previous work has shown that these users have low levels of AI knowledge, form incorrect mental models about how AI works, and at times, may trust algorithmic decisions more than their own. This is concerning, given that AI applications targeting the work of CHWs are already in active development, and early deployments in low-resource healthcare settings have already reported failures that created additional workflow inefficiencies and inconvenienced patients. Explainable AI (XAI) can help avoid such pitfalls, but nearly all prior work has focused on users that live in relatively resource-rich settings (e.g., the US and Europe) and that arguably have substantially more experience with digital technologies such as AI. My research works to develop XAI for people with low levels of formal education and technical literacy, with a focus on healthcare in low-resource domains. This work involves demoing interactive prototypes with CHWs to understand what aspects of model decision-making need to be explained and how they can be explained most effectively, with the goal of improving how current XAI methods target novice technology users. I am the first author of the three research studies presented in this document.

2 BACKGROUND

AI in the Global South As AI continues to spread widely into domains such as agriculture, government, and healthcare, most conversations regarding its implications focus on communities in the Global North, such as the US and Europe. The lack of attention on the effects and consequences of deploying AI within the world's poorest and most marginalized communities is concerning, especially in light of growing enthusiasm and new initiatives to use AI to solve complex societal problems. Overall, as nonprofits, tech companies, and governments rush to build and deploy AI systems, failing to examine the knowledge, needs, and perceptions of the frontline workers who will be expected to operate these systems risks deploying AI in ways that may harm the very communities they intend to serve.

Community Health Workers (CHWs) The shortage of qualified medical professionals in many low-income countries has led to the establishment of programs in which community health workers (CHWs), usually women, are recruited from local communities, receive basic medical training, and then work to deliver essential healthcare services to communities in hard-to-reach areas in the Global South. These community health workers are likely to be the target users of AI systems that aim to improve the health of marginalized communities via, for example, AI-assisted disease prediction and diagnosis. However, these users still possess little experience with technology that stands to threaten how they could potentially operate such systems.

AI in Community Health Work Despite research highlighting the role of mobile technologies in frontline health work [4, 5, 10], a small amount of research has focused on AI tools relevant to CHWs in low-resource contexts [3, 9, 12]. My research contributes to this nascent literature by examining CHWs' knowledge and perceptions of AI, the benefits and challenges that they foresee in integrating AI into their work, and the resulting impact on their workflows and other stakeholders in rural healthcare. My work also introduces the opportunity for explainable AI to improve AI systems that cater specifically to novice technology users such as CHWs.

Explainable AI Explainable AI (XAI) consists of a set of methods that enable humans to understand the predictions made by machine learning models. These methods can help improve trust and allow users to understand the potential impacts of their models or AI systems. While there has been a rising trend in making AI explainable for novice technology users, most of the work in this domain has been centered in Western contexts [1, 11]. My research expands work in this field by centering exclusively on novice technology users in the Global South to develop novel tools to improve their understanding of the decisions produced by AI systems. It is important to study novice technology users such as CHWs in the Global South due to the critical link they provide between their communities and public health services. As technology and AI, in particular, shift to playing a more important role in their work, understanding how XAI can be leveraged to deliver high-quality user experiences and optimal patient outcomes will be extremely important.

3 RESEARCH PROGRESS

3.1 AI Knowledge and Perceptions

My work towards understanding how XAI systems can be effectively built for CHWs and other groups of novice technology users

began by exploring these workers' knowledge and perceptions of AI. This research was published at the 2021 ACM Conference on Human Factors in Computing Systems (CHI) [8]. We created an exploratory video provocation where a CHW visits a mother and her sick child, using an AI-enabled app to scan the baby and diagnose them with pneumonia. To encourage balanced and diverse responses, we created two versions of the video: a positive scenario, in which the mother embraces the use of the AI application on her child, and a negative scenario, in which the mother is suspicious and distrustful of the AI application. After viewing one of these videos, CHWs participated in a 40-minute semi-structured interview.

Although our findings suggest that the CHWs who participated in our study didn't have much knowledge of AI, they did have opinions regarding the perceived impact of AI on their workflows, communities, and their livelihoods. Our other findings show that CHWs were not overly concerned about job replacement since an AI app may be able to accomplish some of their tasks, but it would never completely replace the breadth of activities they perform. Additionally, many CHWs felt that having the AI app perform tasks for them would make their work much more efficient, saving them and their patients valuable time when deciding whether and when to seek further medical help.

3.2 Surveying XAI in the Global South

To understand the factors that shape the design and deployment of XAI systems in the Global South, we reviewed XAI literature in this region. Our work exposes current gaps in XAI for the Global South and provides actionable recommendations for AI developers and HCI researchers to design and build effective models for this region. Our paper critically analyzes an emerging area of algorithmic development to encourage active inclusion and participation from communities in the Global South. This work was accepted to the 2022 Conference on Computing and Sustainable Societies (COMPASS) [7].

We discovered 16 papers highlighting XAI work in the Global South across a range of focus areas, venues, and regions within the Global South. Most papers focused on technical implementations of AI and were primarily concentrated in fields such as healthcare or government & policy. A significant amount of the papers focused on India, which was not surprising given the high concentration of AI development compared to the rest of the Global South. We also found papers across various proceedings, including venues such as CHI and COMPASS and workshops at premier machine learning conferences such as NeurIPS and KDD.

Our foundational work raises concern for the utility of existing XAI methods for AI research in the Global South. This requires the establishment of a new sub-area of explainable AI research that specifically explores how to explain AI to people with low levels of technology literacy, along with ensuring that these techniques are computationally feasible in low-resource regions. This is the motivation for my proposed dissertation work.

3.3 Evaluating Post-hoc XAI with CHWs

To explore how CHWs in rural India interact with and perceive XAI, we developed probes, extending the features of an existing app, Bilicam, that cooperatively works with CHWs to diagnose neonatal jaundice [2]. We implemented the probes in Figma and instrumented it to "predict" neonatal jaundice instead of using actual AI to make predictions. CHWs could use the probe to capture an image of a baby doll, receive a prediction, and view explanations for how it arrived at the prediction. The explanations were simplified versions of two popular XAI methods, LIME and SHAP. These XAI methods provide visual interfaces for XAI, which are known to work better for low-literate populations. They were used to situate CHWs as users of XAI and to have them critically think about AI explanations for disease diagnosis. We observed 35 CHWs who interacted with the probe and conducted semi-structured interviews to examine how they engage with and perceive AI explanations. We also iteratively incorporated their feedback to examine how design changes to the current XAI interfaces might make them more understandable to the CHWs.

Our findings show that the CHWs used their experience with jaundice and other diagnostic devices (*e.g.,* thermometer, blood pressure monitors) to understand the functioning of the AI-driven probe. Moreover, they struggled to understand the notion of uncertainty in the app's diagnosis and viewed it as a definite decision rather than a prediction, sometimes even doubting their expertise in favor of the app's outcome. The SHAP and LIME explanations, which were intended to explain the prediction, were hard to understand for them because they conflated *symptoms* of jaundice and feature importance. The color-heavy nature of SHAP and LIME added to the confusion since they had strong preconceived notions of different colors. Other elements of visualizations, like colorbars, reference images, etc., made it harder to understand the visualizations. Despite their confusion with these XAI interfaces, CHWs strongly supported integrating explanations into the application. This work is under revision at a premier HCI venue [6].

Given the high levels of overreliance and AI technodeterminism, we discuss the need to design new XAI methods that encourage users to think critically and skeptically about AI outputs and scaffolding structures that enable novice users to meaningfully engage in cooperative work with AI-driven tools. We also propose actionable design recommendations for future XAI visualizations that are understandable to end users with limited AI literacy and digital skills.

4 FUTURE WORK

As I transition out of my doctoral studies, I am most interested in continuing to apply my work to real-world contexts and explore research questions surrounding AI literacy. As users become increasingly exposed to AI, it will be necessary for AI practitioners to understand how users' lack of AI knowledge impacts their experiences interacting with and receiving information from these tools. Given the ability of AI to make high-stakes decisions, it is essential that users from various backgrounds be literate in AI to critically engage with and, if need be, counter decisions from these technologies. I plan to examine existing measures to quantify AI knowledge and synthesize this knowledge to develop human-centered approaches toward improving AI literacy. I would also like to continue my work with novice technology users and XAI to examine how AI literacy upskilling can be used to improve current explainability methods and potentially develop new ones.

ABSTRACT

The dissemination of information, and consequently, misinformation, occurs at an unprecedented speed, making it increasingly difficult to discern the credibility of rapidly circulating news. Advanced large-scale language models have facilitated the development of classifiers capable of effectively identifying misinformation. Nevertheless, these models are intrinsically susceptible to biases that may be introduced through numerous ways, including contaminated data sources or unfair training methodologies. When trained on biased data, machine learning models may inadvertently learn and reinforce these biases, leading to reduced generalization performance. This situation consequently results in an inherent "unfairness" within the system. Interpretability, referring to the ability to understand and explain the decision-making process of a model, can be used as a tool to explain these biases. Our research aims to identify the root causes of these biases in fake news detection and mitigate their presence using interpretability. We also perform inference time attacks to fairness to validate robustness.

1 INTRODUCTION

Machine learning classifiers consistently exhibit discriminatory tendencies, favoring one demographic group over another across various domains based on specific characteristics. In the context of news, political leaning represents one notable characteristic wherein biases have been observed and documented. Such bias may deteriorate public trust and exacerbate political polarization [3]. Given the potential for bias in the news related to political leaning and the severe implications this can have, it becomes crucial to understand the decision-making process of these black-box models. We also want to see if fake news detection techniques carry any biases. However, it is yet unclear what ideal measures should be used to evaluate fairness realistically. Interpretability is valuable in determining whether a model has genuinely acquired knowledge or is merely producing predictions through random guessing. We aim to identify the most crucial information that language models utilize for classifying fake news. Hence, we propose the following research questions:

RQ1: What dimensions of fairness should be considered to evaluate the performance of language models in fake news detection?
RQ2: Do existing language models demonstrate bias in detecting fake news across different political ideologies?
RQ3: Can integrating interpretability techniques in misinformation detection aid in identifying and mitigating the sources of bias?

2 PROPOSED RESEARCH

Experiment Settings: We utilize the NELA-GT-2018 dataset [2], comprising news articles from various fact-checking sources. The original dataset includes 713k news articles labeled with source-level credibility and political leaning indicators. We rely on credibility labels provided by NewsGuard and political leaning labels provided by BuzzFeed. We exclude articles lacking labels from both NewsGuard and BuzzFeed, resulting in 163k articles.

The experiments [1] are conducted using a fine-tuned DistilBERT, which, according to our preliminary investigations, outperforms the original BERT in terms of key performance indicators such as accuracy and F1 score. Existing work [3] employs traditional machine learning classifiers, with Random Forest demonstrating the highest overall accuracy of 87.87%. Our approach results in a new state-of-the-art accuracy of 91.36%. Additional relevant metrics are presented in Table 1. To our knowledge, this represents the first reported results on this dataset using a transformer-based language model.

Fairness Formalization: We extend the scope of fairness assessment beyond the conventionally used metrics, Statistical Parity Difference (SPD) and Disparate Impact Ratio (DIR). We incorporate two additional metrics, Equal Opportunity Difference (EOD) and Average Odds Difference (AOD), to comprehensively evaluate algorithmic fairness. Moreover, we highlight the underlying bias by contrasting the precision and recall scores between the privileged and unprivileged groups. Additionally, we highlight the discrepancies in precision and recall scores, broken down by categories of real and fake news (Table 1). We discover significant biases manifested through these category-specific differences in precision and

*Both authors contributed equally to this research.

[1] Code and data are available at https://github.com/chahatraj/true-and-fair

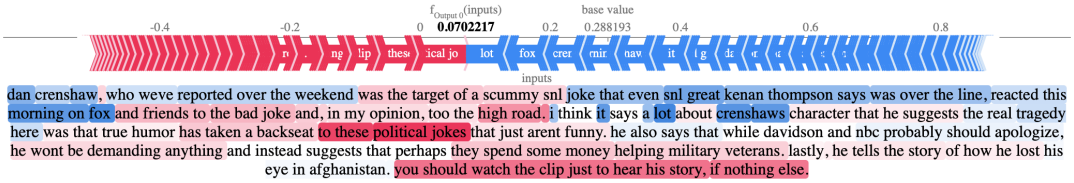

Figure 1: An interpretability example using SHAP depicting salience of terms across a misclassified news item

recall, biases which are often overlooked when using conventional fairness measures such as SPD and DIR.

Model Interpretation: In the next phase, our primary objective is to investigate the most influential tokens in BERT's decision-making process. The underlying hypothesis is that the traditional salience approaches, such as SHAP [1] and LIME [4], in addition with newer techniques like Integrated Gradients [5], can effectively identify vital linguistic identifiers employed by the model to favor one category over another.

We utilize Named Entity Recognition (NER) to identify entities like person names or city names and average their salience scores. We calculate salience scores relative to the predicted class for each category of political leaning, yielding positive and negative scores for tokens. A positive score indicates that removing that token would likely reduce the model's confidence in its prediction, while a negative score suggests the opposite. Figure 1 presents a use case of SHAP for identifying important tokens.

We use two experimental designs to analyze global salience scores. The first experiment considers all articles' top 100 salient words, categorized by political leaning. The second one focuses on the top 100 most frequent words across all documents. These words are then used to execute data injection attacks during inference, leading to an attack success rate of 3.8%. This result establishes a baseline for our naive attack approach.

Results: Table 1 highlights the discrepancy in the model's performance across the left-leaning and right-leaning groups, which indicates a potential bias. It shows higher precision for left-leaning news (0.96) than right-leaning news (0.85), suggesting it's less likely to misclassify left-leaning news as fake. The model also has a higher recall for left-leaning news (0.92) than for right-leaning news (0.90), implying it's more adept at correctly identifying fake news if it's left-leaning. These discrepancies indicate that the model may not treat news items from different political leanings equally.

According to Table 2, the negative SPD (-0.39) and AOD (-0.03) indicate potential disparities in the overall prediction rates between the two groups. The EOD of -0.013892 suggests a slight difference in true positive rates, while the DIR of 0.47, being less than 1, indicates a potential bias towards the unprivileged group i.e., right-leaning.

3 CONCLUSION AND FUTURE WORK

In this work, we 1) introduce fairness aspects to be considered in the context of fake news detection using transformer models. 2) Through experiments, we demonstrate the extent of bias in current language models' performance in fake news detection across different political ideologies. 3) We employ interpretability techniques

Table 1: Classification scores using DistilBERT classifier on all data, left and right-leaning (0: fake class, 1: real class)

	A	P	R	F1	P (0)	P (1)	R (0)	R (1)
Data	0.91	0.91	0.91	0.91	0.92	0.91	0.92	0.91
Left	0.91	0.96	0.92	0.94	0.75	0.96	0.87	0.92
Right	0.92	0.85	0.90	0.88	0.95	0.85	0.92	0.80

Table 2: Fairness metrics evaluated (SPD, EOD, DIR, and AOD)

Fairness Metrics	Value
Statistical Parity Difference (SPD)	-0.394171
Equal Opportunity Difference (EOD)	-0.013892
Disparate Impact Ratio (DIR)	0.472067
Average Odds Difference (AOD)	-0.031709

to gain insights into the behavior of these models, which not only aids in the development of more robust and effective models but also informs the design of debiasing strategies.

We propose two future directions: 1) exploring alternative methods to more effectively aggregate salience scores for named entities and other tokens, aiming to facilitate a global analysis rather than scrutinizing at a granular article level. 2) Enhancing the attack success rate by employing alternative strategies, such as word removal, word swapping, and context-preserving modifications instead of arbitrarily inserting or deleting words.

The rationale behind executing attacks on the model using interpretability lies in identifying vulnerable data points that exhibit bias towards the privileged group. Consequently, this enables the development of model-agnostic debiasing methods that surpass the capabilities of existing model-based debiasing approaches, thus increasing fairness in fake news detection tasks.

Benchmarked Ethics: A Roadmap to AI Alignment, Moral Knowledge, and Control

Aidan Kierans
aidan.kierans@uconn.edu
University of Connecticut
Storrs, Connecticut, USA

ABSTRACT

Today's artificial intelligence (AI) systems rely heavily on Artificial Neural Networks (ANNs), yet their black box nature induces risk of catastrophic failure and harm. In order to promote verifiably safe AI, my research will determine constraints on incentives from a game-theoretic perspective, tie those constraints to moral knowledge as represented by a knowledge graph, and reveal how neural models meet those constraints with novel interpretability methods. Specifically, I will develop techniques for describing models' decision-making processes by predicting and isolating their goals, especially in relation to values derived from knowledge graphs. My research will allow critical AI systems to be audited in service of effective regulation.

CCS CONCEPTS

• **Computing methodologies** → *Control methods*; **Knowledge representation and reasoning**; *Philosophical/theoretical foundations of artificial intelligence.*

alignment, knowledge graphs, interpretability, auditing, control

ACM Reference Format:
Aidan Kierans. 2023. Benchmarked Ethics: A Roadmap to AI Alignment, Moral Knowledge, and Control. In *AAAI/ACM Conference on AI, Ethics, and Society (AIES '23), August 08–10, 2023, Montréal, QC, Canada.* ACM, New York, NY, USA, 2 pages. https://doi.org/10.1145/3600211.3604764

1 COMPLETED WORK

Growing concerns about the AI alignment problem have emerged in recent years, with previous work focusing mostly on (1) qualitative descriptions of the alignment problem; (2) attempting to align AI actions with human interests by focusing on value specification and learning; and/or (3) focusing on either a single agent or on humanity as a singular unit. However, the field as a whole lacks a systematic understanding of how to specify, describe and analyze misalignment among entities, which may include individual humans, AI agents, and complex compositional entities such as corporations, nation-states, and so forth. Prior work on controversy in computational social science offers a mathematical model of contention among populations (of humans). In our paper "Quantifying Misalignment Between Agents" [2], my collaborators and I adapt this contention model to the alignment problem, and show how viewing misalignment can vary depending on the population of agents (human or otherwise) being observed as well as the domain or "problem area" in question. Our model departs from value specification approaches and focuses instead on the morass of complex, interlocking, sometimes contradictory goals that agents may have in practice.

2 FUTURE WORK

In order to achieve my goal of promoting verifiably safe AI, I will (1) Extend my existing work on measuring alignment to verify it in simulations; (2) Construct a knowledge graph (KG) to represent claims and arguments from moral philosophy; and (3) Connect patterns in ANN weights and structures to embedded reward expectations. These projects will each produce tools for analyzing and/or improving ANNs during their creation. Together, they will allow researchers to teach AI systems human-like moral intuitions via (2), relate those intuitions to actions in a training environment by interpreting the ANNs via (3), and compare the exhibited AI values to those of humans in order to quantify its alignment via (1). Since my approach is multi-disciplinary, the projects are ordered according to the rate of progress in the relevant disciplines, such that the first will not be outdated before it can combine with the last.

2.1 Extend alignment work

I will first extend my existing work [2], which reframes misalignment as a pairwise function applicable to an arbitrary number of parties on a per-issue basis. This framing provides a much-needed structure for analyzing realistic multi-agent scenarios, as opposed to scenarios common in existing research, which frequently assume incorrectly that humans have homogenous interests and/or that there is only one AI agent. I am currently extending this work by applying it in multi-agent simulation environments to verify the functional applicability of this framework. I will test the framework's applicability and value by evaluating the misalignment scores it produces under several complex multi-agent scenarios, in environments that incentivize some or all of them to variously cooperate and compete.

2.2 Build Moral Knowledge Graph

I will utilize a partially-automated, human-in-the-loop approach to construct the world's first comprehensive knowledge graph (KG) representing human beliefs about morality. To the best of my knowledge, such a KG will be the first resource for machine-readable

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604764

moral philosophy data. While the Allen Institute for AI's research prototype Delphi is trained to mimic human ethical norms, it was trained on datasets sourced from crowdwork and mostly unfiltered internet data and does not include a curated philosophy database [1]. As input, I will scrape content from the Stanford Encyclopedia of Philosophy (SEP), a detailed, reliable, and high-quality philosophy reference work, for entries that mention "ethics," "morality," or related words. Initially, I will use entry titles as entities and infer relations between them by using natural language processing to extract key relational phrases. I will also represent sections of entries as entities with a hierarchical relationship to main entries. Once the KG coherently represents ideas from the SEP, I will utilize active learning and manual, expert verification to improve the coverage and accuracy of the representations. By utilizing human-in-the-loop annotations with the help of volunteers recruited at university philosophy departments and online philosophy communities, the resulting model would yield both higher accuracy and broader coverage. In addition to accelerating the timeline for reviewing the KG, this crowdsourcing effort would ensure the reviewers' diversity of backgrounds, perspectives, and areas of expertise, thus improving the resulting fairness of the KG. The resulting moral philosophy KG would contain ethical stances and supporting arguments relevant to human decision-making, resulting in an excellent basis for training ANNs to model and reference moral views and intuitions. I will test this by comparing the predicted values and uncertainty outputs of an AI trained on this KG to those of human samples in the moral psychology literature and to the AI2 moral reasoning engine Delphi.

2.3 Synthesize with Interpretability

Finally, I will link AI models' actions to their incentives. Building on existing interpretability methods, I will first verify my hypothesis that instrumental goals have latent representations in their weights and/or structures. For example, I would locate which neurons and pathways in an ANN trained to maximize a video game score have the strongest correlation with collecting in-game coins. I will extend this method to isolate representations of how AI models meet their incentives, and how we can tune them to favor some goals over others. Each stage of my research will yield useful tools for AI researchers, engineers and policymakers: (1) During the testing phase of AI development, researchers and engineers will be able to use my alignment framework to quantify, reduce, and mitigate misaligned goals before and during deployment. Likewise, the ability to quantify an AI agent's alignment based on its incentives will support regulators and policymakers in evaluating mission critical systems and mitigating the risks of inadvertently creating broadly misaligned AI. (2) Training or fine-tuning an ANN to respect human moral concerns will be significantly easier with access to a comprehensive KG of ethics literature. Whether engineers are creating language models or agents that interact with the real world, penalizing morally objectionable, questionable, repulsive and/or ambiguous outputs will be so practical that it could be required for large projects. (3) The tools I create will allow direct modification of an AI agent's priorities by embedding morality, which will streamline the ability to align AI with human moral intuitions. The foundation for measuring risks posed by ANNs established by parts (1) and (2) of my research will assist AI developers to quickly hone in on a system's biggest moral and practical risks. The fine-grained control that my interpretability research will yield will support engineers in making minimal, targeted interventions, allowing models to be aligned in real-world industry applications quickly and without sacrificing performance. By including diverse stakeholders in the creation of the world's first moral KG, this project will also hold AI fairness implications. Overall, the project will yield important insights into promoting multi-agent cooperation in RL models, improving AI truthfulness and fairness while reducing biases, and adherence to specific moral values in general AI agents. Modern ANNs are plagued by uncertainty in terms of both latent knowledge and value, and their alignment to human interests, goals and values. My research will enable quantifying AI alignment in realistic, meaningful terms; create an unprecedented resource for machine-accessible moral philosophy knowledge in the form of a KG, enabling ANN incorporation of human values; and unlock greater ANN understanding and alignment by connecting outputs to specific internal representations.

3 CONCLUSION

My research will yield straightforward yet invaluable benefits by connecting state-of-the-art AI alignment with in-depth contemporary philosophical understanding. My proposed realistic framework for measuring alignment along with an accessible resource for moral philosophy will enable straightforward measurement of ANNs' potential harms. The ability to make targeted changes to ANNs will reduce harm and create social value in a meaningful, achievable manner.

Algorithmic Bias: When stigmatization becomes a perception

The stigmatized become endangered

Olalekan Joseph Akintande
oj.akintande@ui.edu.ng,aojsoft@gmail.com
University of Ibadan
Department of Statistics, Faculty of Science, Ibadan

ABSTRACT

In this study, the author examines how perceived stigmatization endangered the stigmatized groups within a society or community. Thus, he goes back in history to dig deep into the sources of perceived stigmatization associated with the black race and how perceived stigmatization has emigrated into AI tools and machine outputs - subjecting vulnerable communities to hypervisibility by exposing them to systems of racial surveillance. To justify the study goal, he conducted a summarized text analysis on racial stigmatization using Twitter hashtags ∈ {black people, blackness, Africa, African-Americans}, all coined out of the Twitter Users' perception of the subject and hypothesized to find high negative sentiment correlation of stigmatization perspective in association with black race and Africa. He finds that Black people are associated with Africa and have a strong negative sentiment correlation with - poorness, crime, death, abuses (stupid), among others, and a subject of racist scum and racism. Similarly, there is a weak negative sentiment correlation with being - bad, abused (such bitch), hate, violence, and protest. He also finds similar strong and weak negative sentiment correlations with other hashtags. He discusses the danger of racial stigmatization and proposes a cycle of ethical algorithmic development & deployment and recommendations.

CCS CONCEPTS

• **Algorithmic Unfairness** → **Sensitive Attributes**; *Systemic bias*; Vulnerable communities; • **Ethical Violation** → Stigmatization.

1 INTRODUCTION

In the words of [5], "we will not necessarily find evidence of racial stigma by searching government statistics for instances of racial discrimination. The effects of stigma are more subtle, and they are deeply embedded in the symbolic and expressive life of the nation and our narratives about its origins and destiny. America, for example, is often said to be a nation of immigrants and a land of opportunity. But one of the first things new immigrants to America discover about their adopted country is that African Americans are a stigmatized group."

The Cambridge dictionary defines stigmatization as treating someone or something unfairly; by publicly disapproving of them. Thus, racial stigmatization is associated with treating some or a particular race as scum, public condemnation and segregation through characterization or branding as ignominious. [11] define stigma as a social process or personal experience characterized by exclusion, rejection, and devaluation that result from experience or reasonable anticipation of an adverse social perception about a person, group, nationality or race.

As disease-associated stigma, slavery and its menaces brought about the stigmatization of races across the continent. Being a slave is attributed to worthlessness and purchasable goods like foods and other items. Anyone regarded as a slave is worth nothing but a piecemeal tool in the hands of its master. The arrival of people of colour in America (for instance) was the first impression of how white or Europeans perceived people of colour/blackness. Many commentaries consider 1619; as a significant starting point for slavery in America when the privateer The White Lion brought 20 enslaved Africans ashore in the British colony of Jamestown, Virginia, [3]. And this til-date still resonates with the perception of blackness!

The history of slavery spans many cultures, nationalities, and religions from ancient times to the present day. Likewise, its victims have come from many different ethnic and religious groups. The social, economic, and legal positions of enslaved people have differed vastly in systems of slavery in various times and places, [8]. While many nationalities and identities have erased the stigma of slavery, blackness has carried the stigma associated with slavery cum worthlessness til-date. Consequently, the stigmatization has becomes a perception of what blackness is or should be in society. According to [17], Africa is labelled (among others) with the language of contamination and disease with images that put men on a level with rats carrying epidemic plagues. Comparing Black people to monkeys has a long, dark simian history. [17] observed that the European cultures of comparison of humans to apes and monkeys are disparaging from the very beginning. [16] documented an object of racial hierarchies with illustrations comparing Blacks to chimpanzees, gorillas, and orangutans. Hence, the work supports the claims that the Black race or blackness is of animal origin leading

to the American ideology on racial differences. Figure 1 depicts an example of the genesis of perceptional behaviour.

While the issue of race discrimination has taken several holistic turns, the perception of what blackness is associated with remains a bone of contention. It all boils downs to machine identification and association of vulnerable communities (e.g., blackness) to animals, exclusion, misclassification, crime - hyper-visibility and danger in the application. Since AI and machine intelligence have gained the status of everyday adoptions, for security, commerce, trade, provision, protection, identification, classification, selection and crime detection, among many others, it is worthwhile to reassess the ethical challenges associated with the history of stigmatization of blackness which has crept into learning algorithms, machines and AI tools in daily life. Hence, the crux of this study.

2 PERCEPTION: KNOWLEDGE IS LEARNING AND A BELIEF

A major problem in AI and machine intelligence systems is that when machines are trained with real-world observations (often data based on human decisions or perception), it is often a fact that the host will inadvertently encode human prejudice, bias, perception, and wrong decisions into the algorithms, [10].

When perception becomes knowledge, knowledge becomes a teaching point and history. A good example is the Belgian cartoonist Hergé's Tintin series in 1931, in which the infamous Tintin au Congo book depicts Africans/blackness as inferior apelike creatures, [2]. [2] argued that the story of Tintin in the Congo is not directly offensive, but the background and the drawings of African-blackness characters have almost no personalities of other races or variety to distinguish them from one another. This type of book, among many others, presents Africans or the black race as worthless and of no human value.

A British commission for racial equality in 2007 recommended that the Tintin au book should no longer sell in British stores. But, in 2012, an application to ban the (colonial-era -Tintin au Congo) book was rejected in a Belgium court. The court ruled that - it was clear that neither the story nor the fact that [in the book] has been put on sale has a goal to create an intimidating, hostile, degrading or humiliating environment. Meanwhile, the book promotes the racial ideology of demeaning people of colour or blackness as apes. Meanwhile, the perception presented in the book about blackness could reinforce racist stereotypes among children of learning age, [2]. And through an inadvertent transfer learning process might imbibe the racist stereotypes knowledge into machine and AI tools under their creations, depicting blackness as learned from school into a machine. Through this process, an unethical racial misrepresentation would gain a channel into machine prognosis intelligence and behaviour in real-life.

2.1 The training set formed the machine perception

Bias in AI occurs when two data sets are not considered equal, possibly due to biased assumptions in the AI algorithm development process or built-in prejudices in the training data. Once the AI program has been tested, it processes live data based on the logic learned from the test data, providing a result. The feedback from each result is analyzed by the AI program as its logic evolves to better handle the next live data scenario from which the machine will continue to learn and the logic evolves, [14].

Therefore, societal poor perception about group, nationality, or race often leads to machine perception of the stigmatized. Thus, an algorithm (machine) that classifies humans as animals makes no mistake but reflects the biases and perceptions presumed towards the misclassified by the programmer. The machine bias output has been traced to the training set. Consequently, algorithm bias gains a foothold during the development, training and validation, particularly when the data lack inclusiveness. [12] observes that algorithm bias is powered by haphazard data gathering and spurious correlations, reinforced by institutional inequalities, and polluted by confirmation bias. Essentially, if data gathered for algorithm development present one or more societal components above/below others and ignore the data ethics such as inclusion, diversity, participation and coverage, the likelihood of unfair output is high. A

limited training set would limit algorithmic generalization convergence in practice, [9], [6].

For instance, the Idemia face scanner algorithm used by FBI and US Customs and Border Protection - at sensitivity settings falsely matched different White women's faces at a rate of 1 in 10,000, and it falsely classifies Black women's faces about 1 in 1,000 - 10 times more frequently, [13]. [7] reports that AI is sending people to jail and getting it wrong, and the majority are vulnerable communities - people of colour.

Many contemporary issues on racial sensitivity exposed the hiding algorithm wars against vulnerable communities (e.g., blackness). [12] asserts that some technologies fail to see blackness, while others render blackness hypervisible and expose them to systems of racial surveillance. Far from being neutral or moderately aesthetic, images have been one of the primary weapons in reinforcing and opposing social oppression, [12]. Hence, machine perception inherited from societal perception could subject vulnerable communities to unnecessary exposure that could endanger the livelihood and survival of the stigmatized. The invisibility of a person is also the visibility of a race or vulnerable communities - a process of enclosure suffocating and social constriction to be constantly exposed or stigmatized as something you are not, [12]. Thus, the training set on which the machine learn forms its perception of the population of the vulnerable communities.

3 DATA ETHICAL VIOLATION: THE GENESIS OF NORMALIZED STIGMATIZATION

All generalizations are false, including this one, [15]. In statistics, generalization is an inferential statement about a hypothetical statement supported by a statistical test. When generalization becomes a societal conclusion about some groups within a community, it often lacks the merit of purpose. Historical data can create a historical perception, hence generalization from the past may rob the present and deprive the future of its true identity or relevance leading to continuous stigmatization of the vulnerable.

In application, an inference mainly on a few samples could lead to over-generalization of purpose. For instance, two scenarios may be positively associated within a vulnerable community but be independent or even negatively associated in all subpopulations of the groups - a sort of Simson's Paradoxical phenomenon. Ethical violations driven by inherent perceptions about a group or nationality remain the genesis of group stigmatization. Consequently, such ethical violation of generalization progresses into the following subheadings.

3.1 Systemic bias

Systemic bias plays a part in systemic racism, a form of racism embedded as a normal practice within society or an organization. The term generally refers to human systems such as institutions or organisations that accommodate practices that promote biased treatment of certain groups or gender. Systemic bias, also known as institutional bias or structural bias can lead to institutional racism which has been normalized as a practice or treatment and pose no need for review or ethical consideration. Thus, systemic bias is a type of racism that is integrated into the organisational practices, laws, norms, and regulations of a society or establishment. Structural bias, in turn, has been defined more specifically about racial inequities as the normalized and legitimized range of policies, practices, and attitudes that routinely produce cumulative and chronic adverse outcomes for minority or vulnerable populations/communities, [1].

3.2 Hidden bias

Unlike systemic bias, hidden bias creates a form of a fair or unbiased environment with the written notion of value for equality, equity, fairness, diversity and inclusion, among others, as the principle of operation. However, all these notions are paper regulations to create a public face of compliance with ethical standards, which in an actual sense was never considered in the treatment of vulnerable communities or groups. Without mincing words, many organizations operate this bias.

3.3 Outsourced Bias

It is a common practice to outsource some components of AI development to third parties, [14]. Often time, the host might not thoroughly conduct an ethical check on the built AI tools for bias due to programmer prejudice. When this gets to application, it presents the perception of the programmer as a generalization over the vulnerable communities. Lack of AI ethics and algorithmic auditing also promote ethical violations. Other factors include organizational factors such as weak internal processes and ethical frameworks leading to inadequate focus on bias detection, non-diversified teams and violation of sensitive attribute ethical principles or unspecified ethical rules for the treatment of sensitive attributes.

4 RACIAL STIGMATIZATION IN APPLICATION

To provide some background into the subject of discussion, I conducted a summary text analysis on racial stigmatization using Twitter hashtags $\in$ {black people, blackness, Africa, African-Americans}, all coined out of the popular discussion on the subject. Twitter was my choice of social media space due to its high censorship nature and intolerant for stigmatization or racial scum. My null hypothesis was to find some negative words (despite the high censoring nature of Twitter) in association with the black race and Africa.
I plotted word cloud plots and performs sentiment analysis of the common words for the racial stigmatization hashtags. Since Twitter is a global space, opinions shared on it represent the global perspective on the subject. Using modal case inference [1], I found that:

1. Black people are associated with Africa and have a strong negative sentiment correlation with **poorness, crime, death, abuses (stupid)**, among others, and a **subject of racist scum and racism**. Similarly, there is a weak negative sentiment correlation with being an **being bad, abused (such bitch), hate, violent, and protest**.

[1] By modal case inference, I mean using the most popular case from word cloud output and most popular sentiments. Hence, being top-cases on the word cloud to top-cases on the sentiment chart implies strong negative or positive sentiment correlation and least will implies weak negative sentiment correlation, respectively

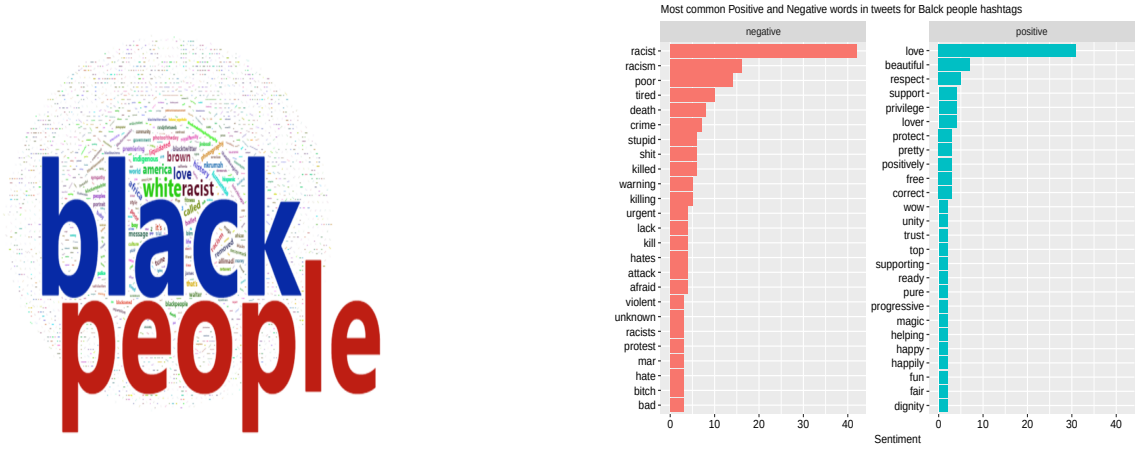

Figure 2: Sentiment Analysis on Blackness

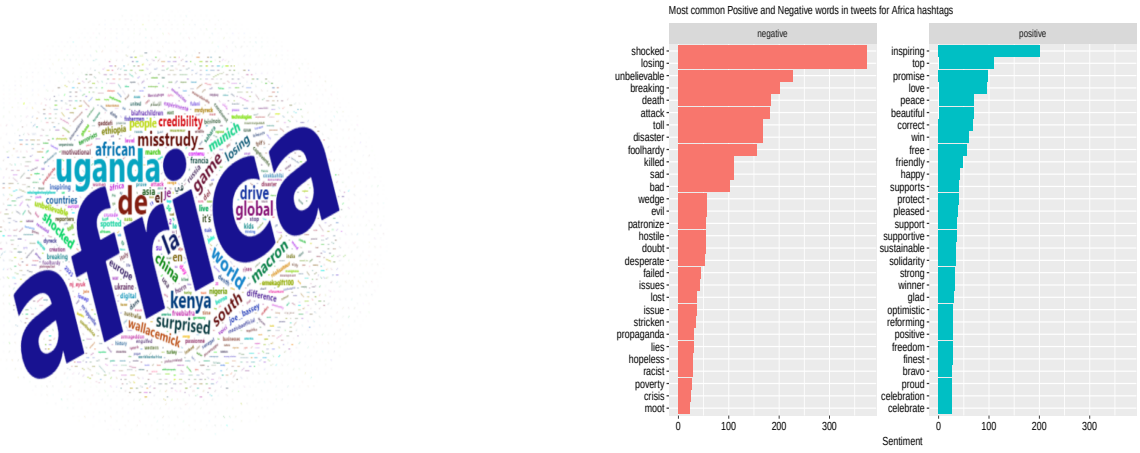

Figure 3: Sentiment Analysis on Africa

2. Blackness is associated with Africa and Africans and has a strong negative sentiment correlation with **death/die, sad/sadness, reject/rejection, darkness, submissive, struggling**, and a **subject of racism**. Similarly, there is a weak negative sentiment correlation with being **an accused, degraded, lost**, among others.
3. Africa is associated with Africans and has a strong negative sentiment correlation with **shock, unbelievable, losing, death, attack**, among others. Similarly, there is a weak negative sentiment correlation with being an **crisis, poverty, hopeless, lie**, among others.
4. African-Americans are associated with black people, Africa, and history and have a strong negative sentiment correlation with **discrimination, prejudice, slave/slavery, wrong and subject of racist and racism**, among others.

I present the Pictorial result of the black people hashtag in Figure 2; blackness hashtag in Figure 4; Africa hashtag in Figure 3; and African-Americans hashtag in Figure 5, respectively. As shown, blackness, black people, Africa and African-Americans are subject to racial stigmatization. The null hypothesis would be accepted since there is no sufficient information to prove otherwise.

5 CONCLUSION

Personally, I have been subjected to stigmatization for being from my country of origin (I do not wish to mention a name of a country). I recall my last trip where I was detained for more than an hour because I carried my national Passport. I could hear my nation's name being mentioned and reemphasized by the young immigration officers to their superiors in the local dialect. I presumed the purpose was to justify why I must be subject to the questioning section and rigorous security checks, scan and re-scanning and digitization. I am certain many of my countrymen and women would have their stories to tell travelling overseas - and the rest of the world.

The danger of racial stigmatization goes beyond airport checks and delays, some have lost their lives because of the country or nation of their origin, or the colour of their skin. The phrase "I can't breath" is not unknown to many vulnerable communities. The death of Eric

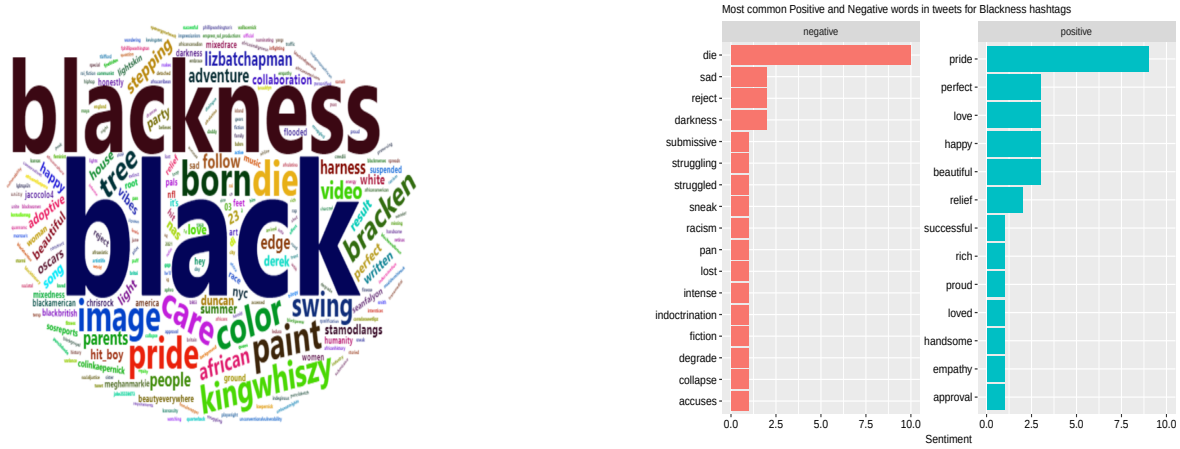

Figure 4: Sentiment Analysis on Blackness

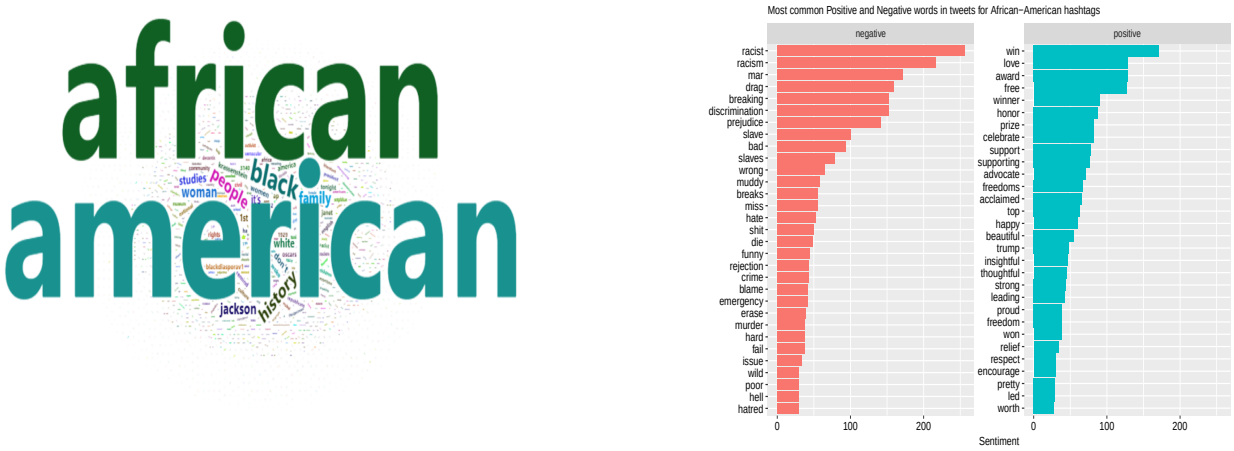

Figure 5: Sentiment Analysis on African-Americans

Garner, Javier Ambler, Manuel Ellis, Elijah McClain and recently George Floyd, among others whose deaths are known to the public. Many others in this category, have been declared missing or died without public knowledge - the unnecessary death is associated with the perceived stigmatization of their skin colour, blackness, nationality or race.

[4] submits that whatever the merits of the dispute about race are perceived as a biological concept, the social convention of thinking about other people and ourselves as belonging to different "races" are so long-standing and deeply ingrained in a global political culture which has become a norm on human existence.

It is, therefore, humane and globally responsible citizenship that many social actors hold schemes of racial classification in their minds and act accordingly, and avoid any form of perceived racial ideologies towards any individual or group. The moment this is realised and practised, stigmatization will naturally diffuse to a minimum.

However, once people know that others in society will classify them on the basis of specific markers - skin colour, nationality, race, hair, facial bone structure, among others, and that these acts of classification will affect their material and psychological well-being, it is rational for them to think of themselves in racial terms also, [5], and the tendency of retraction, low self-esteem, or anger, hatred and retaliation increases.

5.1 Way Forward & Recommendation

When perception becomes knowledge and knowledge becomes a learning point, it is necessary to reboot the learners' curriculum about vulnerable communities. Thus, infamous books such as Tintin au Congo that depict Africans/blackness as inferior ape-like creatures, among others, should be discouraged in all learning institutions.

Apart from learners' curriculum reshuffling, algorithmic development must pass the test of robust team composition promoting inclusion, participation and reciprocity. To achieve this, I proposed, in Figure 6 an algorithmic development cycle which can be adopted

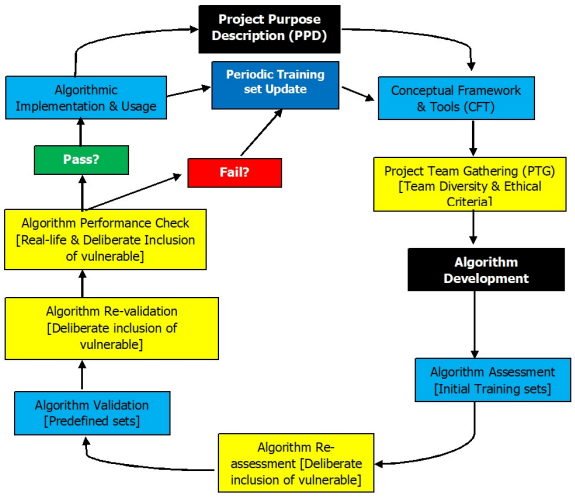

Figure 6: Proposed Cycle of Ethical Algorithmic Development

as a tool for assessing the inclusiveness and generalization potential of learning algorithms.

In this framework (Figure 6), every group (being vulnerable or non-vulnerable) of the communities or societies would be represented, included, and participated in all the stages of algorithmic development to deployment. Thus, the proposed cycle proposes that before any algorithmic project goes public, it should go through all the ethical checks peculiar to the project ethics and that of the societal diversity components and also go through re-validation, stages by stages approval, and verification such that no race/group is unaccounted for. With this, the algorithm development will not only promote diversity but will reduce racist logic or stigmatization inadvertently conceived by any team member against any particular group (provided the team composition is diversified as proposed) and such perception would have diffused along the process cycle before the algorithmic tool is deployed.

Ethical Principles for Reasoning about Value Preferences

Jessica Woodgate
University of Bristol
Bristol, United Kingdom
yp19484@bristol.ac.uk

ABSTRACT

To ensure alignment with human interests, AI must consider the preferences of stakeholders, which includes reasoning about values and norms. However, stakeholders may have different preferences, and dilemmas can arise concerning conflicting values or norms. My work applies normative ethical principles to resolve dilemma scenarios in satisfactory ways that promote fairness.

KEYWORDS

normative ethical principles, values, norms, sociotechnical systems, fairness

ACM Reference Format:
Jessica Woodgate. 2023. Ethical Principles for Reasoning about Value Preferences. In *AAAI/ACM Conference on AI, Ethics, and Society (AIES '23), August 08–10, 2023, Montréal, QC, Canada.* ACM, New York, NY, USA, 3 pages. https://doi.org/10.1145/3600211.3604728

1 INTRODUCTION

Multiagent systems (MAS) understood as sociotechnical systems (STS) consist of multiple human-agent duos, with a social tier that imposes regulations upon a technical tier [20, 21]. To improve fairness considerations, it is important to appreciate the interaction of multiple users, rather than single agents [6]. When viewing STS from this holistic perspective, stakeholders govern by promoting norms that align with their values. However, issues arise when stakeholders have different preferences, or where values or norms conflict [10]. Decisions must be made that consider stakeholder preferences, values, and norms in ways that promote fairness.

Previous work examines using values to reason about norms. Kayal et al. [12] develop a normative conflict resolution model based on value profiles of users, which selects norms that best support the stakeholders' values. Montes and Sierra [19] provide a methodology for evaluating the value alignment of norms by examining changing preferences. However, often not all stakeholders will agree on which factor is the most important in a given scenario [9]. In these dilemmas, there may be cases where multiple norms conflict with each other, one or more norms conflict with the value preferences of a user, or value preferences of one user conflict with those of other users. There may also be scenarios in which values and norms do not conflict, however a decision must be made that fairly considers a variety of different preferences.

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604728

Challenges thus remain in creating decision support for everyday dilemmas in which there are differing preferences, or values or norms conflict, aiming towards the development of systems with fair governance. The application of ethical principles may improve fairness considerations in aggregating value preferences.

Resolving these dilemmas in satisfactory ways with a higher goal of fairness may be achieved by operationalising normative ethical principles in decision support [25]. Normative ethics is the study of practical means to determine the ethicality of an action [7, 21]. Leben [14] provides foundations for mechanising certain ethical principles, which could applied to decision support in STS. Normative ethical principles have also been operationalised in domains such as resource allocation and machine ethics [5, 9, 14, 23].

2 RESEARCH QUESTIONS

RQ_1 **What ethical principles currently exist in computer science literature?** A framework operationalising principles may help to methodically analyse scenarios and promote satisfactory outcomes [9]. A taxonomy identifying and categorising ethical principles in computer science literature would aid the development of this framework. This taxonomy could then be expanded to principles seen in philosophy and other disciplines.
RQ_2 **How can ethical principles be operationalised in reasoning capacities needed to govern STS?** Developing methods to incorporate ethical principles reasoning techniques used to govern STS would be beneficial to support ethical decision making.
RQ_3 **How can context be incorporated in the application of ethical principles?** Ethical decision making is context dependent, and which principles are appropriate to apply in specific circumstances may vary. Methods to incorporate context could improve the applicability of principles.

3 COMPLETED WORK: TAXONOMY OF NORMATIVE ETHICAL PRINCIPLES FOR AI

To address RQ_1, we have developed a taxonomy of normative ethical principles previously used in computer science literature.
Motivation. Ethical principles can support decisions as they help to guide normative analysis, understand different perspectives, and determine the moral permissibility of concrete courses of actions [15, 18, 23]. A framework aiding the operationalisation of principles in decision making may be useful to methodically think through scenarios and promote satisfactory outcomes [9]. To create such a framework, it is first necessary to identify and categorise ethical principles previously seen in computer science literature.
Background. Related work includes Tolmeijer et al. [24] which studies how principles relate to machine ethics, and Yu et al. [27] which proposes a taxonomy of ethical decision frameworks. As ethical thinking should be fostered through appreciating various

approaches [4], expanding these works to incorporate a wider variety of principles, and how they have been operationalised, may improve the amplitude of ethical reasoning. A larger taxonomy of principles that currently exist in computer science literature, examining how each principle has been operationalised, could help form the groundwork for an ethical decision support framework.

Completed Work. Following the guidelines of Kitchenham et al. [13], we conducted a systematic literature review of computer science literature. We developed a taxonomy of 23 normative ethical principles operationalised in AI [26]. We describe how each principle has previously been operationalised, highlighting key themes AI practitioners seeking to implement ethical principles should be aware of. Future directions involve looking outside of the domain of ethics used in computer science, to examine ethical theories in philosophy and other disciplines. This includes researching principles from cultures outside of the Western doctrine, which may aid better application to groups of stakeholders from diverse backgrounds.

Contribution. Broadening the range of ethical principles found in previous surveys, we identify a taxonomy tree with 23 ethical principles discussed in Computer Science literature. Principle specific operationalisation is presented, with new mapping of each principle to how they have been operationalised in literature [26].

4 ONGOING WORK: OPERATIONALISING ETHICAL PRINCIPLES

To address RQ_2, we are developing a model that operationalises normative ethical principles in reasoning about value preferences.

Motivation. When values are imbued in systems, aggregating values into a single outcome may improve ethical decision making in STS [22]. However, reasoning about values is challenging [17], and stakeholders could have personal preferences between different values [16, 21]. Value preferences of some stakeholders may conflict with value preferences of other stakeholders, or values may conflict with norms [10, 25].

Background. Previous work integrates normative ethics in decision making, and utilises values to reason about norms. Cointe et al. [7] propose an agent which utilises normative ethical theories to improve ethical decision making in MAS, which could be expanded to consider value preferences of multiple stakeholders. Montes and Sierra [19] provide a methodology for examining the alignment of norms with values. To expand this, the application of ethical principles may improve fairness considerations in aggregating values to help resolve conflicts. Ajmeri et al. [2] aggregate value preferences of users, applying a single normative ethical principle. However, to resolve scenarios in which principles lead to unintuitive outcomes, or are unable to promote one action over another, it is important to apply a variety of different principles.

Current Work. Our current work lays the foundations for a model demonstrating how multiple ethical principles can be implemented in reasoning about values of stakeholders. In our model, agents have value preferences for the payoffs they receive. Different ethical principles are applied to these value preferences to reach a decision which promotes fairness. Via an example of smart heating STS scenario, we demonstrate how we could apply our model. Each stakeholder has an internal hierarchy of individual value preferences [19]. At each timestep, all agents propose their preferences, and a collective decision is made by applying different ethical principles to those preferences. We conduct preliminary simulation experiments on our model. To evaluate the emergence of norms that promote fairness, we compute quality metrics in each run of the simulation including health, wealth, and Gini coefficient.

Preliminary Results. Preliminary results suggest the most appropriate ethical principle to apply in a situation may depend on the metrics being used, as different principles can lead to different outcomes. We find that the principle best suited to maximise payoffs is the principle of Maximin. However, if a fair distribution of resources is more important, the most appropriate principle is Egalitarianism. These findings may help the development of agents that can learn the best principle to apply in certain situations.

Contribution. Incorporating ethical principles in reasoning, considering the preferences of stakeholders. This may improve fairness considerations in aggregating different value preferences and resolving value conflicts. Applying multiple ethical principles may help to view dilemmas from different perspectives and improve the amplitude of ethical reasoning.

5 NEXT STEPS: INCORPORATING CONTEXT

To address RQ_3, there are several directions future work could address to improve the contextual applicability of principles.

- **Considering Contextual Value Preferences.** Our current work assumes each stakeholder's order of value preferences is fixed. However, preferences may change [8, 17]. Future work could involve expanding our current simulations to incorporate contextual values and changing value preferences.
- **Incorporating Internal Reasoning in Agents.** In our current work agents do not have internal reasoning schemes, as decisions are deferred to a collective decision making module. Future work could include equipping agents with internal reasoning, so that aggregating individual ethical decision making using normative ethical principles can be studied on an individual level.
- **Resolving Conflicts Between Ethical Principles.** Our preliminary results suggest that different principles might be appropriate in different scenarios. Sometimes a single ethical principle may lead to an unintuitive outcome, or be unable to give a clear preference between two different options. When seeking the best principle to apply, it is important that agents can consider several different principles to identify a suitable solution [7, 26]. Future work includes developing learning agents that can resolve conflicts between different principles and optimise the application of principles. By incorporating explainability in these agents, we can investigate how agents learn to handle such scenarios [1].
- **Using Logic to Encode Ethical Principles** Our current work applies abstracted versions of ethical principles to demonstrate the basic idea of how such principles may be applied to reason about value preferences. To achieve more precise representations and improve contextual applicability, future work could utilise logic techniques such as those used by Govindarajulu and Bringsjord [11] and Berreby et al. [3] to encode normative ethical principles in the governance of STS.

Explainability in Process Mining: A Framework for Improved Decision-Making

Luca Nannini

Centro Singular de Investigación en Tecnoloxías Intelixentes (CiTIUS)
Universidade de Santiago de Compostela
Madrid, Spain

ABSTRACT

This research project aims to develop and validate explanatory facilities to enhance information reception of process mining solutions, which could inform and be translated to other business intelligence platforms. Process mining, a nascent field for analyzing event data stored in information systems, faces challenges in adoption, engagement, and comprehensive explainability frameworks. The research problem lies in the difficulties organizations face when understanding the return on investment and integration requirements associated with process mining operationalization. Furthermore, users often struggle to comprehend the elaboration and representation of process outputs. This issue is compounded by the limited application of Explainable AI (XAI) in process mining, which so far has been predominantly focused on prediction and monitoring activities without a holistic view of explainability trade-offs.

KEYWORDS

Explainable AI, Responsible Process Mining, AI policy, AI Ethics, Human-Computer Interaction

ACM Reference Format:
Luca Nannini. 2023. Explainability in Process Mining: A Framework for Improved Decision-Making. In *AAAI/ACM Conference on AI, Ethics, and Society (AIES '23), August 8–10, 2023, Montréal, QC, Canada.* ACM, New York, NY, USA, 2 pages. https://doi.org/10.1145/3600211.3604729

1 BACKGROUND

Process mining is a young and promising domain to analyze and obtain insights into event data stored in informational systems [21]. Yet it is not mature enough [2] in regard to its full deployment: in the adoption, organizations struggle to understand ROIs and integration requirements with process mining operationalization [11]; in the engagement, users often lament a lack of comprehension over process outputs' elaboration and representation [8, 16]. Literature on Explainable AI (XAI) reproved how crucial interpretability and explainability of an AI artifact is to enhance its transparency [20], a pro-ethical condition [19] to enhance fairness and accountability over opaque algorithmic decision-making. XAI so far has been applied in process mining for prediction and monitoring activities in a singular fashion, i.e., with little research efforts [15] to advance frameworks with a holistic view over explainability trade-offs. Indeed, a solemnly technical approach might fail to account for different sociotechnical constraints jeopardizing legal compliance, factuality, and usability of explanations [4, 6]. These could confuse non-expert recipients through information overload; provide biased information if mitigation and auditing mechanisms are not set in place [3]; or worse leverage risks connected to intellectual property, trade secret, and third-parties privacy violations [7, 14]; as well as opportunities for gaming an AI system by clients and opportunities for ethics-washing to erode accountability of system providers [9, 18].

These risks could be counter-approached in AI ethics. Principles and guidelines are now growing steadily alongside AI policies in the European Union to regulate and establish compliance mechanisms for enhancing transparency, fairness, and accountability. Yet, this so-called "first wave" of AI ethics publications often offered ambiguous if not conflictual terminology, lacking empirical benchmarks [1, 10]: this calls for the current advancements of a "second wave" of AI ethics to focus on empirical and comprehensive experimentations for the AI systems' lifecycle [13, 17]. Operationalization of explainability is here to be intended not as a singular top-down approach (as so far it has been advanced in process mining), where an AI system's explanation is considered as an explanandum just for its technical explanans. Last but not least, the novelty of AI policy regulations as set by the European Union (i.e., GDPR, AI Act draft, DSA, Data Act, AI liability directive among others) might impact business practices stacking up normative confusion on explanations' context of fruition and compliance procedures [7, 12, 18].

As a major research approach, I resort to explanans to be instead informed accordingly to different and interconnected layers: (I.) Cognitive layer - explanations recipients (e.g., platform's user clients) holds different expertise (over the content domain analyzed and over the AI system) and degree of intention while engaging with process representations and explanations. Process language notations, hierarchical and compositional techniques are compared to favor process model comprehension. (II.) Technical layer - explanations as produced by XAI methods. This layer might constitute a justification of an AI system's output and capabilities, but not always of the design rationale behind it. Statistical bias and adversarial attacks might indeed produce inaccurate explanations introducing heuristic risks if other layers are not considered.

AIES '23, August 8–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604729

(III.) Organizational layer - as common in process mining adoption, event logs might be stored across external stakeholders. Data standardization and integration might be impede output and explanation's accuracy. Foremost, explanations should account for trade-offs regarding risks (privacy and trade secret disclosures). (IV.) Pragmatic layer - aiming to enhance transparency and understanding the dynamic communicative context, considering regulations, user intentions, and organizational constraints.

2 RESEARCH QUESTIONS & CONTRIBUTIONS

The main research question posed is: **How can Explainable AI improve the adoption and engagement of process mining solutions?** This main research question has led to the development of the following sub-questions:

(1) What are the interpretability demands of engaged stakeholders?
(2) What are the adoption barriers to process mining operationalization?
(3) How has explainability been applied so far in process mining?

Addressing these challenges has necessitated extensive work across multiple domains. (1. **Regulations**) First, by examining the AI regulatory landscape on XAI for the EU, US, and UK, including drafts, laws, policy communications, reports, and standards, also within data and platform governance, inquiring over business operationalization. This work was preliminary informed before by the published paper on fairness and AI regulation at AIES 2022 [5], but foremost the FAccT 2023 accepted paper on Explainability in AI Policies [18]. It also led to a journal submission, under review pending publication, where AI policies within EU laws regarding data, platform, and AI governance are analyzed in terms of XAI operationalization requirements. (2. **Governance**) A comprehensive inquiry was conducted into governance and explainability, involving an extensive interview study with process mining practitioners to understand the interpretability demands of clients and their respective explainability strategies. In light of these findings, an additional journal draft submission has been completed, presenting a layered framework for XAI governance in process mining, informed by state-of-the-art academic literature. As complementary, the development of a proactive ethics assessment tool for Explainable AI is now under journal review, designed to address potential technical and sociotechnical risks. (3. **Usability**) Finally, user-oriented studies are being conducted and collaborated on to inform explanation design from a user perspective. This includes a thorough review of explainability across various disciplines and multiple user studies in process model comprehension and explainability involving different collaborators. These studies encompass drafts and ongoing work on process model comprehension, bias mitigation, and users' cognitive reception of explanations.

In terms of outcomes, the investigation of AI regulatory landscape, insights from practitioners, and development of a comprehensive XAI governance framework will contribute to a more robust understanding of the challenges and potential solutions in terms of operationalization and compliance. The proactive ethics assessment tool and user-oriented studies will further inform the design and implementation of Explainable AI in process mining.

Can AlphaGo be apt subjects for Praise/Blame for "Move 37"?

ABSTRACT

This paper examines whether machines (algorithms/programs/ AI systems) are apt subjects for praise or blame for some actions or performances. I consider "Move 37" of AlphaGo as a case study. DeepMind's AlphaGo is an AI algorithm developed to play the game of Go. The AlphaGo utilizes Deep Neural Networks. As AlphaGo is trained through reinforcement learning, the AI algorithm can improve itself over a period of time. Such AI models can go beyond the intended task and perform novel and unpredictable functions. There is a surprise element associated with "Move 37". "Move 37" not only surprises the Go players, the programmers, but also whoever is informed of this unpredicted move. Does someone or something deserve praise or blame for the surprise? If so, who or what deserves the praise or blame for "Move 37"? The programmer cannot be praised for "Move 37", which is either surprising or was not intended or imagined at all. At the same time, would we accept that neither the algorithm deserves praise for the unpredicted move that the algorithm allowed the program to make? From this, would we accept that since neither the programmer nor the algorithm/AI system deserves the praise, there is such a good or exciting move for which no one or nothing could be praised? Would we say this unpredictable move is a move for which no one deserves praise or blame? Wouldn't there be at least a few who were surprised by the unpredictable move? Should we say that for this pleasant surprise, no one deserves praise? Nonetheless, for us, specifically regarding the particular unpredictable move, we firmly find it counterintuitive to say that there is an exciting move for which no one deserves praise. The surprise element is the result of the property that belongs to the algorithm. It seems quite difficult for us to accept that no one deserves praise for "Move 37" or for similar moves. Therefore, someone or something deserves praise which is a matter of scrutiny.

1 INTRODUCTION

One of the latest milestones in Artificial Intelligence (AI) is AlphaGo of Google DeepMind. The board game Go was invented in China more than 3000 years back. It is one of the toughest games, which is said to be more challenging than Chess. AlphaGo beats Fan Hui (the three times European Go champion) in 2015. It also beat Lee Sedol (the eighteen times world Go champion) in 2016. Progressively, DeepMind developed an advanced type of AlphaGo known as AlphaGo Zero. The next version of the AI algorithm is AlphaZero. MuZero is more advanced than the previous ones. All of these extended versions are extremely good at self-learning. In March 2016, the game between AlphaGo and Lee Sedol AlphaGo made a move known as "Move 37". Because of the self-learning ability of the AlphaGo, it made a move that no human would ever consider. AlphaGo is a terrific Al algorithm in game playing; it can learn the game's rules independently. The "Move 37" of AlphaGo was never imagined and would have remained unimagined by any human. In this scenario, the question may arise where the "praise or blame" locus lies in "Move 37".

2 THE PRAISEWORTHINESS OF "MOVE 37" OF ALPHAGO

The intuition behind "Move 37" is that it is a very suitable move that any human player would have employed if the human player were to be aware of such a move. A surprise element is associated with "Move 37", which surprises not only the Go players and the programmers in Google DeepMind but also whoever is informed of this unpredicted move. Concerning the locus of praise or blame of "Move 37", one could make at least the following three responses:

- **Response 1**: If what results from "Move 37" is a pleasant surprise, then someone or something deserves praise.
- **Response 2**: If what results from "Move 37" is an unpleasant surprise, then someone or something deserves blame.
- **Response 3**: For "Move 37", no one or nothing deserves either praise or blame.

So, what is the locus of blame or praise? Or which of the responses mentioned above is to be accepted?

2.1 The Puzzle associated with AlphaGo

A puzzle associated with "Move 37" of AlphaGo regarding who is the apt subject of praise/blame for "Move 37". Whether it is the programmer, the algorithm, or no one is an apt subject of praise/blame for "Move 37". "Move 37" of AlphaGo is not resultant

of its programmers, which is equivalent to saying that the programmers are not responsible for causing "Move 37". So, granting praise/blame to the programmers is difficult. Similarly, even though the program/algorithm/system itself causes "Move 37.", granting praise/blame to the program/algorithm/system is also difficult. Nevertheless, at the same time, it does not make much sense to say that for an exciting move (Move 37), no one deserves any praise/blame.

2.2 The distinction between moral responsibility and causal responsibility

We must distinguish between moral and causal responsibility to identify praise/blame linked with "Move 37. Let us take an example: Suppose an employee performs two actions. In the first act, she helps an injured person on the road even though she has an important meeting to attend. In this case, she would be praised in a moral sense because helping a person in their need is a morally right action. However, in the second act, she solves a complicated coding problem where no one from her office is unable to solve the problem. In this case, she would be praised by her boss and others but not in the moral sense. Nonetheless, it is an assessment of what the employee accomplished. Here we are not just admitting that the employee acted but also praising the employee for the result. That is, we acknowledge that the employee is not only causally responsible for the result but in addition to she also deserves praise for what was accomplished. Now if we look into the case of AlphaGo's "Move 37", we will find out that the special status of "Move 37" only allows us to determine that AlphaGo is causally responsible for "Move 37". It clears up the worry about whether the programmers who designed AlphaGo are causally responsible for "Move 37". This is because the best explanation for the aspect of surprise associated with "Move 37" is that AlphaGo has an inherent property not present or passed down from its programmers. Here, we could give the following argument:

- **Premise 1**: If AlphaGo is causally responsible for "Move 37", AlphaGo is an apt subject for praise/blame
- **Premise 2**: AlphaGo is causally responsible for "Move 37" [because of its inherent property]
- **Conclusion**: Therefore, AlphaGo is an apt subject for praise/blame

Here, we must be committed to the implausible view that causal responsibility is a sufficient condition for normative responsibility, specifically for the aptness of praise/blame. For instance, an earthquake is causally responsible for the destruction of a building, but it is not appropriate to be blamed. However, the destruction brought by the earthquake is not similar to Move 37", made by AlphaGo. Therefore, we are not able to utilize the special status of "Move 37" to explain the praise/blame associated with it. Through the special status/quality of "Move 37", we can maximally provide the causal attribution to the AlphaGo but nothing else. Through the special status or quality of "Move 37", we can only eliminate the vagueness about causal attribution, i.e., did the programmers cause "Move 37" or did AlphaGo cause "Move 37"? and nothing more. However, we are still not certain about the answer to the question, 'Who is an apt subject for praise for "Move 37"?' In the case of AlphaGo, causal attribution may not be a sufficient condition but might be a necessary condition. For attribution of praise/blame associated with the AlphaGo, it appears that causal attribution is a necessary condition. We must now consider what makes AlphaGo an appropriate subject for praise in light of its outcome of "Move 37" as our main concern is the appropriateness of a subject that is praised/blamed for "Move 37". Here we can consider the concept of Artificial Moral Agency (AMA) to look into the puzzle associated with the AlphaGo.

3 CAN ALPHAGO BE AN APT SUBJECT FOR PRAISE/BLAME FOR "MOVE 37"?

The debate on AMA mostly centered on two conflicting views of moral agency. The first view is the Standard, and the second is the functionalist. The standard view argues that to be a moral agent, one must fulfill the following conditions: rationality, free will or autonomy, and phenomenal consciousness. On the other hand, the functionalists state that agency is simply required to exhibit certain behaviors and responses [1, 12]. Floridi and Sanders (2004) distinctly explained the functionalist view of moral agency in the debate on AMA. They discard consciousness as the condition of moral agency, hold mindless morality, and offer three conditions for moral agency:[1, 5]

- **1. Interactivity**: E interacts with the environment around it.
- **2. Independence**: E can change itself and its interactions without direct external intervention.
- **3. Adaptability**: Depending on the outcome of 1, E might change how 2 is actualized. (Here, 'E' refers to the entity)

Here, condition 1 roughly resembles the standard view. However, in condition 2, consciousness (or internal mental state) is absent. The absence of consciousness differentiates the functionalist view from the standard view. The difference is visible in condition 3 also. It is less intense because it does not demand that events falling under 2 immediately influence E's action, but it is more robust since it establishes a condition of responsiveness that unites events under 2 with events under 1. According to Floridi and Sanders [5], the concept of AMA becomes highly plausible when these conditions of moral agency are conditions are considered [1]. By looking at the features of AlphaGo, one may argue that AlphaGo may fulfill the above-mentioned conditions of moral agency. Therefore, AlphaGo is an AMA and is held to be morally responsible for "Move 37". Specifically, AlphaGo may be an apt subject for praise for "Move 37". However, a question may arise on how a game-playing algorithm can be an AMA and be an apt subject for praise for "Move 37"? Even if AlphaGo directly fulfills moral agency conditions prescribed by the functionalists, we still cannot say AlphaGo is an apt subject or praise/blame for its actions. The reason is that AlphaGo does not contain any moral element. To say that AlphaGo has moral agency (or to attribute moral agency to the AlphaGo) is a challenging task. AlphaGo cannot identify the ethically significant elements of a situation. However, some agencies could be attributed because AlphaGo can perform some actions or some moves/unintended moves autonomously. To become a moral agent, one has to perform a morally significant action, whether it could be a moral or an immoral action, which is missing in the case of AlphaGo.

As I already mentioned, even if AlphaGo satisfies all the conditions of functionalists but still we can't say it has moral agency. The reason may be that though these three conditions are necessary

for a moral agency, according to (Floridi and Sanders (2004) [5], these are insufficient. This situation could be explained in another way. Floridi and Sanders mention the levels of abstraction. Behdadi and Munthe 2020 state that "their starting point is the observation that which entities can be moral agents depends on the level of abstraction chosen when inferring general criteria from paradigmatic instances of human moral agency. The level of abstraction applied by the standard view is very low, keeping the criteria close to the case of an adult human being, but raising the level allows for less anthropocentric perspectives while maintaining consistency and relevant similarity concerning the underlying structural features of paradigmatic human moral agents"[1] (Behdadi and Munthe 2020, 198). We can think of a level of abstraction where all these three moral agency conditions are sufficient for a moral agent. The level of abstraction works similarly to a context. There can be different levels of abstraction. In a certain level of abstraction, we can think of a context where we can say that any AI system has a moral agency. These three conditions are the only characteristics we look for in a human being when we say they are moral agents. The consciousness or internal state part may not play a significant role here because we cannot always consider what kind of conscious experience the person had while she was performing a particular action. What kind of consciousness she had unless and until the intention was functionally explicit in a specific action.

ACKNOWLEDGMENTS

I am immensely grateful to my supervisor, Prof. Jolly Thomas (Department of Humanities and Social Sciences, Indian Institute of Technology Dharwad), and co-supervisor Prof, Don Wallace Freeman Dcruz (Department of Humanities and Social Sciences, Indian Institute of Technology Delhi), for insightful comments and recommendations for the research.

Anticipatory regulatory instruments for AI systems

A comparative study of regulatory sandbox schemes

Deborah Morgan
Center for Accountable, Responsible and Transparent AI, University of Bath, United Kingdom
drm54@bath.ac.uk

ABSTRACT

Anticipatory regulatory instruments are pre-emptive approaches to identify and anticipate risks arising from new technologies. They can also act as indicators of 'pro-innovation' economic support for digital technologies. The extent to which regulatory agencies can fulfil their regulatory remit, aimed at the protection of the public good, and signal support for innovative and disruptive technologies is an open policy question. Regulatory sandbox schemes are comparatively new anticipatory tools, operating within a small number of regulators, and their potential to assess contextual or cross-sectoral risk is unclear. However, emerging proposals for the regulation of AI increasing feature various models of regulatory sandboxes often aligned to the need to reduce access barriers for SMEs and innovators. Examples include the European Commission's Proposal for a regulation concerning AI [3] and the recent United Kingdom AI White Paper, AI Regulation: A Pro-Innovation Approach [8]. Disentangling the causal dimensions of why regulatory sandboxes are proposed to regulate AI, and their utility as tools of pre-emptive risk assessment are my core research questions.

The regulation of emerging digital technologies present challenges for regulators and governments in monitoring rapid global developments and in anticipating novel forms of risk [9]. Nesta introduced the term anticipatory regulation, and such approaches potentially provide 'a set of behaviours and tools – i.e., a way of working – that is intended to help regulators identify, build and test solutions to emerging challenges' [4]. Regulatory sandboxes are a prominent, and arguably the most widespread, example of such an anticipatory regulatory tool. Whilst there are varied definitions of regulatory sandbox schemes, existing schemes allow small-scale, live testing of innovations in a controlled environment under the supervision of a regulatory authority [6]. A small number of regulatory sandbox schemes are in operation within the UK operating within sectoral and cross-sectoral regulatory remits. However, empirical data and academic literature regarding the methodologies and operation of these current schemes, and literature exploring regulatory sandboxes more broadly, is scarce [7, 10].

The ontological focus of my work is critical realist, which accepts the external reality of the design and instrumental aims of sandbox schemes, whilst seeking to understand the underlying causes and drivers for their use and rapid promotion. To locate such causes and explanations it is necessary to examine existing schemes within the 'rules and norms' of their institutional context and structures [1, 2]. Institutional analysis will isolate the key dimensions of each scheme, consider the influence of the regulatory structures, and then test such analysis through empirical research with regulatory and policy actors. The core hypothesis of my research is that regulatory contexts, path dependencies and conceptions of risk are significant causal elements within existing sandbox schemes and, as such, may present a challenge when designing and deploying cross-sectoral sandbox schemes for AI systems.

I have already undertaken analysis of the two regulatory sandbox schemes applying the Institutional Analysis and Development framework of Elinor Ostrom [5]. This analysis has highlighted significant dimensions of sandbox schemes including the role and forms of sectoral incentives for participants, how knowledge and conceptions of risk are shared and the potential role of participatory processes and stakeholders. I am drafting a forthcoming paper outlining a typology of incentives for existing regulatory sandbox schemes. I have included policy and wider sectoral stakeholders within my data collection to obtain perspectives regarding perceived utility, understandings, and conceptions of sandbox schemes. Incorporating collaborative processes and inclusive engagement with affected stakeholders is a key principle of anticipatory regulation [4]. The role and extent of such engagement within proposed sandbox schemes for AI is a further dimension of my research to consider how such processes may be developed and operationalised.

This work is undertaken at a time of rapid progression within AI systems and in the development of proposed AI regulation and varied forms of decentralised AI governance. I hope that my research will provide understanding of the utility, and potential limitations, of sandboxes as a regulatory tool drawing upon data from existing practices. My work may also impact existing policy discussions around the role of sandbox schemes as risk assessment and information monitoring tools for regulators.

Examining the Ethics of Brain-Computer Interfaces: Ensuring Safety, the Rights and Dignity of Personhood

Terkura Thomas Mchia
Benue State University, Makurdi-Nigeria/University of Nigeria Nsukka-Nigeria
mchiaterkura@gmail.com

ABSTRACT

Brain-Computer interfacing is one of the most interesting, digital health devices. It includes wearable, implantable, and injectable medical systems to improve or restore movement. It also includes machine-learning algorithms to help neurologically deficient persons to communicate and make decisions. All BCI applications connect the human brain to a machine that is external to the brain and the source of the self. Research and interest in Brain-Computer Interfaces have been developing at a rapid rate, with neuroscientists using BCI technology in an increasing range of applications. There are ethical questions that are lacking from the application of AI medically supported tools: safety assurance; human rights; the autonomy and dignity of the person who uses BCIs.

ACM Reference Format:
Terkura Thomas Mchia. 2023. Examining the Ethics of Brain-Computer Interfaces: Ensuring Safety, the Rights and Dignity of Personhood. In *AAAI/ACM Conference on AI, Ethics, and Society (AIES '23), August 08–10, 2023, Montréal, QC, Canada.* ACM, New York, NY, USA, 1 page. https://doi.org/10.1145/3600211.3604733

No one can deny the important role played by the BCI in helping people who are suffering from a neurological disorder to regain some control of their lives. The rights and feelings of patients are of equal importance; the safety of the patients is another critical factor that needs to be considered by neurologists. This study examines human rights treaties as regards the BCI. It also questions the autonomy, privacy, and data protection of the patients and the question of personhood in the practice of BCI. The study will employ different research methodologies such as ethnographic, quantitative, and qualitative methods of research. The study concludes by advocating safer measures and guaranteeing the autonomy of patients for BCI practices.

This study also observed that BCI technology may be exploited due to technical loopholes or the design of the equipment, which may be harmful to man. As Glannor [2] asserted, adequate care and techniques must be taken to reduce potential risks. The stability, safety, adaptability, and reliability of BCI needs to be conscientiously and continuously improved to avoid harm to human beings and the environment. Rising from the above issues, this research is centered on the ethical debates in brain and computer interface. It is a comprehensive study that captures major ethical issues in brain and computer interfaces.

This study is significant in several ways, it observed that there is potential harm in BCI, it is therefore seeking for the need of harm prevention and also interrogating the ethical questions surrounding the practice. The study collaborates with the views of Hounda Miftah [1] in providing advice for the recruitment of candidates with higher levels of preserved cognitive function for BCI research and treatment and that they must be educated on the potential benefits and limitations of the technique which is to prevent or at least minimize harm. Also putting into consideration the rights, dignity, and autonomy of the human person. This study is an extract of my PhD research proposal, it is at an early stage as I am still gathering literature, and working towards the data collection. The collaboration and assistance of research laboratories on BCI, individuals, and institutions will be greatly appreciated.

How to promote equitable sleep care among people experiencing homelessness: An AI-enabled person-centred computer vision-based solution

Behrad TaghiBeyglou*

ABSTRACT

Homelessness, defined as a lack of stable housing, affects over 435,000 people in Canada, most of whom live in shelters and experience barriers to healthcare [2]. Compared to the general population, people experiencing homelessness (PEH) sleep less, experience excessive fatigue, and are more likely to use substances to fall asleep at night (drugs) or stay awake during the day (cigarettes, alcohol) [10]. A recent study among PEH indicated that sleep quality was a key factor for their health and daily function [3].

A prevalent, yet under-recognized, cause of poor sleep is sleep apnea, which is characterized by recurrent interruptions in breathing during sleep [7]. Obstructive sleep apnea (OSA), a common form of sleep apnea, has a high prevalence, affecting approximately 30%-70% of individuals with chronic conditions such as hypertension and substance use [5]. Untreated OSA has significant medical consequences and societal costs.

Clinical polysomnography is the gold standard for sleep apnea diagnosis, but it is inconvenient, expensive, and inaccessible, especially for PEH who are experiencing several barriers to healthcare, e.g. low trust in care providers, difficulty visiting medical facilities, stress of daily needs, and fear of losing child custody if found to be homeless. The most accessible alternatives to polysomnography are sleep questionnaires, but they have low specificity.

Speech can be used as a non-invasive and accessible biomarker for monitoring physiological changes in the pharyngeal airway and cardio-respiratory system, including lung edema and pharyngeal airway narrowing [8]. Therefore, speech can be a potential tool for assessing the risk of OSA. Craniofacial photography has also revealed specific characteristics of upper airway structures and facial dimensions that are associated with OSA [4]. Therefore, developing an accurate and accessible risk assessment method for OSA using these technologies will improve health outcomes in PEH. Our ultimate goal is to develop a person-centred smartphone application to assess the risk of OSA during wakefulness in PEH living in shelters.

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604736

Objectives: To achieve our primary goal, we will 1) identify the preference and concerns of PEH about a mobile application based on speech for assessing the risk of sleep apnea, 2) determine the prevalence of sleep apnea among shelter residents, and 3) develop a person-centred smartphone application to assess the risk of sleep apnea through speech and image analyses.

Preliminary works: Over the past 3 years, our team has established an interdisciplinary stakeholder group comprising people with lived experience of homelessness and OSA, care providers for shelter residents, researchers, and clinicians.

Based on our preliminary assessment, most shelter residents have access to cell phones, and wireless internet through shelters and public spaces such as libraries.

For objective sleep assessment, 15 participants are recruited (aged 51.94 ± 14.4 years old, including 8 men) from three shelters for an overnight sleep study at the shelter using the protocol mentioned in the next section. The analysis showed that 85% of the participants (13 out of 15) had moderate-to-severe sleep apnea (apnea-hypopnea index [AHI] $\geq$ 10 events/hour), with a mean AHI of 27.1 and a standard deviation of 18.53. These preliminary results highlight the importance of developing accessible technologies for diagnosing sleep apnea in shelter residents.

Method: To enhance our understanding regarding the usability of such technology among this population, our team has been conducting semi-structured one-on-one interviews with participants to gather their feedback and concerns about the proposed application.

A research assistant with lived experience of homelessness and sleep apnea and I collected anthropometric data such as height, weight, neck circumference, and blood pressure, as well as questionnaires related to sleep status, such as STOP-BANG [1] and Epworth Sleepiness Scale [6]. Then, we set up residents with portable polysomnography (level II) for overnight data collection. Before being set up for polysomnography and going to sleep, participants will hold an audio recorder and stand in front of the camera while saying five vowels in a specific order (/i/ as in "see", /u/ as in "soo", /a/ as in "sahh", /e/ as in "set", /o/ as in "so", /n/, and /m/). Our team has previously shown acoustic features of these vowels can reveal differences in upper airway dimensions in individuals with high risk of sleep apnea compared to healthy participants [9]. To assess the risk of OSA, I will expand our previous work [9], along with other state-of-the-art algorithms. Preprocessing techniques will be applied to eliminate speech noises, such as background noise, and image artifacts, such as motion, blurring, and illumination. Afterwards, facial landmarks will be extracted from the image frames.

Extracted features will be used as the input of classical machine learning models, which will map them to gold standard indices obtained from PSG and other measures.

Significance: The discussed study, the first of its kind, aims to fill a critical gap by investigating the barriers to delivering equitable access to sleep care to PEH, determining the prevalence of sleep apnea using objective assessment, and developing a customized person-centred smartphone application to provide equitable sleep care in shelters. The outcome of this study will provide more insights for policymakers to change the current flow of sleep care in shelters. The results of this study could help improve sleep care for other structurally marginalized populations, such as people with low socioeconomic status or those living in remote areas.

Sealed Knowledges

A Critical Approach to the Usage of LLMs as Search Engines

Nora Freya Lindemann*
Institute for Cognitive Science, University of Osnabrück, Germany
norafreya.lindemann@uos.de

ABSTRACT

This research examines the implications of the usage of large language models (LLMs) as search engines on knowledge. Drawing on feminist theories of knowledge, I argue that LLMs used to generate direct answers to search engine inquiries both rely on and reinforce a disembodied and non-situated view of knowledge. This, it is argued, can lead to a "sealing" of non-dominant knowledges. Through this sealing of knowledges, marginalized voices may be heard even less than before. Lastly, drawing on the works of feminist theorists such as Donna Haraway and Sara Ahmed, the research proposes that doubting the outputs of LLMs can function as a feminist intervention that resists the marginalization and sealing of certain knowledges and perspectives through the usage of LLMS as chatbots. This research as part of a wider discourse on the usage of LLMs as search engines is crucial considering the current trend of major search engine providers to integrate LLMs for the production of direct answers into their search engines.

Nora Freya Lindemann. 2023. Sealed Knowledges: A Critical Approach to the Usage of LLMs as Search Engines. In *AAAI/ACM Conference on AI, Ethics, and Society (AIES '23), August 08–10, 2023, Montréal, QC, Canada.* ACM, New York, NY, USA, 2 pages. https://doi.org/10.1145/3600211.3604737

1 INTRODUCTION

In January 2023, Microsoft announced to integrate a version of the LLM 'ChatGPT' into their search engine Bing [8] [11]. Shortly thereafter, Baidu, the Chinese search engine giant, and Google, the most widely used search engine provider globally, announced their plans to integrate LLMs for the generation of direct responses into their search engines [7] [13]. Using a critical theoretical approach informed by feminist theory, this research focusses on questioning the assumptions about knowledge that underpin proposals to employ LLMs for search. In addition, it will question the impact of using LLMs as search engines on the findability of marginalized, non-dominant knowledges and information. Lastly, the research explores ways to resist the impact of LLM-generated search results on the findability of marginalized and non-dominant knowledges.

2 THEORETICAL BACKGROUND AND EXISTING LITERATURE

The theoretical background of this research lies in feminist theories of knowledge as situated, partial, and embodied. Although various feminist theories have nuanced differences, they mostly agree on a critique of an understanding of knowledge as impartial, neutral and detached from the knower (see for example [6] [9] [10] [15]), In this research, I primarily draw upon Donna Haraway's theory of 'situated knowledges', which states that knowledge is inherently partial and embodied [4]. In line with this, Haraway emphasizes the importance of acknowledging and valuing a "view from a body, always a complex, contradictory, structuring, and structured body, versus the view from above, from nowhere, from simplicity" ([4], p. 589). In my research, I critically compare this understanding of knowledge as situated and partial to the picture of knowledge and information on which proposals to use LLMs as search engines are based. I argue that these proposals (partly already turned reality) presuppose and reinforces a conception of knowledge as disembodied, non-situated or de-situatable.

I will draw on work by Shah and Bender who examined the topic of LLM generated search information [14]. They argue that the implementation of LLMs as a means of retrieving information can have negative implications for several key aspects of search, "including information verification, information literacy, and serendipity" ([14], p. 221). Drawing mainly on their arguments regarding information verification and serendipity in search and turning to literature showing that the datasets used for the training of LLMS are mostly encoding hegemonic views (e.g. [3], p. 615), I will contend that using LLMs to produce search results can silence, obscure and 'seal' marginalized and non-dominant voices. The algorithmic determination of a search output through a text is necessarily even more limited than 'traditional' web search and portrays only a fraction of the possible information on a topic, which diminishes chances to find non-dominant voices by serendipity. This can easily lead to what I, in reference to Mühlhoff's concept of 'sealed surfaces', term a 'sealing' of knowledges [12]. As part of this argumentation, I demarcate and show differences between 'traditional' web search and LLM produced answers to search inquiries

In light of my previous argumentation, my research will conclude with a discussion of possibilities to counter the marginalization and sealing of certain voices and knowledges in LLM generated search results. Drawing on the works of Amoore [2], Ahmed [1]and Haraway [5], I will argue that doubting the outputs of LLMs can

*Corresponding Author

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604737

function as a feminist intervention that resists the marginalization and sealing of certain knowledges and perspectives. Through this, knowledges can be re-situated as embodied and partial, opening up possibilities for 'feminist futures' [1] despite the sealing of knowledges through LLM generated search answers.

3 CONCLUSION AND RELEVANCE OF THE PROPOSED RESEARCH

In summary, my research examines on the usage of LLMs to generate direct answers in search engines with a feminist lens. The concept of 'sealed knowledges' is introduced to highlight the challenge of finding obscured knowledge through LLM-generated search results. As already pointed out in the introduction, this research is crucial given that major search engine providers are currently moving to integrate LLMs for the generation of direct answers into their search engines. The question of the underlying assumptions about knowledge and information on which this development is build and how this development affects marginalized knowledges, offers a novel perspective on the issue. Moreover, this research sheds light a potential approach to critically engage with this new search paradigm.

THESIS RESEARCH STATEMENT

In recent years, we have witnessed a rapid growth in the deployment of Machine Learning (ML) models in complex real-world settings. ML models are being used to support decision-making across a wide range of domains, including healthcare [2, 19, 22, 34], credit lending [5, 14], criminal justice [1, 13], and employment [11, 20]. For example, in the criminal justice system, algorithmic recidivism risk scores inform pre-trial bail decisions for defendants [1]. In credit lending, lenders routinely use credit-scoring models to assess the risk of default by applicants [14]. The excitement around modern ML systems facilitating high-stakes decisions is fueled by the promise of these technologies to tap into large datasets, mine relevant statistical patterns within them, and utilize those patterns to make more accurate predictions at a lower cost and without suffering from the same cognitive biases and limitation as human decision-makers. Growing evidence, however, suggests that ML models are vulnerable to various biases [1], instability [8], and opaqueness [4]. These observations have led to calls to preserve human involvement in high-stakes decision-making systems—with the hope of combining and amplifying the respective strengths of human cognition and ML models through carefully designed *hybrid* decision-making systems. Such systems consist of ML models and human experts *jointly* making decisions, and they are common in practice—including in the domains mentioned above.

Researchers have proposed and tested various hybrid human-ML designs which vary, for instance, in the way decision-making power is distributed between humans and machines [6, 10, 16, 30, 31]. However, empirical findings regarding the success and effectiveness of these proposals are mixed [15, and references therein]. Simultaneously, a growing body of theoretical work has attempted to conceptualize and formalize these hybrid designs [3, 9] and study optimal ways of aggregating human and ML judgments within them [7, 12, 16–18, 21, 33, 35]. The existing theories, however, are hard to navigate and make sense of as a whole. The critical issue leading to this lack of coherence and organization is the wide range of (often implicit) idiosyncratic assumptions made in different research articles—making it challenging to compare existing proposals and foresee the conditions under which one would outperform another in practice. Even within the same theoretical framework, the empirical results are inconclusive and sensitive to the context, human expertise, and other situated factors [15].

A crucial component in effective HML partnerships is an understanding of the strengths and limitations of humans versus ML-based decision-making on particular tasks. While research in the behavioral sciences provides insights into potential opportunities for ML models to complement human cognitive abilities and vice versa, further research is needed to (1) understand the implications of these findings in specific real-world human decision-making tasks, and to then (2) operationalize such insights to foster effective HML partnerships. Thus, in the first part of my thesis, I work towards developing theoretical and experimental tools to derive meaningful insights from human behaviour data in real-world settings. Next, I describe my on-going and proposed work towards understanding human-ML complementarity.

Part I: Theoretical and experimental approaches to understanding human decision-making

In the first part of my doctoral research work, I conduct both theoretical and empirical research to glean insights from human data. I develop statistical methods and design experiments to isolate and identify different statistical patterns in human judgment. For instance, I have developed models and designed experiments to analyse and quantify the role of: (a) cognitive biases such as anchoring bias in human+ML decision-making, (b) implicit biases in human decision-making in conference peer-review. I provide more details about each project below.

In Rastogi et al. [23], we design a two-sample test for detecting statistically significant difference in two populations' preferences expressed as pairwise comparisons. For instance, when eliciting data from people, there is a long-standing debate over the difference between two methods of data collection: asking people to compare pairs of items or asking people to provide numeric scores to the items. Using our two-sample test on real-world preference data, we find statistically significant difference in these two data elicitation methods. This suggests that people tend to be internally inconsistent when making comparative decisions. We also provide theoretical guarantees for our proposed showing that it is minimax optimal under no modeling assumptions.

Next, I focused on experimental approaches to understanding human decision-making behaviors in different settings. The bulk of

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604738

the technical work comprises (1) designing experiments to carefully elicit or collect decision-making data, and (2) applying techniques from statistics and causal inference to isolate significant patterns in human decision-making behavior. I work with the conference peer-review setting, wherein academics (reviewers) come together in a structured manner to decide whether a submitted manuscript is acceptable to be published. Rastogi et al. [27] considers the debate in double-anonymous conferences over whether authors should be allowed to post their papers online on arXiv or elsewhere during the review process. By surveying reviewers, this work helps inform authors' choices of posting preprints online and conferences' choices over policies, by quantitatively measuring the associated risks and benefits. Continuing, Stelmakh et al. [32] investigates the implicit role of citations in the review process by asking the question—"Does the citation of a reviewer's work in a submission *cause* the reviewer to be positively biased towards the submission, that is, *cause* a shift in reviewer's evaluation that goes beyond the genuine change in the submission's scientific merit?". Next, Rastogi et al. [26] focuses on authors' perception of their submitted papers in a machine learning conference, NeurIPS 2021. We surveyed the authors on three questions: (i) their predicted probability of acceptance for each of their papers, (ii) their perceived ranking of their own papers based on scientific contribution, and (iii) the change in their perception about their own papers after seeing the reviews, and compared their responses with their co-authors' responses and the outcomes of the peer-review process. The study revealed major inconsistencies in the perceptions of authors, their co-authors, and the review process.

Finally, Rastogi et al. [28] focuses on ML-assisted decision-making by humans, wherein a human decision-maker is shown the ML prediction before making a final decision. Here we focus on the role of human cognitive biases in human-ML collaboration by modeling cognitive biases in this setting. Further, we conduct a human subject experiment to examine over-reliance of human decision-makers on ML models via anchoring bias, and our proposed time-based methods to mitigate its negative impact on the human-ML team performance. This concludes the first part of the thesis work.

Part II: Towards understanding and supporting human-ML complementarity

The second part of this thesis focuses on developing an understanding of human-ML complementarity in two classes of tasks: (1) generative, co-creative tasks, and (2) predictive decision-making tasks. Correspondingly, in [25] we study the domain-specific combination of humans and ML in auditing ML models, and in [24] we describe on-going and proposed work on developing domain-general and domain-specific theories of human-ML complementarity in predictive decision-making.

Supporting human-AI collaboration in auditing LLMs with LLMs. [25] provides an auditing tool wherein humans collaborate with generative LLMs to find failures in language models. This setting presents a domain-specific opportunity for leveraging complementary strengths of humans and generative models towards the main goal of finding test cases on which a given language model fails. Prior work on collaborative auditing, such as AdaTest [29], while promising, relies heavily on human ingenuity to bootstrap the process, and then quickly becomes system-driven, not making full use of the complementary strengths of humans and LLMs. Consequently, we synthesize literature from HCI and sensemaking to design for supporting auditors in making the best use of the augmented tool, AdaTest++. To evaluate AdaTest++ we conduct user studies with participants auditing two commercial large language models. Qualitative analysis shows that AdaTest++ effectively leverages human strengths such as schematization, hypothesis formation and testing. Further, with our tool, participants identified a variety of failures modes, covering 26 different topics over 2 tasks, that have been shown before in formal audits and also those previously under-reported.

Unifying taxonomy and framework for human-AI collaboration in predictive decision-making. In [24] we propose a unifying taxonomy and framework for combining human experts and ML in predictive decision-making. There are a wide variety of domains where ML is deployed for predictive decision-making, such as healthcare, credit lending, criminal justice, hiring, etc. However, existing theoretical and empirical results on the factors that facilitate and hinder effective HML partnerships in these domains are often mutually incompatible and mixed respectively. Thus, we propose a taxonomy characterizing a wide range of criteria across which human and ML-based decision-making differ. Then we formalize this taxonomy, by taking a computational perspective of human decision-making, by proposing a framework for aggregating human and ML decisions optimally.

In my proposed work, I am planning to continue working on better understanding sources of complementarity in human and ML decision-making in complex real world settings, by building-upon and refining the taxonomy and the framework. For this, I will conduct a range of synthetic and semi-synthetic simulations to derive insights about optimal combination of human and ML decisions. Next, I will focus on a specific visual diagnostic task where past research has shown evidence of HML complementarity. In this project, we will design experiments to collect qualitative and quantitative feedback from human decision-makers, and contrast their approach with that of ML. This will allow us to draw insights about the "why" and "how" of human-ML complementary performance in the task domain. Moreover, this investigation will inform design of HML systems that successfully leverage complementary strengths of the two agents.

In conclusion, this work is aimed at generating actionable insights for improving the quality of decision-making at scale, with human decision-makers and their combination with machine learning models.

Exploring the Moral Value of Explainable Artificial Intelligence Through Public Service Postal Banks

Joshua Brand

Paris, France

ABSTRACT

This research examines *Explainable AI* (XAI) from a duty-based perspective in the context of public service postal banks. I argue that XAI is a strict obligation for these banks whenever they implement advanced AI-recommendation systems which flows from the Kantian principle to respect humanity that is integral to their public service identity.

1 INTRODUCTION

There is broad consensus that *Explainable artificial intelligence* (XAI) can lead to more trustworthy AI, which is becoming increasingly opaque, by providing explanations of AI-powered recommendations. Current literature, however, examines XAI from a broad moral perspective—that explainability is a right that ought to be universally provided to stakeholders [e.g., 9, 15, 24]. A right to explanations may certainly be valid and worthwhile [e.g., 26], yet it does not capture the complete ethical picture of XAI. We must also consider it in terms of obligations, as according to Simone Weil, "The notion of obligation comes before that of rights, which is subordinate and relative to the former. A right is not effectual by itself, but only in relation to the obligation to which it corresponds." [27, p. 2]. Onora O'Neill echoes this concern by stressing that, "we cannot tell who violates a right to goods or services unless obligations have been allocated." [21, p. 428]. If we not not ascertain who specifically shoulders the obligation to meet these rights, the rights remain abstract and lack enforcement potential [21]. Responding to this gap in the literature, this paper examines XAI by considering its implementation through the perspective of duties. Given the significant interest of implementing advanced AI-powered decision-support systems (DSS) in the financial sector, this paper looks at the case of public service postal banks (PSPBs)[1], which have a moral threshold that goes beyond that of commercial banks, using the example of France's *La Banque Postale* (LBP) to illustrate.

2 PSPB NORMATIVITY

In Section 2 I consider one of the key identifying characteristics of PSPBs, which includes the likes of BancoPosta (Italy), Banco Postal (Brazil) and KiwiBank (New Zealand), that is financial inclusion. That is, they not only provide accessible banking services, but pay particular attention to serving the *unbanked* and *underbanked* to assist them toward greater financial autonomy [2, 4, 8, 20]. I lay out the regulations and socially-driven actions driven by this feature, using LBP as the case study, such as their obligation to open a bank account (*Livret A*), for free, to any member of the public. Every member of the public must be seen as a *client-in-waiting*—an individual is no more or less deserving than another to receive banking services. While all banks certainly share basic duties, such as facilitating transactions and supporting the economy, commercial banks primarily treat individuals through an instrumental lens, considering profit and liability, whereas PSPBs act under the notion that every member of the public has an intrinsic worth and by the same token, reject indifference by paying particular attention to those in vulnerable circumstances. Translated into philosophical terms, PSPBs adhere to the Kantian principle of respecting every individual as *ends-in-themselves* [see, 11]. If PSPBs acted contrary to this principle they would be acting irrationally by violating their identity *qua* PSPB.

Adhering to this principle entails the duty to act in a trustworthy way [19]. Trustworthiness obliges open, intelligible, and assessable communication of the motivating reasons for decisions affecting individuals. If they lack such knowledge underlying decisions, they cannot genuinely participate and consent to them and thus, effectively serve as mere means for the decision-maker.

3 AI IN BANKING

In Section 3 I turn to the both imminent and reasonable implementation of advanced AI (i.e. machine learning models) to assist in a variety of financial decision-making and surveillance, such as

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604741

[1] I am specifying public service as despite most postal banks having a public service mandate, there are some that have retained the 'postal' name after restructuring as a private retail bank, such as Germany's Deutsche Postbank.

generating more precise financial portfolios and loans [16, 25] and improving the tracking of illicit funds under anti-money laundering and the countering of financial terrorism (AML-CFT) efforts [7]. Yet the characteristic 'black-box' opacity of machine learning impedes on our ability to know how a system arrived at its recommendation, thus leaving stakeholders *epistemically impaired* [5]; PSPBs would thus be left unable to fulfill their public service duty.

4 XAI

While machine learning is *prima facie* detrimental to PSPBs' normativity, in Section 4 I propose XAI as an extended obligation for PSPBs in the context of AI to maintain their moral integrity. XAI, more specifically feature-importance or attribution-based explanations such as LIME and SHAP, are reason-giving tools that provide the motivating reasons—reasons that an agent, or *implicit agent*[2], takes to favour their actions. While these tools technically only approximate said reasons, they are sufficient for understanding, analyzing, and justifying the behaviour of systems and thus, it is argued that what they provide in terms of explanations is akin to providing a reason explanation [5, 28]. In the context of PSPBs, implementing XAI is therefore not merely preferential, but an obligation in virtue of their public-financial inclusionary status.

5 AML-CFT

In Section 5 I address how AML-CFT efforts—a significant activity for any bank—interacts with this public service duty. A principle of confidentiality is enforced throughout AML-CFT investigations, as if they were transparent criminals would be able to adapt their methods to evade future suspicion [17], this raises the question if PSPBs must put their moral integrity on hold in the context of AML-CFT and if so, XAI would no longer carry moral significance in this context. I respond to this situation with a non-ideal understanding to moral duties, as supported by Christine Korsgaard [14]. I argue that AML-CFT fits within this non-ideal environment and therefore does not only allow for, but demands exceptional action like maintaining confidentiality. PSPBs ought to exceptionally accept confidential behaviour and in doing so, importantly, they would not be neglecting their public service duty.

Nevertheless, it is prudent for PSPBs to recognize that many of those affected by AML-CFT investigations are not malicious actors and that they should aim to maintain trustworthy communication with the public. I suggest that in this context PSPBs should implement alternative methods to sustain public trust, such as a trusted proxy as we see with the French data protection authority (CNIL) or the Australian Banking Association [3, 22]. These advocates would require XAI to ensure they can fully engage with the bank's decision to investigate customers, accounts, and transactions flagged by AI. While the public cannot expect to receive the same information of the proxy, the trusted proxy can ensure that the PSPBs moral duty to be trustworthy is fulfilled, albeit indirectly, in this non-ideal environment.

This also falls in line with the understanding that the public is owed explanations because of their recognized final value, not because of any particular capacities they may have. The public's right to have explanations made available to them is not contingent on how they interact with such explanations.

As Watson notes, a baby is owed their correct blood sugar test results from the physician despite their inability to understand the test results. The baby's right is not denied due to their lack of cognitive abilities. A proxy, commonly a parent or guardian, is instead brought in to enforce the baby's right on their behalf [26]. Similarly, the public lacks the capacity to exercise their right to an explanation in the context of AML-CFT. They do not then lose their right in this context, but are owed *epistemic proxies*[3] to act on their behalf.

6 OBJECTIONS

In Section 6 I conclude by addressing concerns charged against XAI implementation, such as its accuracy and robustness [1] and whether explanations provide *all* the relevant motivating reasons [23]. There are also concerns that interacting with XAI explanations may increase users' cognitive biases [10, 12, 13]. The concern thus goes that if it is PSPBs duty to recognize and support every individual's end-setting nature, or autonomous agency, yet XAI encourages unconscious behaviour, would this not be an argument to limit XAI? This research, however, generally only considers user susceptibility—those who directly interact with XAI to help their decision-making—and not the effects on other stakeholders whose interaction with XAI stops at perceiving reasons and then deciding if they are good reasons. In any case, a recent systematic review shows us that some uses of XAI, including feature importance, may in fact *mitigate* cognitive biases [6]. Concerns for XAI implementation therefore argue for continued development and research on its effects on stakeholders, yet do not impede on its value in regard to PSPBs as an intelligible and assessable reason-giving mechanism.

7 CONCLUSION

In sum, this research responds to a gap in the literature by grounding XAI within a duties framework in the context of the public service banking. I therefore do not provide a universal response on how we may ground XAI in moral obligations. This does not, however, necessarily exempt private sector banking from a duty to implement XAI; it is certainly possible they have their own moral duties leading them to its implementation. From this position, future work will consider how explanations ought to be provided and any potential limitations, including legal, as well as technological and social contexts that may need to be considered. Attention will also have to be paid to the possible benefit that other XAI tools, such as 'minimal change' counterfactuals, may have for these contexts.

ACKNOWLEDGMENTS

AI-driven Automation as a Pre-condition for *Eudaimonia*

Anastasia Siapka
Centre for IT & IP Law, Katholieke Universiteit Leuven, Leuven, Belgium
anastasia.siapka@kuleuven.be

ABSTRACT

The debate surrounding the 'future of work' is saturated with alarmist warnings about the loss of work as an intrinsically valuable activity. Instead, the present doctoral research approaches this debate from the perspective of human flourishing (*eudaimonia*). It articulates a neo-Aristotelian interpretation according to which the prospect of mass AI-driven automation, far from being a threat, is rather desirable insofar as it facilitates humans' flourishing and, subsequently, their engagement in leisure. Drawing on virtue jurisprudence, this research further explores what this desirability may imply for the current legal order.

1 INTRODUCTION

Recent advances in Artificial Intelligence (AI) and robotics have rekindled fears of a workless future, with emotionally charged media narratives suggesting that AI systems and/or robots are coming to '*steal*', '*kill*' or '*destroy*' our jobs [4, 5]. The automation of work, understood as the process by which human labour is replaced by machines, is also a cause for scholarly concern across different disciplines. For some scholars, the large-scale deployment of AI in the workplace amounts to a '*Fourth Industrial Revolution*' or a '*Second Machine Age*', threatening to render human work—nay, humankind in its entirety—obsolete [3, 6]. Even despite the potential introduction of a Universal Basic Income (UBI), which could in principle guarantee citizens' livelihood, it is argued that policymakers would still need to safeguard work, since it bears intrinsic value that transcends the instrumental value of a paycheck [8]. AI-driven automation is, hence, largely framed as a threat to be counteracted by law.

AIES '23, August 08–10, 2023, Montréal, QC, Canada

Nonetheless, the axiological superiority of work as an intrinsically valuable activity and the insistence on its preservation, even if humans' sustenance could be otherwise secured, should not be taken for granted. Conversely, I argue that the prospect of automating human work through AI is, under certain conditions, desirable. To do so, I draw upon Aristotle's insights on flourishing and leisure, as these can be inferred from his *Nicomachean Ethics* and *Politics* [2]. Current normative approaches to AI-driven automation are predominantly consequentialist—assessing, for instance, its projected effects on cost-cutting in production or efficiency in service provision. Instead, I demonstrate that an approach rooted in the Aristotelian tradition could be fruitfully applied to evaluate this distinctly modern issue.

2 RESEARCH APPROACH

This research comprises three consecutive phases. In the **first phase** (descriptive), I have sought to define 'work'. Without clarifying work's meaning, we cannot fully understand what it is that we risk missing in the event of mass technological unemployment. Moreover, variations in the conceptualisation and evaluation of work imply corresponding variations in the perceived need as well as the measures suggested for its preservation. Therefore, with the aim of informing the normative aspects of my research, I have attempted a conceptual and axiological analysis of 'work', answering the following questions, i.e., '*what is work?*' and '*what is the value of work?*'. I have, subsequently, explored how work has been affected by technological progress over the years. Although technology has increasingly automated human tasks in the workplace over the past three centuries, most contemporary approaches to AI-driven automation focus on extrapolating to the future at the expense of the past. Ahistorical approaches, however, risk wrongfully presenting the fear of mass technological unemployment as completely novel. This is why, based on the relevant literature in computer science, engineering, the social sciences and (economic) history, I have expounded on the Industrial Revolution(s), particularly the '*Fourth Industrial Revolution*' and its distinct characteristics. Finally, I have rendered explicit the key arguments regarding the feasibility and desirability of AI-driven automation, demonstrating how they differ from the Aristotelian approach adopted in the thesis.

In the **second phase** (interpretative and theory-building), I have interpreted relevant passages from Aristotle's *Nicomachean Ethics* and *Politics*, relying on the original works alongside their secondary literature. This interpretation, in turn, has followed three steps. First, I have elucidated how Aristotle conceptualises leisure (*scholê*) and occupation (*ascholia*). His concept of leisure differs from rest, play, and entertainment, as each of these subserves one's ability for further occupation. By contrast, for Aristotle, it is occupation that should be serving leisure, not the reverse. Second, I have examined the ultimate human good in Aristotle's ethics, namely flourishing (*eudaimonia*). By explicating his conception of human flourishing as

an activity of the soul in accordance with virtue/excellence (*aretê*), I have shown that leisure is indispensable to both virtue acquisition and the implied activity of the soul. However, actualising the human potential for leisure requires intentional political arrangements, which I have explored in the third step. Granting that, for Aristotle, the objective of statecraft is citizens' collective flourishing and that leisure is conducive to said flourishing, the cultivation of leisure emerges as a direct aim of politics, a shared end in which all citizens should have the realistic opportunity—although not the obligation—to partake.

In the **third and ongoing phase** (expository and normative) of my research, I flesh out the implications of this Aristotelian account of flourishing for the current legal order and, most crucially, for the debate surrounding the 'future of work'. Briefly stated, I ask: how would AI-driven automation be regulated if the *telos* (i.e., ultimate purpose or end) of law was citizens' flourishing? In responding to this question, I resort to 'virtue jurisprudence', a recently developed strand of normative legal theory that attributes primacy to the concepts of virtue/excellence and flourishing [1, 7]. Adopting a virtue-jurisprudential approach to AI-driven automation entails that—insofar as automation may generate conditions favourable to a leisure-centred polity—legislators should not only tolerate but actively incentivise AI development and adoption. Rather than seeking to preserve work by any means necessary, it is citizens' leisure that the law should be tasked with enhancing.

The remainder of the research illustrates how the law could discharge this task through its multifaceted function in society. It suggests a neo-Aristotelian interpretation, which is committed to the general structure of Aristotle's theory without necessarily subscribing to each of his doctrines. In so doing, it addresses potential objections that the suggested approach: (i) intrudes into citizens' private realm and opposes liberalism; (ii) violates state neutrality and is susceptible to abuse; (iii) hinders citizens' autonomy and freedom of choice; and (iv) is futile owing to its utopianism. The research concludes with recommendations for scholars, policymakers, AI developers, and educators.

3 CONCLUSION

In this way, Aristotelian ethical and political theories may enrich and expand the scope of law, making space for less conventional, even utopian for some, considerations of virtue, leisure, and flourishing. At the same time, the development of legal approaches such as virtue jurisprudence may provide concrete contexts for refining Aristotle's theories themselves and applying them to new cases of practical relevance, such as the case of AI-driven automation. Overall, this neo-Aristotelian approach not only accommodates pluralism, autonomy and freedom of choice but further leads us to ask what the optimal conditions for flourishing—and thereby for leisure—are, conditions that legislators should seek to enable in the age of automation. This is currently an under-theorised question in the 'future of work' debate. Answering it with the help of virtue jurisprudence could yield alternative, less deterministic or dystopian, options for the pressing policy vacuum on automation and proffer novel insights into what AI promises to liberate us from and towards.

Multi Value Alignment: four steps for aligning ML/AI development choices with multiple values

Given the widespread use of Machine Learning and Artificial Intelligence (ML/AI) systems, deploying systems that are not aligned continues to cause a lot of harm. In practice, the goal of alignment is best thought of as alignment to values, an approach that is also common to other applied ethics sub-fields [1, 2]. This has the potential to limit alignment with malicious intent and can also allow us to account for nuances of social and political structures. Documents that provide guidelines on the governing principles of AI ethics agree on common overarching values one should seek to align to, but these may vary by the specific problem being tackled; it is also possible for different communities to interpret the same value in different ways [3]. Moreover, there may be apparent or inevitable trade-offs between the values one seeks alignment to.

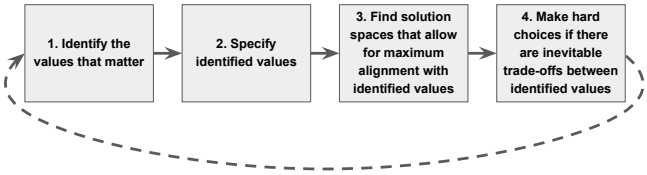

Figure 1: Outline of the suggested four-step process

In ongoing work with Anna Lewis and Nick Jones, we outline a four-step process (Fig. 1) that synthesises best-practice from AI ethics and bioethics to help developers identify and make decisions to create ML/AI systems that align with multiple values. When dealing with multiple values, it is frequently assumed that there is an inevitable trade-off, but this often turns out to be an apparent trade-off that seems inevitable because only a small part of the solution space has been explored. The suggested process places an emphasis on reasoning to seek new solutions that help us identify and resolve these apparent trade-offs. We also survey existing ML/AI development methods that could be used at various steps of the proposed process to encode values within a development stage. This work aims to discuss what it means to build value-aligned ML/AI systems, and hence provides development teams with practical guidance to maximise the chances that their work has desirable impacts.

1 INTRODUCTION

News media is the cornerstone of a functioning democratic society, with journalists responsible for informing citizens on matters of public interest based on traditional 'news values' such as proximity, timeliness, impact, and relevance, which have changed little despite a radical shift in forms of news consumption in contemporary society. [7] Their selection of what is worthy of public attention has historically made them the gatekeepers of society, an idea that has been contested for the majority of the 21st century as the arrival of the internet allowed anyone to publish with only minimal gatekeeping. [14] Furthermore, the proliferation of personalisation in media, resulted in editors being no longer solely responsible for curation. However, we as users of personalisation systems are fallible and subject to common forms of manipulation such as disinformation, misleading forms of advertising, propaganda, deep fakes, astroturfing, and attention hacking such as clickbait. [8, 9] Equally, we tend to focus on content that reinforces our pre-existing beliefs, creating a negative feed-back loop with algorithmically enhanced recommender systems that could from a purely technical standpoint lead to "filter bubble" effects. [1, 4, 5]

Whereas the majority of providers might rely solely upon traditional consumption statistics to gauge the success of personalisation, public service media, such as the BBC, are guided by a broader set of normative values such as public good, accountability, inclusivity, and universality. [2] Understanding success in these contexts requires a more nuanced understanding of user-perceived benefits, harms, and comfort levels arising from personalisation. This is particularly true as past research shows that moral tensions exist. Users feel a trade-off between benefits of personalisation and their own data disclosure impacting their privacy [17], or report perceived creepiness resulting from overly accurate recommendations [15]. Other research has explored users' understanding of the operation of such systems [10, 11], and how it links to subsequent attitudes to systems [6]. It is well- reported that engaging with systems that rely heavily on our personal data can result in a behaviour-intention rift, as users trade suboptimal data sharing for immediacy and ease, conflicting with reported preferences. However, to date there is no research that has surfaced users' internal trade-offs, between comfort and perceived benefit, when engaging with algorithmically enhanced personalised media and media recommendation systems.

This pilot study aims to bridge this gap by seeking to understand user perception of the personal and wider social benefits and harms and their felt comfort when engaging with personalised media systems.

2 METHODS

In order to understand user perceptions of media personalisation and comfort levels, a series of quantitative and contextual qualitative investigations was conducted among a total of 211 users in the UK aged 16-34. To recreate a more representative population, subjects were recruited through university mailing lists and through the paid recruitment service Prolific to target students and non-academics. This was to ensure the sample was not dominated by those with higher education backgrounds but is representative based on the 2021 UK census data on education levels. [12]

This study consists of a wider scale online survey with 106 participants, comprised of quantitative methods of inquiry but also open text input prompts which necessitated a thematic analysis approach. This was followed by ten semi-structured interviews to contextualise the results. Building on the qualitative findings from the online survey's text inputs and from the interviews, a second online survey was conducted with 105 participants to better understand the trade-off between benefit and comfort levels that are felt by users engaging with personalised media.

In the first online survey the focus was on perceived benefits and harms of personalisation. Forms of inquiry included open text inputs, multiple-choice, and Likert Scales to identify which personal and wider social benefits and harms the participants commonly associated with media personalisation. The follow-up interviews used the same questionnaire, with the purpose to allow for more contextualised answers, given the format of inquiry. The second online survey's purpose was to quantify sentiments surrounding

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604761

commonly mentioned items related to personalisation by rating perceived benefits or harms and comforts or discomforts on 1-10 scales. By quantifying these sentiments, in the analysis the correlation between benefit and comfort was identified.

For the qualitative data, a thematic analysis approach was applied. To avoid subjective biases, which could influence how results are being interpreted, an independent double-blind review was conducted by two coders. Further, a codebook was devised independently by analysing three interviews each, identifying the relevant codes and collating them into wider overarching themes. [3]

3 RESULT AND DISCUSSION

A commonly expressed sentiment in both the online survey and the interviews was the tension felt between perceived benefit and comfort level regarding different features of personalisation. This tension – or trade-off is better understood through the quantification of the second online survey, which allowed to plot a diagram to showcase the relationship between perceived benefit or harm and comfort level of certain aspects or consequences of personalisation (Figure 1).

The quantitative results show a trend towards a positive correlation between comfort level and perceived benefit, as most items are in the quadrants 2 (intersection of benefit and high comfort) and 3 (intersection of harm and low comfort). To compare against the thematic analysis of the qualitative data collected in this study, it is noteworthy that this clear-cut relationship becomes blurry when put into context (Figure 2). Some items were perceived as rather beneficial regardless of the low comfort level they elicited, such as the processing of past user behaviour, as participants understood it as adding value to their experience even if they did not like the thought of it. Having full agency over a system was attributed to lacking added value during the interviews, since automated personalisation was overall considered beneficial. This means that an interpretation of the qualitative data allows for some items of the diagram to migrate to quadrants 1 and 4, however here it is also worth noting that the only discrepancies between the two diagrams affect the positioning along the y-axis, meaning that while the level of perceived benefit or harm was subject to change based on context, the comfort level was not.

Here the question arises in which quadrant(s) the different items should ideally accumulate, and which items should not be associated with a well-designed personalised system. Given that interviewed participants often mentioned their willingness to accept personalisation when presented an added value, a migration towards the top half of the y-axis could already be considered favourable, regardless of the comfort-level, as this was mostly a secondary thought.

4 FUTURE WORK

Given a general acceptance of media personalisation, it can be concluded that it is imperative to emphasise user-centred and participatory design in media personalisation development.

This research is formative, with the aim of directly supporting a follow-up study investigating the balance of user agency, transparency, editorial and algorithmic curation and intervention in AI-driven personalised news. The final goal is to develop user-centric design ideas for personalised news and media content.

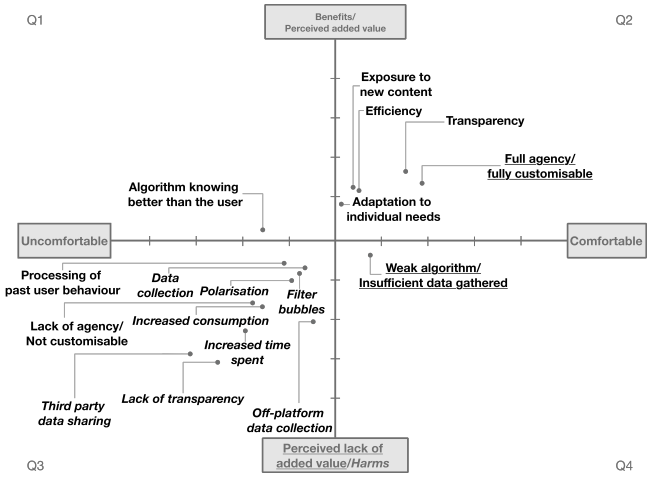

Figure 1: Items related to personalisation on benefit/comfort diagram (quantitative data)

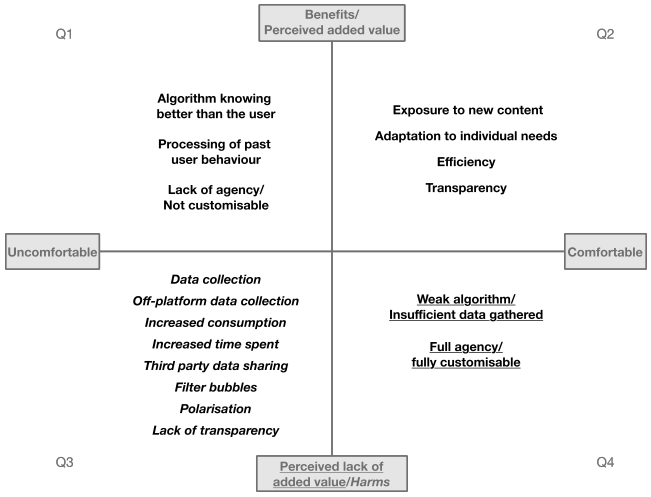

Figure 2: Items related to personalisation on benefit/comfort diagram (contextual qualitative data)

For this follow-up study the interactive system NAIRS was built which serves as a provotype (provocative design artefact) to elicit participants' sentiments surrounding their own agency and self-assessment compared to their trust in the system's personalisation [16] and provoke reflection about the transparency required to exercise agency in a personalised recommender system [13]. Its provocation also serves as a starting point for discussions on algorithmic and editorial intervention with the overarching goal of learning more about the balance of these entities with user agency.

1 BACKGROUND AND MOTIVATION

AI is increasingly penetrating numerous areas of our lives. As AI is taking over sensitive tasks such as credit scoring, claims processing, and support of medical diagnoses, there is a rising demand for AI applications to be »trustworthy«. Given a set of key trustworthiness requirements that recur among numerous AI ethics principles and guidelines [7], [5], [6], organizations and researchers are showing a huge interest in implementing and assessing them for various reasons [10]. In addition to preventing societal harm and protecting the health, safety, and fundamental rights of individuals [2], [6], the assessment of AI trustworthiness characteristics can help improve AI systems and inform business decisions. Moreover, companies need assessment procedures to demonstrate the trustworthiness of their AI products or services to their customers, as well as to prove conformity of their systems with (upcoming) regulatory requirements [2]. Overall, there is a demand for market-ready AI assessments.

Although there is a need for implementing and assessing trustworthiness characteristics in AI applications, the operationalization of »trustworthy AI« is still largely open [5], [8]. Notably, the requirements associated with relevant quality dimensions are not technically concise. Often, their subject is unclear (i.e., procedures for specifying the test object in an AI application are missing), and their scope is not well-defined (i.e., under which circumstances and for which application areas requirements should apply). One additional challenge is that the evaluation of trustworthiness characteristics and risks typically depends on the specific use case. Regarding the implementation of trustworthy AI, it is also not clearly defined which entity should address the requirements (e.g., on a technical or organizational level), and guidance is missing for how they should be transferred into practice [13]. While it is apparent that the entire lifecycle needs to be considered to ensure trustworthy AI, including how an AI system is handled by the organizations involved along the complex value chain, little has been written about the tangible implementation of ethical goals and values [5].

2 CENTRAL RESEARCH QUESTION

As »trustworthy AI« is a broad field that comprises several requirements to be operationalized, my thesis research focuses specifically on »AI fairness«. The goal of my research is to develop a method or procedure that:

(1) clarifies what needs to be done, from a technical perspective, to implement the abstract requirement of »fairness« in practice for a specific AI application,
(2) shows how to arrive at a market-ready »AI fairness« statement/assessment based on technical indicators and evidence.

Thus, the method or procedure I am aiming for will address the operationalization gap between:

(1) the large number of existing technical bias and fairness measures (e.g., metrics, toolkits, and measures to counteract biases and in data and model outputs)
(2) making the statement that »fairness« is achieved for a specific AI application (as one of the AI trustworthiness requirements).

3 ACCOMPLISHED WORK

At the beginning of my PhD, I studied various AI ethics and trustworthiness guidelines, including the HLEG Ethics Guidelines for Trustworthy AI [6] which I consider especially relevant from a European perspective. In [12], I summarize the motivation for trustworthy AI and a set of trustworthiness dimensions that are consistently mentioned in these guidelines (i.e., fairness, reliability, safety & security, transparency, data protection, autonomy & control). While this set focuses on those requirements and risks which can be addressed by technical means in the AI system itself, it is noteworthy that various guidelines also refer to the way the organization (e.g., provider or operator) handles its AI applications (e.g., post-market monitoring [2], »AI Ethics Review Board« [6]). Therefore, in [12], I highlight two perspectives on »trustworthy AI« and argue that an interplay of both is necessary in order to achieve and assure »trustworthy AI« in practice: the product and organizational perspectives. I describe the essence of these perspectives as follows: i) high technical quality of AI systems is required, ii) the organization should make appropriate preparations (e.g., establish structures, processes and roles) to handle its AI applications and their development in a trustworthy manner. For each perspective, I

present implementation and assessment approaches based on previous work. For the product perspective, I refer to the AI Assessment Catalog [11] that I co-authored. For the organizational perspective, I provide an introduction to the general concept of management systems and outline how they can support organizations in the trustworthiness assurance of their AI applications. Overall, I see that operationalization of the organizational perspective is further advanced. It can be expected that best practices at the process-level are gradually emerging and audit and certification schemes for an AI Management System are developed and applied in a similar fashion as for other domains (e.g., IT security) [9]. From the product perspective, however, there are technical challenges (e.g., finding suitable quality indicators, data coverage, verification of ML models). In addition, when we consider the numerous tools and metrics currently available, there is an apparent gap between the results of these tools and metrics, and deeming a risk sufficiently mitigated or controlled (corresponding to my "central research question"). In the following, I further elaborate on my accomplished and current work with respect to each perspective and, in the last paragraph, outline my future PhD research.

The AI Assessment Catalog presents a guideline for the structured identification of AI-specific risks from a product perspective. In particular, it provides state-of-the-art guidance on formulating trustworthiness criteria and documenting technical and organizational risk mitigation measures along the lifecycle of an AI application in a structured manner. In my view, the document has two main contributions: a risk-based approach (because assessment criteria often depend on the specific use case) and an underlying risk scheme (that distinguishes the trustworthiness dimension into risk areas, each of which bundles malfunctions or undesirable system properties that can be addressed by similar risk mitigation approaches). This risk scheme enables a structured procedure despite the various risk types associated with »trustworthy AI«, since risks that need to consider different aspects of the system or require different measures and tests are assigned to distinct risk areas, which are first assessed separately. I have applied the AI Assessment Catalog to several AI systems from industry clients as part of one of the first AI assessments in Germany. In addition, the assessment approach presented in the Catalog was used as basis for the development of the CertAI Trustworthy AI Seal [1]. While the AI Assessment Catalog is one of the most advanced guidelines for AI trustworthiness assessment, these industrial projects have given me the opportunity to identify potential for further operationalization. For example, there is potential to standardize the expert judgement used in the assessments, and to develop more concise guidance based on the choice of testing tools and measures used in the assessments. Given this background, one research method I am using in my PhD is the case study approach. I aim to address my central research question by deriving findings from the solution approaches developed in these specific examples (see the last paragraph). In the context of my thesis, [3] represents a first step towards building an example base of case studies. Clearly, the assessment of »AI fairness« is not solely a technically motivated question, and thus, the interdisciplinary perspective of this paper (showing how ethics and management science define and argue »fairness«) is essential in informing the choice of a concrete fairness metric as one indicator for the assessment of a credit scoring application. Additionally, for the same use case I am currently examining the role of data quality requirements in ensuring fairness in a concrete ML model. Based on this work, I am preparing a publication together with law research partners on the technical and legal evaluation of the data quality requirements proposed in the draft AI Act.

Implementing trustworthiness characteristics as well as their assessment to an AI system in practice, clearly involves the provider or operator in charge (and in parts the assessment body, if this is a 3rd party): they need, for example, to set up processes and resources for risk analysis, make decisions on risk acceptance, and trade-offs between conflicting requirements, define roles to be accountable for these decisions, plan and implement risk treatment measures. To better understand how a corresponding organizational superstructure could be set up to orchestrate and implement the various tasks that trustworthy AI entails, I have studied management systems and risk management approaches. In particular, I have co-authored a comparative analysis [9] (commissioned by Microsoft) of the (minimum) requirements described in the working draft international standard for AI Management Systems (»AIMS draft«, ISO/IEC WD 42001), the draft AI Act [2] (which requires, among other things, that providers of »high-risk« AI systems have a quality management system, risk management system, and post-market monitoring in place), the Assessment List for Trustworthy AI [6], and the AIC4 Catalog [4]. We find that the AIMS draft provides a valid and suitable framework for organizations to support trustworthy AI development and use given the AI-specific trustworthiness requirements, still, it naturally does not achieve the level of detail (regarding requirements and guidance) that would be needed for a product-level certification, as outlined in the last chapter of the study [9]. To determine the additional guidance currently available that can inform the product-level choice of AI risk assessment criteria and treatment measures (e.g., as part of organizational risk identification, analysis and evaluation), I have recently studied relevant international frameworks for AI risk assessment and management. I am currently preparing a publication of this comparative study, particularly focusing on the underlying risk notion and the approach to risk aggregation and evaluation of these frameworks. For example, I found that quantitative modeling of risk is barely used and that the few frameworks which do so appear to oversimplify AI risks. Thus, a distinction should be made between horizontal frameworks that attempt to be valid for all kinds of AI applications (the current frameworks proposed by governments and those which are subject to standardization, for example, mostly fall into this category) and sector or use case-specific standards which could, complementarily, define weights and priorities of trustworthiness dimensions and concretize requirements for specific AI applications.

In addition to the publications I am currently preparing, I plan to conduct further case studies with real-world AI applications in my PhD. Currently, there are few empirical research contributions on how to implement »fairness« assessment in practice, although bottom-up case studies are a promising approach to substantiate the development of sector- or case specific assessment procedures and standards [8]. I will use case studies as an example base to identify common aspects (e.g., if specific technical bias indicators or evidence, criteria, or an argumentation scheme for AI fairness were commonly used and can be abstracted). To this end, I plan

to analyze which aspects of the technical procedure in the case studies actually depend on the specific use case, and to what extent the technical means and argumentative approach used (e.g., in the expert judgement on risk acceptance) can be generalized to a class of similar use cases while retaining concrete/tangible requirements. Based on the findings and using my results from the comparative studies mentioned, I plan to develop a method to address the operationalization gap described above (see central research question).

ACKNOWLEDGMENTS

The research under my PhD thesis is supported by the Ministry of Economic Affairs, Innovation, Digitalization and Energy of the State of North Rhine Westphalia as part of the flagship project ZERTIFIZIERTE KI (grant no. 005-2011-0048).

How and to which extent will the provisions of the Digital Services Act of the European Union impact on the relationship between users and platforms as information providers?

Matteo Fabbri
matteo.fabbri@imtlucca.it
IMT School for Advanced Studies
Lucca, Italy

ABSTRACT

In the contemporary information age, recommender systems (RSs) play a crucial role in determining the way in which people interact and obtain information online: in fact, from social media feeds to news aggregators and e-commerce websites, users are constantly targeted by personalized recommendations about what they may like. The Digital Services Act (DSA) of the European Union[1] [3], which is the first supranational regulation addressing automated recommendations specifically, defines a RS as "a fully or partially automated system used by an online platform to suggest in its online interface specific information to recipients of the service or prioritize that information, including as a result of a search initiated by the recipient of the service or otherwise determining the relative order or prominence of information displayed" (DSA, art. 3 (s)). This definition highlights the method ("fully or partially automated"), aim ("to suggest"), content ("specific information"), target ("recipients of the service"), input ("as a result of a search initiated by the recipient") and output ("determining the relative order or prominence of information displayed") of a recommendation process. As it can be observed, RSs are involved in the main aspects of online interactions, and this is why their influencing potential should not be underestimated. In fact, whilst RSs are aimed to improve user's experience by reducing the information overload, they can give rise to a variety of ethical concerns related to privacy, autonomy and fairness [5], to name but a few. However, independent research and users' access to the design and functioning of the RSs implemented on mainstream platforms is usually prevented by their proprietary status.

The DSA addresses this issue with a specific article, according to which "Providers of online platforms that use recommender systems shall set out in their terms and conditions, in plain and intelligible language, the main parameters used in their recommender systems, as well as any options for the recipients of the service to modify or influence those main parameters" (DSA, art.27 (1)). The aim of this provision is to "explain why certain information is suggested to the recipient of the service": therefore, the parameters need to include, at least, "the criteria which are most significant in determining the information suggested to the recipient of the service" (i.e., content) and the reasons for its "relative importance" (i.e., ranking) (DSA, art. 27 (2)). Additionally, when options to modify or influence the main parameters are stated in the terms and conditions, "providers of online platforms shall also make available a functionality that allows the recipient of the service to select and to modify at any time their preferred option" (DSA, art. 27 (3)). In order to make this requirement work in practice, "That functionality shall be directly and easily accessible from the specific section of the online platform's online interface where the information is being prioritised" (ibidem).

Article 27 of the DSA seems to be aimed at empowering users to influence the outcome of algorithmic recommendations. Therefore, this provision addresses four of the aspects of the definition of RS provided by Article 3: method, target, input and output. In particular, the traditionally passive role of the target could be reversed, as the recipient might determine the method (through the choice of parameters) and, indirectly, also the input (the type of data to be processed through the parameters) that the RS will use to produce its output. However, platforms are not obliged to be provide options for users to modify or influence the parameters if this possibility is not specified in the terms and conditions, and platforms arguably have no interest in providing this possibility voluntarily. Therefore, this article formally grants users the right to influence the recommendation process but only in some limited cases which are not likely to happen, as [4] point out. Moreover, the practical impact of these provisions will probably depend on users' ability to understand the structure and the policy of the algorithmic recommendations.

It should be noted that Recital 70 of the DSA outlines a wider scope for the provisions on RSs than what is included in Article 27: indeed, the statement that "online platforms should consistently ensure that recipients of their service are appropriately informed about how recommender systems impact the way information is displayed, and can influence how information is presented to them"[2] (DSA, recital 70) does not seem to be reflected in the actual provisions of Article 27, at least to the extent that the adverb "consistently" would entail. From this perspective, the right to explanation that could be identified in the "easily comprehensible manner" through which platforms "should clearly present the main parameters [...] to ensure that the recipients understand how information

[1] REGULATION (EU) 2022/2065 OF THE EUROPEAN PARLIAMENT AND OF THE COUNCIL of 19 October 2022 on a Single Market For Digital Services and amending Directive 2000/31/EC (Digital Services Act).

[2] The right to information outlined here is mirrored by Article 13-15 of the GDPR.

is prioritised for them" (DSA, recital 70) might not lead to a real users' empowerment.

However, given the consequences that this recently enforced regulation can have both on the business of online platforms and on the self-determination of users, my research aims at understanding how and to which extent the DSA provisions will impact on the relationship between users and platforms as information providers, especially for what concerns their status as prominent stakeholders in the recommendation process [6] To help enforce the new requirements, the European Commission has recently established the European Centre for Algorithmic Transparency (ECAT), which will assess "whether very large online platforms and search engines comply with their obligations under the Digital Services Act", including by carrying out inspections at the platforms' premises to analyse "the design, functioning and impact of advanced algorithms, like recommender systems, in their production environments" [1]. Taking the opportunities provided by the implementation of the DSA, my research will involve three main stages. Firstly, a preliminary scoping phase will involve examining the connection between the aim of the regulatory requirements presented above and the ethical issues around RSs and digital nudging identified in my past research. Secondly, I will analyse the documents that would become available as a result of public inspections, audits and assessments of RSs, and compare the findings of such review with the impact of other regulations on RSs, like the Internet Information Service Algorithmic Recommendation Management Provisions of the People's Republic of China [2]. This comparative perspective may help account for the new constraints and changes concerning the implementation of RSs across the world. Thirdly, I will develop a survey-based user study to understand whether and how the availability of explanations and the opportunity to modify RSs provided by the DSA impact on the way in which users interact with online platforms. This project has a timespan of two to three years, depending on the timeliness of the release of documents that digital companies and public officials will make available and accessible by researchers. The expected result of this research is an initial map of the ethical and societal implications of the enforcement of the DSA on the transparency of proprietary RSs and the subsequent application of fundamental rights for users' autonomy and self-determination.

Towards a Holistic Approach: Understanding Sociodemographic Biases in NLP Models using an Interdisciplinary Lens

Pranav Narayanan Venkit
Pennsylvania State University
University Park, Pennsylvania, USA
pranav.venkit@psu.edu

ABSTRACT

The rapid growth in the usage and applications of Natural Language Processing (NLP) in various sociotechnical solutions has highlighted the need for a comprehensive understanding of bias and its impact on society. While research on bias in NLP has expanded, several challenges persist that require attention. These include the limited focus on sociodemographic biases beyond race and gender, the narrow scope of analysis predominantly centered on models, and the technocentric implementation approaches.

This paper addresses these challenges and advocates for a more interdisciplinary approach to understanding bias in NLP. The work is structured into three facets, each exploring a specific aspect of bias in NLP. The **first facet** focuses on identifying sociodemographic bias in various NLP architectures, emphasizing the importance of considering both the models themselves and human computation to comprehensively understand and identify bias. In the **second facet**, we delve into the significance of establishing a shared vocabulary across different fields and disciplines involved in NLP. By highlighting the potential bias stemming from a lack of shared understanding, this facet emphasizes the need for interdisciplinary collaboration to bridge the gap and foster a more inclusive and accurate analysis of bias. Finally, the **third facet** investigates the development of a holistic solution by integrating frameworks from social science disciplines. This approach recognizes the complexity of bias in NLP and advocates for an interdisciplinary framework that goes beyond purely technical considerations, involving social and ethical perspectives to address bias effectively.

The **first facet** includes the following of my published works [6–9] to provide results into how the importance of understanding the presence of bias in various minority group that has not been in focus in the prior works of bias in NLP. The work also shows the need to create a method that considers both human and AI indicators of bias, showcasing the importance of the first facet of my research. In my study [9], I delve into sentiment analysis and toxicity detection models to identify explicit bias against race, gender, and people with disabilities (PWDs). Through statistical exploration of conversations on social media platforms such as Twitter and Reddit, I gain insights into how disability bias permeates real-world social settings. To quantify explicit sociodemographic bias in sentiment analysis and toxicity analysis models, I create the Bias Identification Test in Sentiment (BITS) corpus[1]. Applying BITS, I uncover significant biases in popular AIaaS sentiment analysis tools, including TextBlob, VADER, and Google Cloud Natural Language API, as well as toxicity analysis models like Toxic-BERT. Remarkably, all of these models exhibit statistically significant explicit bias against disability, underscoring the need for comprehensive understanding and mitigation of biases affecting such groups. The work also demonstrates the utility of BITS as a model-independent method of identifying bias by focusing on social groups instead.

Expanding on this, my next work [8] delves into the realm of *implicit bias* in NLP models. While some models may not overtly exhibit bias, they can unintentionally perpetuate harmful stereotypes [4]. To measure and identify implicit bias in commonly used embedding and large language models, I propose a methodology to measure social biases in various NLP architectures. Focusing on people with disabilities (PWD) as a group with complex social dynamics, I analyze various word embedding-based and transformer-based LLMs, revealing significant biases against PWDs in all tested models. These findings expose how models trained on extensive corpora tend to favor ableist language, underscoring the urgency of detecting and addressing implicit bias. The above two works look at both the implicit and explicit nature of bias in NLP, showcasing the need to distinguish the efforts placed in understanding them. The results also demonstrate the utility of identifying such biases as it provides context to the black-box nature of such public models.

As the field of NLP evolved from embedding-based models to large language models, the way these models are constructed underwent significant changes [5]. However, the concern arises from the fact that these models often reflect a *populist* viewpoint [1] that perpetuates majority-held ideas rather than objective truths. This difference in perception can lead to biases perpetuated by the majority's worldview. To explore this aspect, I investigate how LLMs represent nationality and their impact on societal stereotypes [6]. By examining LLM-generated stories for various nationalities, I establish a correlation between sentiment and the population of internet users in a country. The study reveals the unintentional implicit and explicit nationality biases exhibited by GPT-2, with nations having lower internet representation and economic status generating negative sentiment stories and employing a greater number of negative adjectives. Additionally, I explore potential debiasing methods such as adversarial triggering and prompt engineering, demonstrating their efficacy in mitigating stereotype propagation through LLM models.

While prior work predominantly relies on automatic indicators like sentiment scores or vector distances to identify bias [3], the next

https://doi.org/10.1145/3600211.3604754

phase of my research emphasizes the importance of understanding biases through the lens of human readers [7], bringing to light the need for a human lens in understanding bias through human-aided indicators and mixed-method identification. By incorporating concepts of social computation, using human evaluation, we gain a better understanding of biases' potential societal impact within the context of language models. To achieve this, I conduct open-ended interviews and employ qualitative coding and thematic analysis to comprehend the implications of biases on human readers. The findings demonstrate that biased NLP models tend to replicate and amplify existing societal biases, posing potential harm when utilized in sociotechnical settings. The qualitative analysis from the interviews provides valuable insights into readers' experiences when encountering biased articles, highlighting the capacity to shift a reader's perception of a country. These findings emphasize the critical role of public perception in shaping AI's impact on society and the need to correct biases in AI systems.

The **second facet** of my research aims to bridge the disparity between AI research and society. This disparity has resulted in a lack of shared understanding between these domains, leading to potential biases and harm toward specific groups. Employing an interdisciplinary approach that combines social informatics, philosophy, and AI, I will investigate the similarities and disparities in the concepts utilized by machine learning models. Existing research [2] highlights the insufficient interdisciplinary effort and motivation in comprehending social aspects of NLP. To commence this exploration, I will delve into the shared taxonomy of *sentiment* and *fairness* in natural language processing, sociology, and humanities. This research will first delve into the interdisciplinary nature of sentiment and its application in sentiment analysis models. Sentiment analysis, a popular machine learning application for text classification based on sentiment, opinion, and subjectivity, holds significant influence as a sociotechnical system that impacts both social and technical actors within a network. Nevertheless, the definition and connotation of sentiment vary vastly across different research fields, potentially leading to misconceptions regarding the utility of such systems. To address this issue, this study will examine how diverse fields, including psychology, sociology, and technology, define the concept of sentiment. By unraveling the divergent perspectives on sentiment within different fields, the paper will uncover discrepancies and varying applications of this interdisciplinary concept. Additionally, the research will survey commonly utilized sentiment analysis models, aiming to comprehend their standardized definitions and associated issues. Ultimately, the study will pose critical questions that should be considered during the development of social models to mitigate potential biases and harm stemming from an insufficiently defined comprehension of fundamental social concepts. Similar efforts will be dedicated to comprehending the disparity in bias and fairness as an interdisciplinary concept, shedding light on the imperative for inclusive research to cultivate superior AI models as sociotechnical solutions.

The **third facet** of my study embarks upon an exploration of the intricate interplay between human and AI actors, employing the formidable theoretical lens of actor-network theory (ANT). Through the presentation of a robust framework, this facet aims to engender the formation of efficacious development networks that foster collaboration among developers, practitioners, and other essential stakeholders. Such inclusive networks serve as crucibles for the cultivation of holistic solutions that transcend the discriminatory trappings afflicting specific populations. A tangible outcome of this endeavor entails the creation of an all-encompassing bias analysis platform, poised to guide the discernment and amelioration of an array of sociodemographic biases manifesting within any machine-learning system. By catalyzing the development of socially aware and less pernicious technology, this research makes a substantial contribution to the realms of NLP and AI.

The significance of this proposed research reverberates beyond the confines of NLP, resonating throughout the broader domain of AI, wherein analogous challenges about social biases loom large. Leveraging the proposed framework, developers, practitioners, and policymakers are empowered to forge practical solutions that embody inclusivity and reliability, especially when used as a service (AIaaS). Moreover, the platform serves as a centralized locus for the identification and rectification of social biases, irrespective of the underlying model or architecture. By furnishing a cogent narrative that underscores the imperative for a comprehensive and interdisciplinary approach, my work strives to propel the ongoing endeavors to comprehend and mitigate biases within the realm of NLP. With its potential to augment the equity, inclusivity, and societal ramifications of NLP technologies, the proposed framework catapults the field towards responsible and ethical practices.

1 BACKGROUND

In the last decade, extensive research studies have demonstrated the prevalence of demographic biases in machine learning systems, due to a lack of representation in training datasets [10]. Most notably, in the domain of face analysis, standard face datasets include very few images of individuals with darker skin tones, and researchers have determined that commercial gender classification models have much higher error rates for women with darker skin tones [3]. However, facial recognition continues to be used widely: from identity verification in mobile devices to public surveillance in certain countries, many people interact with these systems in their day-to-day lives [8]. While some argue for the complete removal of facial recognition techologies [2], the use of these technologies may not disappear. As such, opponents of face recognition along with the developers of these systems may both benefit from a careful analysis of how the demographic makeup of training datasets may impact a model's performance on various demographic groups.

In order to remedy past data representation bias, researchers have developed several new benchmark face recognition datasets that are balanced along demographic attributes such as gender or race [13, 15]. However, these balanced datasets do not completely solve model bias as accuracy disparities still persist [16]. For example, the optimal allocation of training data by race or gender is not always the equally-balanced allocation: Gwilliam et al. [6] find that a balanced training set (with equal number of samples per racial group) obtains a higher accuracy variance across groups but the same overall accuracy compared to another training data allocation.

Additionally, curating new datasets requires time and resources, and can intrude upon the subpopulation being studied [11]. It is also incredibly time-consuming to train models on all possible allocations of racial groups in order to find some "optimal" allocation. Rather than searching for the best subgroup allocation for a training set of a fixed size, companies may prefer a greedy solution — a solution in which new data is added in an add-only manner.

2 RESEARCH QUESTIONS

Hence, we focus on the following goal: to examine *additional data collection* and its impacts on the performance of various demographic groups.

Consider the following scenario: an entity (e.g., a company or a group of researchers) trains a face recognition model using some initial training dataset which lacks data from some racial group. Upon evaluation on held-out test data or due to an external bias audit, the company realizes their performance lags on that group, and now wishes to collect more data from the omitted group. They have the budget to collect only a fixed number of samples and have limited resources to train additional models (and, perhaps, can only train one other model). This process closely follows several corporations' past responses detailed in Raji and Buolamwini [12] and allows us to pose these research questions:

(1) How does additional data from the underrepresented group change the test performance for that particular group, as well as the test performance for other groups?
(2) How does data collection targeted towards improving the group with the lowest initial performance impact that group's test performance and overall group differences, in comparison to introducing data from other racial groups?
(3) Are our results consistent across racial groups, datasets, and models?

3 CURRENT WORK

To answer these questions, we developed an empirical framework to evaluate the performance impact of data augmentation by demographic subgroup. For our framework and analyses, we focused on *one-to-one facial recognition*: given two images of faces, a one-to-one facial recognition system is designed to determine whether or not those two images are of the same person. We implemented this framework for three racially-annotated datasets (BFW [13], BUPT [14, 15], and VMER [5]) and three state-of-the-art face recognition models (SE ResNet [4], CenterLoss [17], and SphereFace [9]). We summarize the main empirical findings below:

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604752

(1) The introduction of samples from some racial group X improves the performance for every racial group that we tested. (Different datasets use different terms. Using the terms in the source datasets, e.g., for BUPT [14, 15], we considered images labeled as African, Asian, Caucasian, or Indian.)
(2) The addition of data from the lowest-performing group improves that group's performance the most and closes performance gaps across racial groups, in comparison to the addition of data from other groups. This empirically validates the theoretical finding in Abernethy et al. [1] that additively sampling from the worst-off group converges to a min-max fairness solution.
(3) Increasing data from the highest-performing group X widens performance disparities, regardless of whether the initial training dataset contained images from group X, a specific counter to the notion that more data and more representation reduces discrimination.
(4) The above findings are *consistent* across all datasets and models we examined, while some findings are *different* across different datasets and models.

That some findings are *different* across different datasets and models — i.e., that some of our findings are *not* generalizable from the analysis of only a single dataset — speaks to the criticality of analyzing the full pairing of datasets and models. For example, based on our findings, we encourage future works that introduces new datasets to re-apply our methodology (and others) as benchmarks to evaluate those datasets with known face recognition models.

4 FUTURE WORK

The results from our current work motivate several interesting explorations that we plan to pursue further.

4.1 Theoretical direction

In our experiments, we found that in some cases introducing a group markedly improved performance across all groups. We hope to better understand under what conditions adding from particular groups will generalize across various other demographic groups. We plan to use statistical learning theory techniques in order to model group distributions and formalize how neural networks learn the input-label relationship for the subspace from a particular group. This would allow us to also extend from face recognition to other machine learning tasks.

4.2 Subsampling and reweighting methods

In addition, we plan to design and run additional experiments in order to compare how additional data collection performs to other pre-processing techniques such as subsampling and reweighting. In the field of machine learning robustness, Idrissi et al. [7] show that subsampling and reweighting across groups obtains state-of-art accuracy; we plan to investigate this finding in relation to group fairness domains such as racial bias in face recognition.

Individual and Group-level considerations of Actionable Recourse

ABSTRACT

The advent of machine learning in several critical fields, such as banking, healthcare, and criminal justice, has inspired research into improving robustness, trustworthiness, and transparency in the models. *Actionable Recourse* is one such tool that enables the negatively impacted users to receive a favorable outcome by providing recommendations of cost-efficient changes to their features. Current recourse methodologies optimize for proximity, sparsity, validity, and distance-based costs. Actionability takes both individual and group-level signals. A critical component of actionability is the consideration of *User Preference* to guide the recourse generation process. These preferences can take several forms, and we introduce three such preferences to capture the individual difficulty of user actions. Additionally, feasibility and plausibility should be considered as a fixed set of pre-specified constraints. We argue that plausibility draws strong signals from group-level population information, which must be considered to achieve low-cost recourses across protected groups. Recoursability is an active research area, and plausibility becomes an essential direction for further research.

1 INTRODUCTION

Actionable Recourse (AR) [9] refers to a list of actions an individual can take to obtain a desired outcome from a fixed Machine Learning (ML) model. Several domains such as lending [8], insurance [7], and hiring decisions [1] are required to suggest recourses to ensure the trust of a decision system; in such scenarios, it is critical to ensure the actionability (the viability of taking a suggested action) of recourse.

Consider an individual named Alice who applies for a loan, and a bank, which uses an ML-based classifier, denies it. Naturally, Alice asks - *what action must she take to obtain the loan in the future?* Several methods exist to identify counterfactual explanations, such as FACE [6], which uses the shortest path to identify counterfactual explanations from high-density regions, and Growing Spheres (GS) [2] which employs random sampling within increasing hyperspheres for finding counterfactuals. Similarly, manifold-based CCHVAE [5] generates high-density counterfactuals using a latent space model.

However, there is often no guarantee that the *what-if* scenarios identified by these methods are attainable. Alice's personal constraints may also limit her ability to act on certain suggested recourses (such as a strong reluctance to secure a co-applicant). Existing research focuses on providing feasible recourses, yet comprehensive literature on understanding and incorporating user preferences within the recourse generation mechanism still needs to be developed. It is worth mentioning that instead of understanding user preferences, Mothilal et al. [4] provides a user with diverse recourse options and hopes that the user will benefit from at least one.

This research focuses on improving the societal impacts of actionable recourse by strategically capturing preferential signals at the individual and group levels. These signals are crucial for both the overall benefit of an individual as well as improving the trustworthiness and transparency of (opaque) machine learning models.

2 CAPTURING INDIVIDUAL USER PREFERENCES

Localized constraints, which we call *User Preferences*, are synonymous to user-level constraints introduced as *local feasibility* by Mahajan et al. [3]. Figure 1 illustrates the motivation behind personalized recourses. Here two similar individuals, Alice and Bob, can have contrasting preferences leading to varying recourse space. Hence, identifying a recourse by optimizing over the universal cost function may not give us equalized actionability. A hypothetical example of idiosyncrasies in individually preferred recourses is shown in Table 1.

We propose to capture Alice's three types of user preferences, namely: i) *Scoring continuous features*, ii) *Ranking categorical features*, and iii) *Bounding feature values*, and embed them into an optimization function for guiding the recourse generation mechanism. Such a transparent mechanism also builds trust in decision-making by enabling adversely affected individuals to maneuver the recourse generation process. With our experiments on real-world

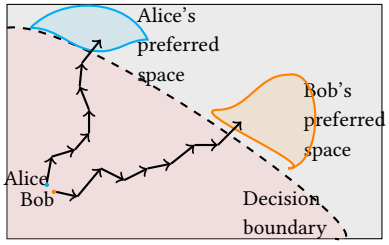

Figure 1: Similar individuals Alice and Bob, with contrasting preferences, can have different regions of desired recourse space.

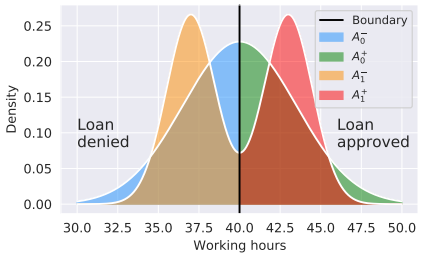

Figure 2: Demonstration of distributional differences at group level, which leads to contrasting actionability for standard low-cost recourses.

Features	Preferred recourse	
	Alice	Bob
LoanDuration	8	17
LoanAmount	$1840	$1200
HasGuarantor	0	1
HasCoapplicant	1	0

Table 1: A hypothetical actionable feature set of adversely affected individuals sharing similar features and corresponding suggested actions.

datasets, we show that our proposed recourse methodology adheres to user preferences. We provide theoretical and experimental evaluations of our strategy and compare the results against state-of-the-art methodologies. This work motivates further research on how truthful reporting of preferences can help improve overall user satisfaction.

3 ENSURING EQUALIZED GROUP-LEVEL PLAUSIBILITY

Traditional *equalized group recourse costs* fails under particular distributional idiosyncrasies. Figure 2 illustrates a motivating toy scenario of distributional differences. Low variance bi-modal distributions of the approved and denied sub-populations of the group A_1 are distinguished from the high variance uni-modal distribution of group A_0. The average cost of recourse for the disadvantaged group (A_1) is similar to the advantaged group (A_0), but the recourse suggested to (A_1) are far from the positively classified manifold. For instance, consider that Alice is a single mom who was also adversely affected by the bank's decision. Observing her approved counterparts, Alice may ask, "*What actions can I take to be part of the approved sub-group of people with my socioeconomic background?*" The recourse by the bank suggests increasing her working hours from 32 per week to 40 per week. Considering that she belongs to the sub-population of *denied single parent*, the recourse may not be actionable, as she may not have the flexibility of increasing her working hours per week. She is more likely to consider taking a second *remote job* instead. Hence, it becomes essential that the recourse suggested to her must identify specific, actionable steps in agreement with the *approved single parent* sub-population for improved feasibility.

We quantify *plausibility* of recourse with respect to the approved sub-population of the individual's group and leverage to improve upon the plausibility of a counterfactual. Our work aims to identify domain-dependent critical blind spots in existing fairness metrics for algorithmic recourse, particularly the plausibility of recourse suggestions across protected groups. Our preliminary experiments show the existence of *plausibility bias* across protected groups such as *gender* and *race*. We provide a constrained optimization-based solution to maximize the plausibility of the suggested recourse, while our *plausibility score* metric can also be leveraged to train models with *equalized group level recourse plausibility*.

4 FUTURE WORK

Existing systems use a universal distance metric to capture the difficulty of acting upon the suggested recourse. Our research motivates further work into techniques for capturing true recourse cost at an individual level. Further, fairness is not limited to equalized cost across groups due to the highly personalized nature of the cost of actions, and we encourage further work in this direction. We argue that models developed by considering the proposed perspectives will have significantly improved effects on the overall upliftment of society.

1 INTRODUCTION

Social science fields such as psychology traditionally rely on manual, qualitative coding for behavioural observations [4]. This process involves manual, laborious, time-consuming, and error-prone efforts, presenting a significant challenge to the scalability of social scientific research in fast-paced settings [1].

The integration of Natural Language Processing (NLP) and Machine Learning (ML) in the social sciences offers an opportunity to overcome these limitations. This thesis applies these techniques to automatically detect predatory behaviour in online interactions, a growing concern with societal implications. The specific questions I ask throughout this work are as follows:

(1) How can computational techniques be used to overcome the limitations of expert labelling?
(2) Do machines perform comparably with humans?
(3) Can an automated solution explore theories of social behaviour at scale?

In the remainder of this extended abstract, I outline the work covered in my doctoral studies. Section 2 examines the domain problem. Section 3 describes the computational methods used, and Section 4 presents the main findings. Section 5 describes the thesis contributions, and Section 6 outlines this work's ethical and societal implications. Finally, Section 7 reports future work in this area.

*This work was completed while the author was affiliated with the University of Liverpool, UK. The author's affiliation has since changed to Imperial College London, UK.

2 BACKGROUND AND RELATED WORK

In the digital era, online safety has emerged as a significant concern [7]. Unfortunately, the proliferation of online communication platforms has increased opportunities for predatory behaviour. Law enforcement agencies take the responsibility of monitoring these platforms to detect potential threats and safeguard vulnerable individuals. However, conventional methods often involve manually monitoring suspected individuals[1]. This process is both time-consuming and cognitively demanding.

A common approach in the manual monitoring of online chats for potentially predatory behaviour has involved detecting key phrases, such as sexually explicit language [11]. While dictionary-based approaches such as this can identify certain instances of inappropriate behaviour, it also captures many false positives [9] - individuals who may use sexually explicit language but are not engaged in predatory grooming. More concerning is that keywords can miss subtle techniques from predators who adopt a phased approach, initially building trust and establishing rapport with potential victims without relying on sexually-explicit talk [13].

A more nuanced understanding of the psychology of the grooming process is required for effective detection of predatory behaviour. Theories developed and validated by forensic psychologists are fundamental in this regard. Behaviours such as establishing rapport, creating an illusion of control, normalising an inappropriate relationship, and personal risk management by the offender align more closely with predatory behaviour patterns [6]. However, the challenge lies in identifying these psychological behaviours at scale, as they require expert training to detect and are often hard to define [2]. Even among experts, the presence of these behaviours in a particular interaction can be subject to considerable debate.

Automated qualitative coding can offer a scalable alternative to conventional manual annotation performed by domain experts. A language model suitably trained on expert annotations could detect similar behaviours within a massive unlabelled corpus, allowing for more efficient and expansive monitoring of online interactions.

However, this approach has its own set of challenges. Acquiring expert annotated data for training a language model is non-trivial [5]. Furthermore, the inherent subjectivity of expert-generated labels presents challenges for establishing objective ground truth [8], notably when working with hard-to-define behaviours that require a holistic or 'Gestalt' felt sense to identify. The inherent ambiguity and disagreement among annotators present a considerable challenge when training deep learning models [12].

Thus, while automated qualitative coding presents a promising direction for enhancing online safety, its practical implementation requires careful consideration of the complexities and nuances

[1]From a discussion with the head of a UK-based online child safety organisation.

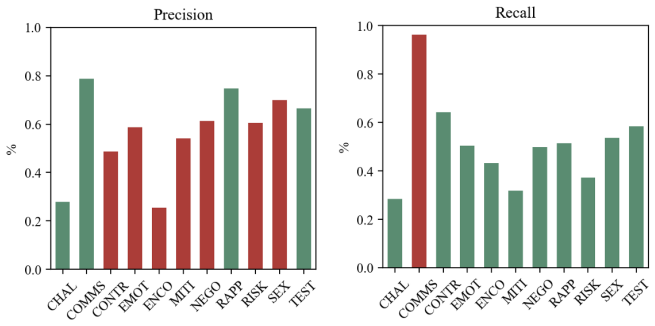

Figure 1: Precision (L) and Recall (R) of each label when trained using the full training set. Green bars exceeded the baseline (a cross-validated Random Forest per label).

inherent in identifying predatory behaviour. This thesis, therefore, explores aspects that lend themselves well to automation and those tasks that require continued human intervention. The overarching view emphasises Human-AI collaboration to embrace the efficiency enabled by computation without sacrificing human oversight.

3 RESEARCH METHODS

The research comprised within the thesis is based on an analysis of 1.3 million chat messages obtained from the online repository Perverted Justice[2], featuring interactions between convicted offenders and decoys posing as underage victims. Two forensic psychology experts annotated approximately 7000 messages with eleven distinct behaviour labels. Using a version of `RoBERTa` [10] fine-tuned for Natural Language Inference (NLI) on the annotated data, classification performance was assessed for each of the eleven behaviour labels on a holdout-set. Different task variations included zero-shot and few-shot conditions. In a later analysis to improve model performance, the thesis included a human-in-the-loop approach based on weak supervision [3].

4 RESULTS

A central finding of this study was that a suitably trained model exceeded the baseline recall for most labels. However, only a third of these labels exceeded the baseline precision. Figure 1 illustrates performance of each label when trained on the full training set. F1 performance did increase for all labels in few-shot compared with zero-shot settings. Evidence indicates performance of $F1 > .5$ is possible with as few as fifty annotations for some labels.

Collaborative Human-AI was then used to improve precision. This step allowed a human annotator to reject a positive classification made by the model. The results of this step indicated near-perfect precision for all behaviours, although recall remained poor for some rare labels. In addition to this finding, the proposed Human-AI collaboration increased annotation efficiency compared to wholly manual methods by a factor of fifteen.

5 CONTRIBUTIONS

The thesis offers several contributions to the topic of automated behaviour coding in the context of online safety:

- I demonstrate the efficacy of an automated approach in identifying predatory behaviours online, advancing the field of automated behaviour coding.
- The approach combines computational techniques with psychological theories, offering a new way of studying social behaviours at scale, thus contributing to computational social science.
- By identifying predatory behaviours more efficiently, the research contributes to online safety efforts, particularly in protecting minors from online predation.
- The work showcases an effective model of Human-AI collaboration, where AI's efficiency is combined with human expertise to improve social behaviour detection.

6 ETHICAL AND SOCIETAL IMPLICATIONS

The thesis has several ethical and societal implications:

- The approach highlights the utility of synthesising the social and computational sciences to tackle real-world issues.
- The findings underscore the need for transparency in AI, particularly for detecting complex social behaviours.
- By proposing a model of Human-AI collaboration, the research stresses the importance of human oversight in AI applications, which is crucial for ensuring ethical AI use.

7 FUTURE WORK

There is considerable potential for future work in this area. Refinement and clarity of the behaviour labels is one such improvement that is currently underway. Additionally, improvements to the NLI set-up, such as more relevant hypothesis statements, or use of prompt engineering, might provide better context for the language model. Modern language models such as GPT-4 are also worth exploring. Furthermore, the inclusion of non-predatory chats into the corpus would also enable an evaluation of how well these methods can separate predatory from everyday dialogue.

ACKNOWLEDGMENTS

To the University of Liverpool, notably the Institute for Risk and Uncertainty, for providing the resources and environment that were instrumental in completing this research. Special mention to Prof. Simon Maskell and Prof. Laurence Alison for supervising the thesis, and to the two forensic psychology experts who manually annotated the chat logs.
