Welcome!

We are delighted to welcome you to the 2023 *AAAI / ACM Conference on Artificial Intelligence, Ethics, and Society – AIES 2023* in Montreal, Canada.

Artificial Intelligence (AI) is increasingly pervasive, powerful, and contested. While AI has the potential to empower individuals and improve society, the ethical ramifications of AI systems and their impact on human societies requires deep and urgent reflection. International organizations, governments, universities, corporations, and philanthropists have recognized this need to embark on an interdisciplinary investigation to help chart a course through the new territory enabled by AI. As has been noted by past program chairs, earlier iterations of this conference and others have seen the first fruits of these calls to action, as programs for research have been set out in many fields relevant to AI, Ethics, and Society.

The AIES conference is convened each year by the AIES Steering Committee and its technical program is designed by program co-chairs from Computer Science, Law and Policy, the Social Sciences, Ethics and Philosophy. Our goal is to encourage talented scholars in these and related fields to present and discuss the best work related to morality, law, policy, psychology, the other social sciences, and AI. In addition to the community of scholars who have participated in these discussions from the outset, we explicitly welcome disciplinary experts who are newer to this topic, and see ways to break new ground in their own fields by thinking about AI.

AIES 2023 received 237 submissions to the main track. Papers were reviewed by members of the program committee, and final decisions were made by the program co-chairs in consultation with the program committee members who reviewed each paper. We made a serious effort to ensure that each paper was reviewed by a team with sufficient expertise to give that paper a thorough evaluation. We decided to accept 68 papers, one of which was later withdrawn, so these Proceedings contain the remaining 67. In addition, students accepted to the student program had the option of publishing an abstract of their work, and we are excited to be able to feature 31 of these in the Proceedings.

We have three keynote speakers scheduled. Annette Zimmermann of the University of Wisconsin will speak on “The Generative AI Deployment Rush: How to Democratize the Politics of Pace.” Jamie Morgenstern of the University of Washington and Amazon will speak on “Changing Distributions and Preferences in Learning Systems.” Paola Ricaurte Quijano of Tecnologico de Monterrey and the Berkman Klein Center for Internet & Society at Harvard University will speak on “AI for/by the Majority World: From Technologies of Dispossession to Technologies of Radical Care.”. In addition, we will have a keynote panel, moderated by Program Co-Chair Alex John London of Carnegie Mellon University, on “Large Language Models: Hype, Hope, and Harm.” The panel will feature Roxana Daneshjou of Stanford University, Atoosa Kasirzadeh of the University of Edinburgh, Kate Larson of the University of Waterloo, and Gary Marchant of Arizona State University.

Organizing AIES would not have been possible without the contributions of many people. Francesca Rossi has been a model leader as Conference Chair. Theodore Lechterman, Su Lin Blodgett, Wenbin Zhang, and Brent Venable have put tremendous energy into organizing the student program. Gaurab Pokharel and Tasfia Mashiat were of great help in the innumerable tasks involved in organizing the paper reviewing and selection process. Francisco Cruz provided invaluable support for our web presence. Marc-Antoine Dilhac has graciously helped us with local organization and involving Mila, Vince Conitzer was always available for advice, and none of this would have been possible without the incredible organizational abilities of Meredith Ellison and Chesley Grove at AAAI.

AIES is co-sponsored by ACM SIGAI and AAAI. We are grateful for financial support from several corporate and nonprofit sponsors, the US National Science Foundation, and ACM SIGAI. This support allows us to keep costs low for attendees, as well as allowing many students to attend who would otherwise not have been able to.

Finally, the biggest thanks must go to the authors who submitted papers, the program committee members who spent countless hours thoughtfully reviewing them, as well as the broader AIES community, who keep working on and thinking about the important questions. We are grateful for this opportunity to support the community in its goals, and look forward to sharing an experience in Montreal that is both intellectually rich and of genuine importance in the world today.

Annette Zimmermann. 2023. The Generative AI Deployment Rush: How to Democratize the Politics of Pace. In *AAAI/ACM Conference on AI, Ethics, and Society (AIES '23), August 08–10, 2023, Montréal, QC, Canada.* ACM, New York, NY, USA, 1 page. https://doi.org/10.1145/3600211.3607545

The most recent wave of generative AI deployment has rapidly accelerated its pace over the past months. This has prompted a cluster of competing and controversial responses from tech industry practitioners and the wider public: on the one hand, those that call for temporary deployment moratoria, and on the other hand, those that resist blunt restrictions on deployment itself, but instead propose different mechanisms for subjecting AI deployment to regulation, such as through oversight and safety review via newly created institutions, or through licencing requirements that would-be deployers must meet.

Each one of these positions—as different as they may be—is *unusual*, because each one seems to signal a significant and philosophically interesting departure from a formerly widely shared attitude amongst technology industry practitioners: the view that prioritizing deployment speed, that 'moving fast and breaking things', is a non-negotiable requirement for enabling innovation. Thus, the reasoning used to be, rapidly paced AI deployment must not be unduly constrained, neither by heavy-handed bans, nor by more restrictive regulation. In contrast to that view, these recent responses ostensibly all suggest a more cautious approach towards rapid, large-scale AI deployment.

This apparent shift in industry attitudes about the appropriate pace of deployment may well align with existing attitudes of parts of the wider public. However, this shift alone does not negate the fact that the brute *ability* to deploy quickly and at scale still lies primarily with a relatively small number of corporate actors benefitting from a significant concentration of wealth and power. Importantly, this creates a deployment dynamic in which technology companies get to dictate the pace of AI deployment first, putting citizens and governments in a position of merely being able to *react ex post* to industry decisions to deploy. This deployment dynamic sustains a *politics of pace* that continues to insulate corporate actors from meaningful democratic control.

This talk extends conceptual and normative work in political philosophy to develop and defend the view that the question of which AI tools get deployed at scale, and—crucially—how quickly, is a fundamentally political problem. In order to identify suitable solutions to this problem that align with core democratic values, democratic constituencies must regain control over decisions affecting deployment pace. This talk critically evaluates competing possible strategies for achieving that goal.

Changing distributions and preferences in learning systems

Jamie Morgenstern
University of Washington and Amazon

ABSTRACT

In this talk, I'll describe some recent work outlining how distribution shifts are fundamental to working with human-centric data. Some of these shifts come from attempting to "join" datasets gathered in different contexts, others may be the result of people's preferences affecting which data they provide to which systems, and even more can arise when peoples' preferences themselves are shaped by ML systems' recommendations. Each of these types of shift require different modeling and analysis to more accurately predict the behavior of ML pipelines deployed in a way where they interact repeatedly with people who care about their predictions.

1 BIO

Jamie is an assistant professor in the Paul G. Allen School of Computer Science & Engineering at the University of Washington. She was previously an assistant professor in the School of Computer Science at Georgia Tech. Prior to starting as faculty, she was hosted by Michael Kearns, Aaron Roth, and Rakesh Vohra as a Warren Center fellow at the University of Pennsylvania. She completed her PhD working with Avrim Blum at Carnegie Mellon University. Her work studies the social impact of machine learning and the impact of social behavior on ML's guarantees. How should machine learning be made robust to behavior of the people generating training or test data for it? How should ensure that the models we design do not exacerbate inequalities already present in society?

AI for/by the majority world: From technologies of dispossession to technologies of radical care

Paola Ricaurte
pricaurt@tec.mx
Tecnologico de Monterrey
Monterrey, Nuevo Leon, Mexico
Harvard University
Cambridge, USA

ABSTRACT

The dominant and celebratory discourse surrounding AI often fails to acknowledge the intricate dynamics and implications associated with the human, material, and environmental costs of technological development, particularly in the midst of a civilizational crisis [5]. Furthermore, hegemonic AI, primarily developed by large technology corporations, capitalizes on the resources, data, and labor of the majority world only to be deployed as a glamorous product that furthers the accumulation of privilege, wealth, and power by global elites. As a result, these hegemonic intelligent technologies originate from a predatory and violent world model that has been imposed as a universal paradigm of existence. These dominant technologies are intentionally designed to perpetuate power asymmetries. The so-called artificial intelligence, marketed as a revolutionary innovation, has proven to be the offspring of interconnected systems of oppression: a capitalist mode of production; a colonial system of epistemic, economic, social, racial, and cultural dominance; and a patriarchal order of violence that fulfills its own prophecy [10]. Artificial intelligence, driven by influential global actors with market-driven and war-driven interests, materializes as a socio-technical assemblage that optimizes capital accumulation through dispossession [3] and the exertion of violence over the territories and populations of the majority world [8]. Hegemonic AI technologies are fundamentally technologies of dispossession, appropriating the commons for their development. Their creation is governed by macro-structural forces guided by the market and powerful actors seeking control, as control is a prerequisite for wealth accumulation. Control encompasses natural resources (territory), knowledge (processing information and data), labor (productive force), bodies (labor and the capacity to produce knowledge), subjectivity (sensibility and identity), and intersubjective relations (ways of relating, living, and coexisting) [7]. Dispossession arises from the interconnections of violent systems operating at both micro and macro scales. Dispossession manifests throughout the entire lifecycle of AI, spanning from design and development to deployment, use, and disposal [6]. The human, material, and environmental costs associated with technological development are obscured by narratives emphasizing efficiency, optimization, and the automation of the world. Big capital, including finance, pharmaceuticals, agribusiness, mining, and technology, forms alliances to control global value chains and knowledge production systems, ensuring that the ultimate benefits remain concentrated in the hands of a few. Concentration of power, wealth, and knowledge widens the gaps between individuals, communities, countries, and regions, erasing them physically, socially, and epistemically. As the gap continues to widen due to the accelerating momentum of production and capitalist accumulation, the depletion of the planet's resources and life-supporting systems draws nearer. To dismantle socio-technically mediated systems of violence, it is imperative to address power imbalances and rediscover the fundamental relational nature of existence. Alternative models of the world and dignified futures necessitate alternative models of technological development that are grounded in values associated with a radical ethics of care [1], communality [2], conviviality [4], and shared responsibility for the consequences of human impact on the planet [9].

ABSTRACT

The growing popularity of social media raises concerns about children's online safety. Of particular concern are interactions between minors and adults with predatory intentions. Unfortunately, previous research on online sexual grooming has relied on time-intensive manual annotation by domain experts, limiting both the scale and scope of possible interventions. This work explores the possibility of detecting predatory behaviours with accuracy comparable to expert annotators using machine learning (ML). Using a dataset of 6771 chat messages sent by child sex offenders, labelled by two of the authors who are forensic psychology experts, we study how well can deep learning algorithms identify eleven known predatory behaviours. We find that the best-performing ML models are consistent but not on par with expert annotation. We therefore consider a system where an expert annotator validates the ML algorithms outputs. The combination of human decision-making and computer efficiency yields precision—but not recall—comparable to manual annotation, while taking only a fraction of the time needed by a human annotator. Our findings underscore the promise of ML as a tool for assisting researchers in this area, but also highlight the current limitations in reliably detecting online sexual exploitation using ML.

1 INTRODUCTION

Online sexual grooming is an increasing problem in the digital age [25]. In 2021 alone, UK police forces recorded over 5,000 offences relating to sexual communication with a child, representing an increase of over 70% on the three years prior [42]. In the US, 5.4% of adolescents experience online grooming between the ages of 13–17 [23]. The victims of online predators often endure significant harm, with many abusers seeking physical contact offline [48]. Early identification of these predators is therefore crucial.

In prior work on identifying such predators [6, 43, 51, 52], researchers have largely relied on manual annotation of online conversations between predators and their victims. This work is time-consuming and prone to error. While machine learning (ML) has the potential to automate some of this effort, its use for preventing child endangerment online remains underexplored.

We investigate the extent to which ML algorithms can help with detection of online predatory behaviours. One of the involved challenges is that acquiring real-world data featuring minors is inherently difficult due to moral concerns regarding the protection of victims, logistical issues in data collection, and ethical constraints ensuring that data is handled sensitively. Consequently, we utilise a corpus of chat logs from Perverted Justice [21], an online watchdog featuring adult decoys impersonating underage victims.

We focus on identifying 11 communication strategies characteristic of predatory interactions, based on a framework developed, established, and validated by forensic psychologists [18]. While these strategies do not cover all predatory behaviours, they represent many of the actions that law enforcement deems problematic. The 11 behaviours are also subtle and difficult to discern even for experts, leading to frequent disagreement. Therefore, in addition to conventional metrics like precision and recall, we also examined the level of inter-rater agreement, and how it relates to the deviations of machine-generated annotations from the experts.

Section 2 outlines the background and challenges of automatic detection of online predatory behaviours. We then describe our methodology in Section 3.1 and investigate the performance of fully

automated annotation in Section 3.2. The results are unsatisfactory for several behaviours, especially those which appear more rarely in the manually annotated corpus. We address this in Section 4, where we aim to enhance performance via human-computer collaboration. We let the computer extract conversation segments representative of one of the communication strategies before one of the authors, a forensic psychology expert, verifies the resulting predictions. This approach significantly improves the overall precision while maintaining an order of magnitude higher efficiency relative to manual annotation. In Section 5, we address the ethical implications of automated detection of predatory behaviour. Finally, we discuss limitations and summarise our findings in Section 6.

2 BACKGROUND

2.1 Online Child Sexual Exploitation

Existing social science literature on online grooming is extensive, focusing primarily on classifying predatory behaviours in order to aid law enforcement. Researchers have identified two types of sexual predators based on whether they seek to establish physical contact, or wish to engage in fantasy-like discourse [15]. Unsurprisingly, due to the added risk of offline offending, most research has focused on identifying offenders who seek physical contact with their victim [6, 43, 51, 52]. However, the notion that predatory behaviour can be parsed into wholly online or offline offending is oversimplified. For instance, a systematic review of 22 empirical studies found minimal evidence of offenders who solely engage in contact or fantasy-seeking behaviours [8]. Recognising the spectrum of tactics used by offenders is crucial for improving detection methods and tailored interventions.

Current models of online grooming do not account for how the role of the victim impacts the predator's response [14, 15, 33–35, 37]. This lack of understanding in bilateral communication between offender and victim has meant that law enforcement often relies on rudimentary methods such as detecting hyper-sexualised keywords to identify predatory activity. Where the literature has taken a bilateral approach, results have highlighted the importance of understanding the linguistic exchange between offenders and victims. For example, Seymour-Smith and Kloess [47] found that predators would request sexually explicit images in part to trap and control their victims. Once in possession of the images, predators utilised overt persuasion and extortion to overcome victim non-compliance. Such insight demonstrates the utility that can be gleaned from considering the victim's role and the predator's tactics, something that would not be possible by merely scanning for hyper-sexualised keywords, and underscores the necessity for more sophisticated approaches to detecting online predatory behaviour.

Elliot's Self-Regulation model [22] is the first to incorporate victims' behaviour into a model of online predatory grooming. Self-Regulation is a feedback system comprising two phases: a) potentiality, and b) disclosure. *Potentiality* includes mechanisms for rapport-building, incentivising the relationship, disinhibiting the victim, and managing security risks. *Disclosure* primarily concerns whether the predator's behaviour has sufficiently desensitised the victim. Outcomes of this stage can include seeking agreement on a common goal (e.g., arranging offline contact).

As the landscape of online communication continues to evolve, so does the complexity of predatory tactics. While invaluable in providing a foundational understanding, traditional methods have shown limitations in scalability and adaptability to the changing modus operandi of online groomers. This limitation necessitates the exploration of more automated approaches like machine learning.

2.2 Automated Approaches

Offenders use a variety of subtle behaviours to manipulate the conversation flow, such as flattery to build trust [2], or threats and bribes as a coercion tactic [30]. This subtlety can be challenging for automated approaches to detecting predatory behaviours [9]. Prior attempts like [3] relied on dictionary-based approaches, which often result in a large number of both false positives and negatives [7, 31].

Another strain of literature has focused on identifying predators from a mixed corpus of illicit and everyday conversations [20, 26, 27, 29, 41, 45]. While valuable in its own right, this line of research does not offer significant value to law enforcement, as it lacks psychological insight that could justify a preventative intervention. Furthermore, an ML algorithm trained to distinguish between mundane and predatory conversations may overly rely on sexual words [19], while missing more subtle intimacy-seeking, social, and opportunistic behaviours. For example, some predators withhold sexually explicit talk to establish rapport and control [22], or fulfil their fantasy of a a conventional relationship with the victim [24].

Finally, most similar to our work is research on using ML to detect behaviours domain experts regard as problematic. For instance, Gupta et al. [27] used psycholinguistic features to identify six phases of a predatory interaction: friendship forming, relationship forming, exclusivity, risk assessment, sexual activity and conclusion. Similarly, Gunawan et al. [26] used supervised ML to align these phases with specific behaviours such as asking for a picture, talking about friends, discussing hobbies, and building mutual trust. Cano et al. [12] undertook a similar task using a social signal processing approach. Other studies have used a combination of ML and dictionaries to detect qualitative differences in linguistic behaviour between the messages produced by predators and those generated by victims [19], or quantify the level of predatory behaviour from crowd-sourced metrics [45].

While there has been progress in understanding online child sexual exploitation and developing suitable detection methods, a gap remains in addressing the complexity of predatory tactics. Moreover, existing approaches often struggle to detect subtle predatory behaviours and instead rely on detecting sexually-explicit keywords. This study aims to address these gaps by employing advanced machine learning techniques to develop a more nuanced detection model to identify the subtle behaviours predators use throughout the online grooming process.

3 AUTOMATED LABELLING OF COMMUNICATION STRATEGIES

3.1 Method

3.1.1 Dataset. This work uses chat log data between online sexual offenders and adult decoys posing as children and teens. We

Table 1: Behaviour labels used for manual annotation of predator messages, including characteristics of each communication strategy.

Strategy	Code	Characteristics
Communication	COMM	Sustaining the interaction
		Asking questions
		Using linguistic fillers
Rapport	RAPP	Sweet talk
		Show interest
		State shared experiences
Control	CONT	Make demands
		Illusion of victim control
		Ask permission
Challenge	CHAL	Direct confrontation
		Mock insult
		Challenge abilities
Negotiation	NEGO	Arrange to meet
		Offer incentives
Use of Emotion	EMOT	Guilt tripping
		Vilifying third parties
		Playing the victim
Testing Boundaries	TEST	Checks engagement
		Setting boundaries
Sexual Topics	SEX	Stating sexual preferences
		Fantasy talk
		Suggest media production
Mitigation	MITI	Normalising sex
		Downplay age differences
Encouragement	ENCO	Flirting
		Acting as mentor
Risk Management	RISK	Emphasise secrecy
		Acknowledge wrongdoing
		Discuss consequences

compiled twenty-four chat logs from Perverted Justice[1] using an automated web scraping tool built on top of the `beautifulsoup` [46] library in Python. Perverted Justice is a publicly available online repository of two-way instant messaging interactions from sites such as MySpace and Yahoo Instant Messenger. The chats took place between 2003 and 2016. We randomly chose our chat logs from the over 600 available on the Perverted Justice website. On average, chat logs contained 539 messages sent between the two speakers. The interaction would often take place over several days, comprising multiple conversations. The offender always initiated the interaction. The chat logs comprised 12,942 messages in total. Offender messages to the victim accounted for 6,771 (52%) of these.

3.1.2 Data Processing. We extracted chat logs from the Perverted Justice website as plain text files, then inspected and cleaned the data to standardise formatting and remove additional commentary. We also anonymised the text, identifying the speakers only based on their role in the conversation (predator or decoy).

[1]Perverted Justice ceased operations in 2016 but continued to make their data publicly available until March 2023. We originally accessed the data in 2020.

Two of the authors of this work, both possessing a forensic psychology background, used a grounded theoretical approach to label the offender messages. Grounded theory is a flexible methodology designed to extract descriptive (i.e., qualitative) patterns in data [13]. Codes are developed inductively (i.e., data-driven) through an iterative approach to the point of data saturation. The annotators then reviewed and amended prospective codes until they reliably described the interaction. A final coding framework was agreed upon, resulting in eleven communication strategies predators use when responding to their victims. We also included an additional control variable corresponding to a null annotation, i.e., where none of the strategies were found in the respective message. The communication strategies are briefly described in Table 1, and in detail in **??**.

Coding the corpus took four months and over 600 hours to complete. In addition, codes were not mutually exclusive, meaning a predator could display multiple strategies within the same message. This approach and the time-consuming nature of manual coding significantly contributed to the required effort and highlighted the infeasibility of a manual approach for coding large datasets. Based on the time required for this corpus, manually coding the entire corpus held by Perverted Justice would likely require several years of effort.

Due to the time and effort required, it was not feasible to perform repeat coding of our entire corpus. However, inter-rater agreement was sample tested, in addition to collaborative coding exercise during the initial development of the framework. We split the coded predator message corpus into training, testing, and validation regions. 70% was used for training, 20% for testing, and 10% for validation. Data splits were stratified to ensure coverage in each region mirrored that observed in the full corpus. Table 2 reports the distribution of messages per region.

Table 2: Split of predator-to-victim messages in our dataset into training, testing, and validation regions using a 70-20-10 ratio. Splits were stratified to ensure distribution of labels in each region matched the full corpus.

Region	Messages	Data Split
Train	4712	70%
Test	1355	20%
Validation	704	10%

3.1.3 Models. We used a natural language inference (NLI) approach to predict how messages relate to communication strategies. NLI is an NLP technique that focuses on comparing two statements of the text. Specifically, determining whether a given statement (the hypothesis) is inferred or contradicted by another statement (the premise) [5]. If the hypothesis can be inferred from the premise, the relationship is one of entailment. On the other hand, contradiction or neutral outcomes occur when we cannot infer a relationship between the two statements.

In this work, we use each predator message as a hypothesis and form one premise from each communication strategy. For example, "This message is an example of control" would be used for the control strategy [32]. We used each message/label sentence pair during training as input to a deep learning model. We used a version of

`RoBERTa-large` [39] hosted on Huggingface, with an implementation built in `Pytorch` [44]. In addition to pretraining, this model has been fine-tuned for NLI tasks using the Multi-Genre Natural Language Inference corpus [50]. We performed further fine-tuning using our training and validation sets. Model parameters are identical to [49]. We trained our models for 10 epochs with batch size 32 and a learning rate of 10^{-5}.

Model predictions for each message in the test set were binarized by finding an optimal threshold, i.e., one that maximizes correlation with the actual labels, as in [32]. This means we set a different threshold per label, allowing us to achieve better results compared to a pre-determined value (such as a universal 50% cut-off).

3.1.4 Comparing zero-shot and few-shot learning. As the time required to manually label our corpus is a bottleneck that hinders the mobility of our approach to larger datasets, we were interested in how prediction performance suffered when we used a reduced training sample. In addition to training on the entire training set, we experimented with few-shot and zero-shot conditions. In the zero-shot condition, we made predictions on the test set with no additional training. In few-shot settings, we experimented with different amounts of positive training examples between 5 and 150. As before, we used a stratified approach when sampling the positive classes to ensure that the class distribution in the few-shot settings matched the actual distribution of the whole training set.

3.1.5 Expanding the contextual window. We also tested whether the surrounding messages increased the contextual understanding of the model. To examine this, we expanded the message window to include multiple prior messages sent by both speakers, and concatenated them into a single input. In addition to the single message input, we experimented with five-message windows. The five-message window combines each predator message with the two preceding victim and predator messages.

3.2 Experiments and results

3.2.1 Coverage Statistics. We report coverage statistics for each communication strategy in Table 3. We calculate coverage as the proportion of messages with a positive class label. Each of the eleven behaviour codes is highly imbalanced. Except for 'communication' (coverage = 73%), positive labels form the minority class. Inspection of messages that were labelled with the 'communication' label revealed that predators were engaging in considerable amounts of both information-sharing and information-gathering. This was particularly prominent at the beginning of conversations, and characterised by a series of targeted, and directive questioning: "asl?"[2], "are you there alone?", "do you want to give me your number?". There were also a considerable number of attempts to use humour-related acronyms (i.e., "lol", "LMAO", "hehe") that explained the high coverage of 'communication' throughout the corpus.

By contrast, mitigation was the rarest label and appeared in only 3% of predator messages. Aside from communication, the average coverage of the remaining labels was 14.3%, suggesting behaviours appeared rarely. Equally, however, the majority of predator messages (92%) were labelled with at least one behaviour. Threshold values were similarly broad—thresholds for communication, control, challenge and encouragement were all within 0.005, while, rapport, use of sex, and risk management all generated a threshold ≥ .85.

[2]The phrase 'asl' is text-speak for "age, sex, location?"

Table 3: Coverage statistics of each communication strategy over all offender messages. Coverage represents the percentage of messages in the dataset that use the corresponding strategy. Train and Test columns indicate the number of manually labelled positive class instances in the train and test regions, respectively. The threshold column shows the optimized threshold based on the largest cross-validated Matthews correlation coefficient (MCC) between predicted and actual labels.

Strategy	Coverage (%)	Train	Test	Threshold
Communication	73	3445	991	.002
Rapport	15	718	206	.98
Control	21	979	282	.004
Challenge	5	211	60	.005
Negotiation	21	986	283	.75
Use of emotion	16	773	222	.71
Testing boundaries	31	1470	423	.78
Use of sex	18	861	248	.98
Mitigation	3	144	41	.7
Encouragement	8	378	109	.004
Risk management	5	217	62	.88

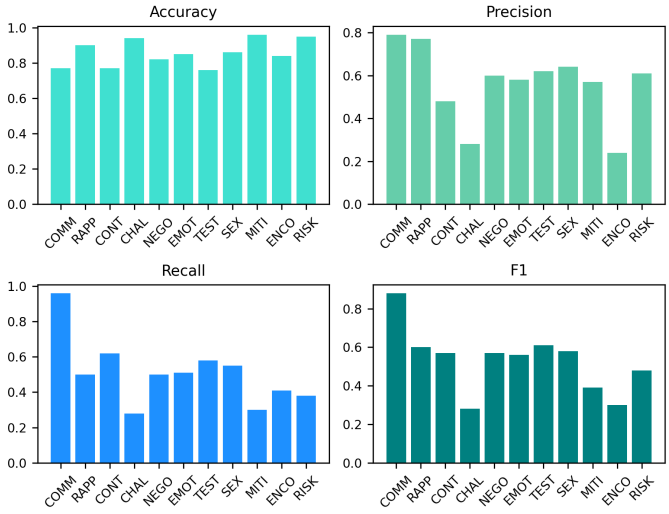

Figure 1: Performance metrics for NLI models trained on all available data for each communication strategy. The subplot shows accuracy, precision, recall, and F1 scores for offender messages within the test set.

3.2.2 Classification of predatory behaviour when trained on all available data. Figure 1 reports the performance of each label when trained with all available training data. Seven of the eleven behaviours also obtain an $F1$ score above 50%, with the best-performing behaviour being 'communication' ($F1$ = .87), followed by 'testing

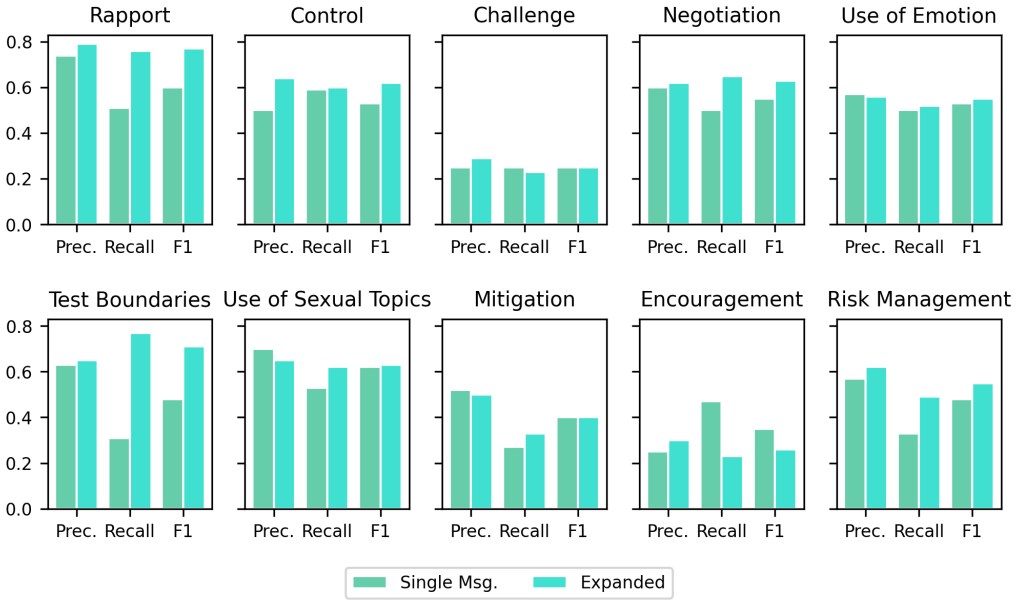

Figure 2: Comparison of precision, recall, and F1 scores for NLI models trained on single and expanded message inputs for each communication strategy. Each subplot displays the evaluation metrics for a specific communication strategy. The x-axis represents the performance metric, while the y-axis represents the score for the metric. The green bars represent the scores achieved by the model trained on a single message input, while the turquoise bars represent the scores achieved by the model trained on an expanded window of 5 messages.

boundaries' ($F1 = .62$), 'rapport' ($F1 = .61$), and 'use of sexual topics' ($F1 = .61$). Performance was poorest for 'challenge' ($F1 = .28$), followed by 'encouragement' ($F1 = .32$), and 'mitigation' ($F1 = .4$). Precision was an issue for the majority of labels, indicating a number of false positives and suggesting that the model had learned some rules that were contributing to a high false-positive rate. To better understand performance, a brief qualitative exploration was performed on a random sample of ≈ 10% of the test set.

The rapport model correctly recognised complements and sweet talk as positive examples, but missed more everyday examples of rapport building such as social greetings, (e.g., "hi, how are you? asl?"). It also routinely failed to identify general conversational patter as evidence of rapport (e.g., "how was your spring break?").

Some aspects of control appeared to take place over longer ranges than single messages. For example, persistently asking the same question was often misclassified, as each message was considered an independent event.

In trying to predict encouragement, which was amongst the worst performing labels, the model appeared to overfit on short verbal nods (i.e., "kool" and "sure"). This appeared regularly in predator speech, but was not always labelled as encouragement by our annotators. Over-reliance on these phrases seems to substantially increase the false positive rate. Risk management appeared to perform better than other rare behaviours. Examination of the positive classifications indicated that this was largely a consequence of recognising attempts to establish the presence of a parent, (e.g.,"is ur dad gona be home tomoro?" and "when are they getting home?").

3.2.3 Comparing classification accuracy with an expanded message window. Figure 2 reports a per behaviour comparison of precision, recall, and F1 between single and multi-message input. Due to the high performance and coverage of the communication strategy, we dropped this label from the remainder of our analysis. The general performance increase was marginal for model precision. However, rapport, control, risk management, and testing boundaries all increased when we included the additional context. However, 'use of sexual topics' decreased precision by 5% (from 70% to 65%) when we used a multi-message window.

An expanded message window markedly increased the recall of several behaviours, including rapport (increased from 52% to 81%), negotiation (from 50% to 67%), testing boundaries (from 31% to 76%), and risk management (from 37% to 48%). This suggests that the added context from the previous messages decreased the false negatives for these behaviours.

3.2.4 Comparing classification accuracy in few-shot and zero-shot conditions. Figure 3 reports the change in the $F1$ as the number of positive training examples increases. At zero-shot, all categories had an F1 score below 50% and half were below 15%. The subjectivity of the behaviours is a possible cause of lacking performance. As noted by [28], concepts such as "rapport" are tough to define, even for humans. It is therefore not surprising that a machine fails at this task without any positive examples for training.

As demonstrated in Figure 3, however, most behaviours notably improved with a small amount of positive training examples. On

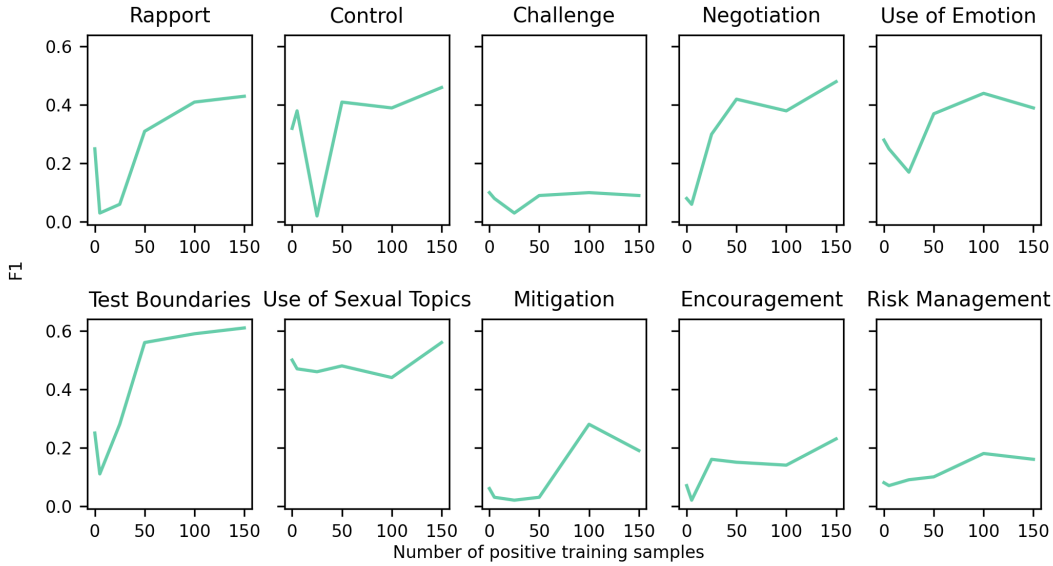

Figure 3: Change in F1 score as the size of the training set increases for each communication strategy. The x-axis represents the number of manually labelled positive instances in the training set, ranging from 0 (zero-shot) to 150. The y-axis represents the F1 score. Each subplot shows the change in F1 score as a line per communication strategy.

average, results indicate that the model attained considerable improvement by training on 50–100 positive examples.

3.2.5 Comparing pairwise agreement between machine and expert annotation. We performed a validation study to explore differences in annotations generated by our forensic psychology experts with those generated automatically by our models. In total, the first author of this work validated the classifications of 645 messages. This step generated a third set of annotations and was deemed a more efficient alternative to re-labelling the corpus from scratch. Cohen's K [16], a standard metric, was used for measuring pairwise agreement between annotators, where larger values of K indicate more agreement between raters. An acceptable level of agreement is subjectively defined. However, social scientists often use the interpretation provided by [38]. In our case, we take the agreement between the two human annotators as the level of 'acceptable' agreement.

Figure 4 reports pairwise agreement scores for each behaviour. Across all behaviours, and for each combination of raters, including the automated one, values of K ranged between .46 and .95, indicating a minimum of 'moderate' agreement on any pairwise combination. Comparing H1 (initial annotations) with H2 (validations performed by the first author), several of the behaviours received a K value above .8, indicating near-perfect levels of agreement. Comparing these agreement scores with those generated by human-machine comparisons (H1 & AI or H2 & AI), values of K are significantly and consistently lower. This finding suggests that our best-performing model was unable to achieve an agreement comparable to an additional human rater. For example, the average agreement between H1 and H2 for 'risk management', 'mitigation', 'negotiation', and 'challenge' was .91 – comfortably within the 'near perfect' range. Conversely, the average agreement between AI and H1 or H2 on the same behaviours was .58. We note that despite being trained on data only from H1, the model did not systemically agree with H1 more than with H2.

4 HUMAN-MACHINE COLLABORATION FOR DETECTION OF PREDATORY COMMUNICATION STRATEGIES

The results presented in Section 3 indicate that whilst a ML solution offer a significant improvement in performance when sufficient training data is available, model precision remains an issue for most behaviours. Over-prediction can result in lost time in high-stakes settings where precision is essential. While in the case of online grooming, it is arguably more tolerable to misidentify non-predatory behaviour as predatory (i.e., lower precision) than to identify predatory behaviour as non-predatory (i.e., lower recall), law enforcement will sacrifice considerable resource unnecessarily if detection of predatory behaviour is consistently poor. It is, therefore, vital that automated systems address this.

This section examines the potential of resolving this issue via a human-in-the-loop approach. While human experts can identify contextual nuances and subtle behaviours that machines may miss, the manual effort required for such annotation is time-consuming, and thus not scalable to large chat datasets. On the other hand, machines need a fraction of the time for processing but, as we have seen, do not achieve the required accuracy. Following [10], we therefore use a weak supervision approach, where the machine is tasked with identifying relevant segments of the chat log, which are then verified by a human expert.

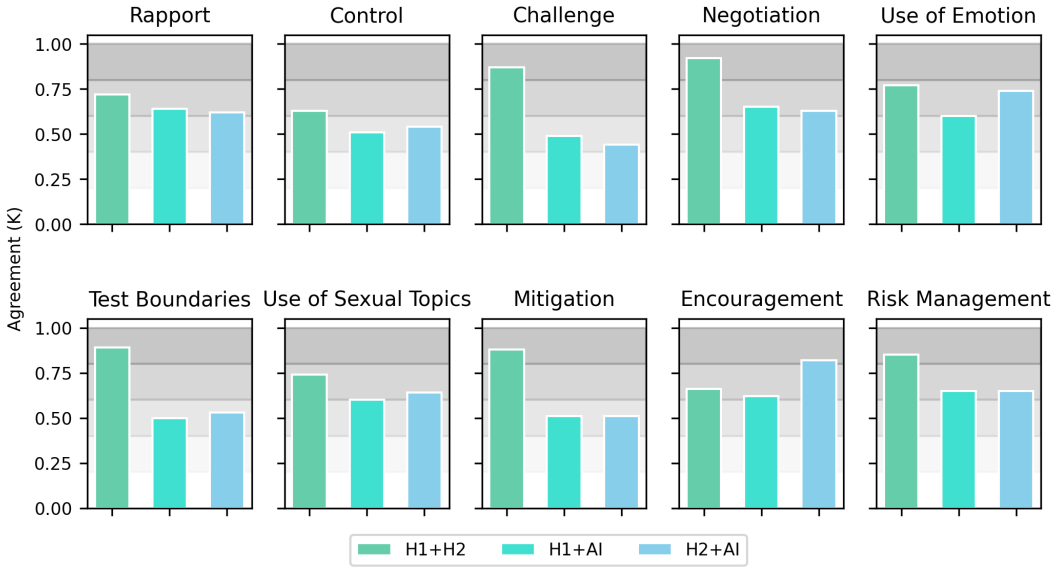

Figure 4: Pairwise agreement between the original human annotations (H1), human verified annotations (H2), and machine-generated annotations (AI) for each communication strategy. The x-axis shows each pairwise combination of raters, and the y-axis displays the Cohen's kappa score, a measure of inter-rater agreement. Shaded areas indicate the level of agreement, ranging from almost perfect (dark grey) to slight agreement (white), according to the interpretation in [38]. Each subplot corresponds to a single communication strategy. The results demonstrate the extent of agreement between different raters and provide insight into the quality of machine-generated annotations compared to human-verified annotations

4.1 Method

4.1.1 Dataset. We used the same twenty-four chat logs used in Section 3, and trained our models with the same data split. In addition, we labelled a further fifteen chat logs from Perverted Justice to increase the size of the test set. In total, we annotated 12,426 messages sent by an offender.

Instead of predicting behaviours at the message level, we grouped messages occurring within a set period into conversations, defined as a continuous sequence of messages where the gap between two messages did not exceed one hour. This step generated sixty-seven conversations, with an average of 185.46 (SD = 188.77) offender messages per conversation. For each conversation and each behaviour label, we extract the conversation segment that best represents each label. This means that the resulting labels indicate which communication strategies were present in each conversation at least once. Note that we omitted the communication category from this analysis as it is likely to be present in all conversations.

4.1.2 Task. We performed our analysis on each conversation within the expanded test set. For each conversation, we used an ensemble of labelling functions–automated methods to annotate data—to extract the segment of text that best represented each behaviour label. Extracted segments were then ranked according to their confidence level, with the top-k segments passed to a human verifier (the first author) to either accept or reject.

4.1.3 Schema. We constructed five labelling functions to extract the text segments. These were: (i) NLI sequence classifier fine-tuned on our training set, (ii) Zero-Shot Q&A classifier, (iii) Zero-Shot Q&A classifier with cosine similarity, (iv) Sentence embeddings with cosine similarity, (v) keyword detection. We provide a complete overview of each of these labelling functions in Appendix **??**.

4.2 Experiments and results

Figure 5 reports performance in precision and recall when $k = 1$ compared to $k = 3$, i.e., when the human validator saw only the model's best guess ($k = 1$) or the top three ($k = 3$). Precision performance was generally very high for both $k = 1$ and $k = 3$, with two labels (Control and Negotiation) obtaining perfect precision when compared to manual annotation. The average precision score across all behaviours was similar, with both conditions performing ≈ 0.94. Given the subjective nature of the labels, imperfect precision mostly corresponds to disagreement between annotators. The lowest performing behaviour was 'Challenge', which dropped by 13% (from 0.8 to 0.73) between the two conditions. This drop in performance is likely due to the $k = 3$ model incorrectly providing more information to the user to verify, thus increasing the likelihood of a false positive. Overall, our findings suggest that a human-in-the-loop approach can consistently extract relevant text segments for the user to review.

However, for most categories, the collaborative set up did not improve recall compared to fully automated methods. In the present context, low recall (an excess of false negatives) can be explained either as a consequence of inter-annotator disagreement (i.e., the model provided excerpts that the verifier rejected, in disagreement with the original annotation), or an inability of the model to identify salient information for a given category (i.e., the model fails to

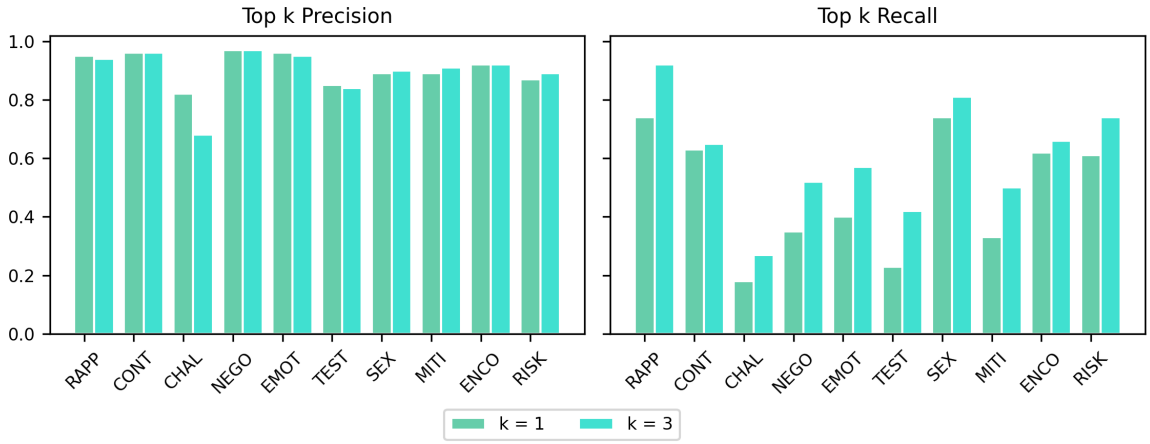

Figure 5: Comparison of precision and recall scores for each communication strategy using top k extraction. The AI-generated evidence was manually verified by humans. High precision scores indicate that the AI-selected evidence aligned with human interpretation of each communication strategy. Lower recall scores suggest that the AI may not have identified all relevant evidence for human review. The green and turquoise bars represent top k extraction with k=1 and k=3, respectively

return anything for the user to verify). Supporting the latter explanation, providing more information for the user to review by increasing the value of k did improve recall for all categories. The average improvement in recall was 11%, from 0.52 ($k = 1$) to 0.63 ($k = 3$).

With respect to the inter-rater disagreement artificially lowering recall, removing such effects would typically require manually re-annotating the entire corpus. However, the high time intensity of manual annotation meant this was not possible in the present context. As an efficient alternative, the first author manually inspected points of disagreement between the original annotations and the output from Section 4.1.2. The first author then re-coded original annotations, and performance metrics were recalculated. Figure 6 reports F1 scores with these amended annotations.

5 ETHICAL AND SOCIETAL CONSIDERATIONS

Developing frameworks to support the automatic detection of online grooming raises critical ethical considerations. For example, data acquisition regulations may hinder accessing the large volumes of data required to train a machine learning algorithm suitably [4]. Other cyber-security issues, such as proper data storage and the potential for hacking, also mean that law enforcement is often reluctant to release actual investigative material, such as chatlogs, for academic purposes [36]. Other privacy issues behind using actual investigative data include difficulties obtaining informed consent for bulk data collection [40].

This work utilises a large corpus of online predatory chat logs archived by a child-safety watchdog organisation. Both the creation and use of this data are controversial. For example, the Perverted Justice model has been criticised for encouraging cyber-vigilantism [54]. Moreover, the fact that offline meetings were routinely televised as part of NBC's To Catch a Predator series has resulted in claims of unnecessary humiliation towards individuals who, at that point, had been neither charged nor convicted of a crime [1]. Additionally, debate exists around whether the persistence of some volunteers constituted legal or moral entrapment [11, 21].

While using the Perverted Justice corpus raises ethical questions, it is important to consider the context in which this data was collected. All predators featured in the chat logs were later convicted of a crime (according to the administrators of the Perverted Justice website, the undercover volunteers' activities resulted in the criminal conviction of over 600 predators between 2003 and 2016). Decoys did not initiate contact with the offender or introduce sexual content, and the conversations did not feature children but an adult playing the role of an underage victim. Notwithstanding these ethical challenges, the difficulties associated with accessing chat logs with real victims have meant that the Perverted Justice archives have become a viable and effective alternative.

Another ethical consideration is the risk of perpetuating harm towards children who have experienced sexual abuse, if researchers mishandle the data used to train an algorithm. There is a need to consider the potential impact of using sensitive information, and to ensure that the rights and dignity of children are respected. Additionally, use of automated detection systems may have unintended consequences, such as false positives or misidentification, which can lead to unjust accusations and damage to innocent individuals' reputations [53]. However, in a deployed system, false negatives are more severe, as they may prevent law enforcement from saving a child from harm.

Due to the high-risk nature of this application, and the level of performance our system achieves, it is clear the technology is not ready to reliably assist in detecting online grooming behaviour in the real world. However, it shows promise in helping researchers working on this crucial domain streamline and speed up their annotation process. Annotating large volumes of text data containing potentially disturbing content can be emotionally challenging. While research that explicitly explores annotator well-being is scarce,

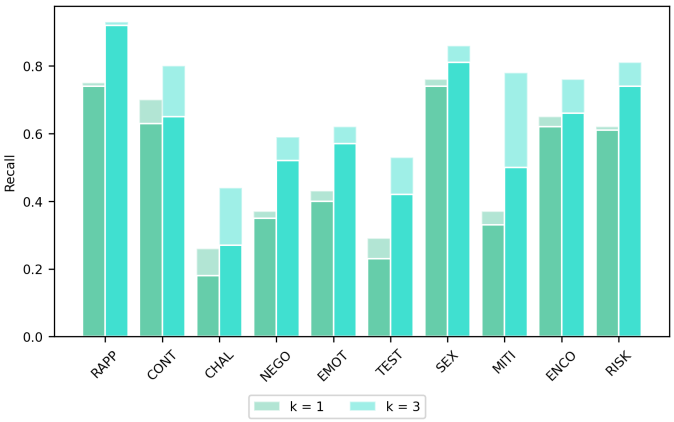

Figure 6: Comparison of adjusted recall scores for each communication strategy after resolving disagreement between original annotations and human verified annotations. Original annotations and human verified annotations were re-annotated by the first author to account for potential discrepancies between the two sources. Bars represent the recall score, where an increase indicates improved recall after adjusting annotations. The analysis aims to investigate whether low recall scores are due to differences in annotators or an inability of the AI to generate relevant evidence. Top 3 extraction, where k = 1 (green) and k = 3 (turquoise) respectively, was used to automatically extract segments of messages as evidence of each communication strategy for human verification.

a related area that has received attention is the role of content moderators on social media. Research has shown that prolonged exposure to harmful material can cause psychological distress, such as post-traumatic stress disorder [17]. The development of automated systems could be helpful in proactively protecting the mental well being of those on the front-lines of data annotation.

6 CONCLUSIONS

Manually labelling the 24 chat logs used in this work took over 600 hours. Given that the full Perverted-Justice corpus contains 850 chat logs, it would be infeasible to label the entire corpus without the help of automated methods. We find that an ML based approach shows potential when applied to the detection of online predatory behaviour. However, even with training, the agreement between the model and a human annotator is not comparable to the agreement between two human annotators.

Adding a human validation step to the annotation process improves precision significantly for the cost of a small-time investment compared to human annotation. However, recall remains an issue even in the collaborative setting. Issues in predicting the correct behaviours seem to stem from the rarity of certain behaviours, but also due to their nuanced nature. These conclusions may be transferable to other contexts and annotation schemes involving highly-subjective class labels. Performing post-validation on the automatic classifications allowed us to gain qualitative insight into the model's performance, which may be used to design better prompts and improve performance further. Overall, our results are an encouraging step towards building tools that may assist researchers within this domain, even if the current capabilities are insufficient to build a sufficiently reliable automated model for detection of online sexual exploitation in the real world.

ACKNOWLEDGMENTS

Given the nature of our topic, ethical approval was sought for the initial data collection and manual labelling of the Perverted Justice corpus. Ethical approval was granted by the University of Liverpool's Institute of Population Health Research Ethics Committee (REF: 9972). This project was supported by the Leverhulme Centre for the Future of Intelligence project RC-2015-067.

We are grateful to Jiri Hron of the University of Cambridge for providing critical insights and invaluable feedback on the final draft of this paper.

ABSTRACT

Climate change is the defining issue of our time, and we are at a defining moment. Various interest groups, social movement organizations, and individuals engage in collective action on this issue on social media. In addition, issue advocacy campaigns on social media often arise in response to ongoing societal concerns, especially those faced by energy industries. Our goal in this paper is to analyze how those industries, their advocacy group, and climate advocacy group use social media to influence the narrative on climate change. In this work, we propose a minimally supervised model soup [57] approach combined with messaging themes to identify the stances of climate ads on Facebook. Finally, we release our stance dataset, model, and set of themes related to climate campaigns for future work on opinion mining and the automatic detection of climate change stances.

1 INTRODUCTION

We are approaching a decisive moment for international efforts to tackle the climate crisis, and International Energy Agency (IEA) report sets out a pathway for achieving this goal by reducing global carbon dioxide (CO_2) emissions to *net zero by 2050*. IEA emphasizes policy interventions by governments worldwide to drive the energy transition and lower greenhouse gas emissions. Towards a net-zero future, the United Nations (UN) campaign for individual action on climate change and sustainability called ActNow[1] so that by making choices that have less harmful effects on the environment, we can be part of the solution and influence change. Despite the urgency to avoid catastrophic climate change [42], scientific explanation [15], the policy plans of the world's governments [1], digital activism [25], we are still lagging from climate goals. The reason behind this lag is the negative influence of fossil fuel companies working to undermine and weaken much-needed climate action [44].

Over the last decade, online advertising has significantly increased to disseminate agendas and sponsored content has been used to reach more people on social media [7, 8, 22, 29, 33]. Advertising plays a pivotal role in climate change because some advertising defends the destructive oil and gas industry, greenwashes brands and drives consumption. At a congressional hearing in April 2021, Facebook chief Mark Zuckerberg admitted that climate misinformation was a "big issue"[2]. A Bloomberg analysis pointed out that millions of climate change-denial ads continue to be approved on the platform despite increasing pressure from climate groups to more effectively regulate content[3]. Oil and gas industries have been using paid-for social media advertising on Facebook to capture the narrative on climate change. However, climate scientists have reached a consensus that climate change is real and is caused by human activity on the planet, which has and will have adverse effects on humanity and the biosphere around the planet [13]. Stakeholders supporting climate change also use the Facebook advertising platform to influence the targeted audience, focusing on transitioning to renewable energy. Though the transition to a renewable energy economy may be exciting to renewable energy advocates and scholars, many industries and community has different perspectives on it [43, 50]. For example, Fig. 1 presents two sponsored ads

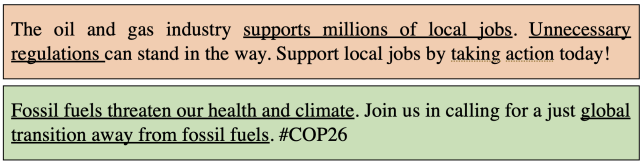

Figure 1: Example of sponsored ads in Facebook where the advertisers have different stances on climate change focusing on different themes.

on Facebook having two different stances on climate change. The

stance of the top ad (inside the brown box in Fig. 1) is (`pro-energy`) as the sponsor is against 'unnecessary regulations on oil and gas industry' and the ad *theme* is (`economy_pro`) mentioning 'oil and gas industry supports local jobs'. The *stance* of the bottom ad (inside the green box in Fig. 1) is (`clean-energy`) as the sponsor supports 'transition away from fossil fuels' and the reason for this is the 'threatening effect of fossil fuels on our health'. So the ad *theme* is (`HumanHealth`).

In this work, we aim to understand how climate advocates and fossil fuel corporations are using advertising to control the narrative on climate change and climate policy. Our goal is twofold: first, to characterize the themes of the ads, and second to build on this characterization to identify the stances of the ads, i.e., **pro-energy**, **clean-energy**, **neutral**.

Our theme assignment process is motivated by a thematic analysis approach [5]. We begin by defining a seed set of relevant arguments based on recent studies [10, 41], where each pro-energy theme is defined by multiple sentences. Since the initial set of themes contains only pro-energy arguments, we add clean-energy themes and phrases. We fine-tune a pre-trained textual inference model using a contrastive learning approach to identify paraphrases in a large collection of climate related ads.

In recent years, research has shown that models pre-trained on large and diverse datasets learn representations that transfer well to a variety of tasks [11, 19, 26, 30]. The fine-tuning process has two steps: (1) fine-tune models with a variety of hyperparameter configurations, and (2) select the model which achieves the highest accuracy on the held-out validation set and discard remaining models. Wortsman et al. [57] recently showed that selecting a single model and discarding the rest has several downsides, and they proposed *model soup*, which averages the weights of fine-tuned models independently. While Wortsman et al. [57] showed model soup performance on four text classification datasets from the GLUE benchmark [54], we develop a minimally supervised model soup approach leveraging messaging theme to detect stance for analyzing climate campaigns on Facebook. We focus on the following research questions (RQ) to analyze climate campaigns on social media:

- **RQ1.** Can a model trained with minimal supervision using theme information be leveraged to predict the presence of stances in Facebook ads related to climate change?
- **RQ2.** What are the intersecting themes of the messaging?
- **RQ3.** What demographics and geographic are targeted by the advertisers?
- **RQ4.** Do the messages differ based on entity type?

Our contributions are summarized as follows:

(1) We formulate a novel problem of exploiting minimal supervision and Bayesian model averaging to analyze the landscape of climate advertising on social media.
(2) We identify the themes of the climate campaigns using an unsupervised approach.
(3) We propose a minimally supervised model soup approach to identify stance combining themes of the content of climate campaigns. We show that our model outperforms the baselines.
(4) We conduct quantitative and qualitative analysis on real-world dataset to demonstrate the effectiveness of our proposed model.

The remaining sections of the paper are structured as follows: we commence with a discussion on related work, followed by the presentation of dataset details. Subsequently, we introduce the problem formulation, after which we outline the methodology employed. Later, we provide comprehensive information on the experimental settings, including the results, baselines, and ablation study. Finally, we address the research questions **RQ2**, **RQ3**, and **RQ4** through a detailed analysis. Our data, code, and model are publicly available at https://github.com/tunazislam/BMA-FB-ad-Climate

2 RELATED WORK

Recent studies have shown climate change activism in social media and news media [4, 52, 53]. Sponsored content on social media – especially Facebook, is the main channel to reach the targeted audience on a specific event such as US Presidential election [29], or specific issues, i.e., COVID [28, 39, 51], immigration[9, 49].

Several studies have analyzed the discourse around climate change. Luo et al. [36] proposed an opinion framing task on the global warming debate on media. Koenecke and Feliu-Faba [32] studied whether climate change related sentiment in tweets changed in response to five natural disasters occurring in the US in 2018. Dey et al. [17] explored stance with respect to certain topics, including climate change in a tweet-based setting. To understand the narratives of climate change skepticism, Bhatia et al. [3] studied the automatic classification of neutralization techniques. Diggelmann et al. [18] introduced a veracity prediction task in a fact-checking setting on climate claims. Our work differs from these in that we use a **probabilistic approach** to detect stance incorporating **theme information** of climate related ads on social media.

Our work falls in the broad scope of minimal supervision [2, 27, 28, 40, 45, 47], contrastive learning [20, 21, 55, 58] and Bayesian model averaging [37, 38] where averaging the weights of multiple models fine-tuned with different hyperparameter configurations improves accuracy and robustness [57].

Table 1: List of the keywords for data collection.

3 DATA

We collect 88, 022 climate related English ads focusing on the United States from January 2021 - January 2022 using Facebook Ad Library API[4] with the keywords 'climate change', 'energy', 'fracking', 'coal'. To create the list of keywords for collecting ads about climate and

[4] https://www.facebook.com/ads/library/api

oil & gas industries, we read multiple articles about climate policy, environmental justice, climate change mentioning green/clean energy, transition from fossil fuel to renewable energy, coal dependent US states, protection of fossil-fuel workers and communities, and other climate debates, and made a list of repeating statements. Then, we consult two researchers in Computational Social Science and construct a list of relevant keywords. The full list of keywords is in Table 1. Our collected ads are written in English. For each ad, the API provides the ad ID, title, ad description, ad body, funding entity, spend, impressions, distribution over impressions broken down by gender (male, female, unknown), age (7 groups), and location down to states in the USA. So far, we have 408 unique funding entities whose stances are known based on their affiliation from their websites and Facebook pages. These funding entities are the source of supervision in our model. As we don't know the stance of the ads, we assign the same stance for all ads sponsored by the same funding entity. This way, we have 25, 232 ads whose stances are known.

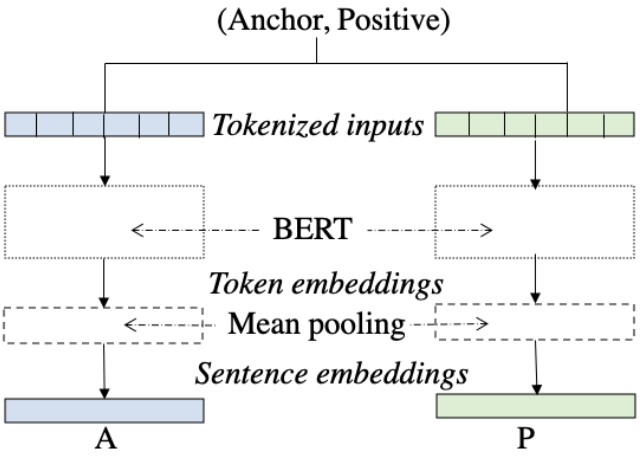

Figure 2: Siamese-BERT network for contrastive learning to generate sentence embeddings.

4 PROBLEM FORMULATION

We formulate our stance prediction problem as a minimally supervised model soup approach. We know the stance of the funding entity, but we don't know the stance of the ads. We assign the same stance for all ads sponsored by the same funding entity. We want to predict the stance of the ad using the model soup approach in the following way:

$$\text{Point estimation: } P(y_s|X_a, \theta, y_t) \tag{1}$$

$$\text{Bayesian posterior: } P(\theta|y_s, X_a, y_t) \propto P(\theta)P(y_s|X_a, \theta, y_t) \tag{2}$$

where, X_a is the ad, y_s is the predicted stance, y_t is the assigned themes, θ is the model parameter. For the point estimation in Equation 1, we fine-tuned the pre-trained BERT model [16] by concatenating theme information. For Bayesian model averaging (Equation 2), we implement both the uniform and greedy soup approaches provided by Wortsman et al. [57] including messaging theme, which can be regarded as cheap Bayesian posterior approximations. We get the theme y_t, using the contrastive learning approach following Reimers and Gurevych [48].

CLEAN-ENERGY	Economy_clean, Future generation, Environmental, Human health, Animals, Support climate policy, Alternative energy, Political affiliation.

Table 2: Resulting themes.

5 METHODOLOGY

In this section, we describe how to obtain sentence embedding using contrastive learning, generate themes and phrases, assign themes for the ad content, and implement model soup in our problem.

5.1 Sentence Embeddings with Contrastive Learning

We use $88k$ unlabeled ads for finetuning Sentence BERT (SBERT) [48]. Our training approach uses a siamese-BERT architecture during fine-tuning (Fig. 2). During each step, we process a sentence S (anchor) into BERT, followed by sentence T (positive example). In our case, the anchor is the ad text, and a positive example is the ad description or ad summary. Some ads do not have ad descriptions. In that case, we generate an ad summary using BART summarizer [34]. BERT generates token embeddings. Finally, those token embeddings are converted into averaged sentence embeddings using mean-pooling. Using the siamese approach, we produce two of these per step — one for the anchor A and another for the positive called P. We use multiple negatives ranking loss which is a great loss function if we only have positive pairs, for example, only pairs of similar texts like pairs of paraphrases. In our case, positive pairs are ad text and description/summary.

5.2 Themes and Phrases Generation

To analyze climate campaigns, we model the climate related stance expressed in each ad (i.e., pro-energy, clean-energy) and the underlying reason behind such stance. For example, the top ad (brown box) of Fig. 1 expresses a pro-energy stance and mentions their support for local jobs as the reason to take this stance.

Three main challenges are involved in this analysis: 1) constructing the space of possible themes, 2) mapping ads to the relevant themes, and 3) predicting the stance leveraging the themes. We combine computational and qualitative techniques to uncover the most frequent themes cited for pro-energy and clean-energy stances. We build on previous studies that characterized the arguments supporting the oil and gas industries [41]. In this work, researchers develop four broad categories of pro-energy themes by looking at audience responses to ads from fossil fuel companies. As energy is an economic, social, security, and environmental concern, we go through relevant research conducted by United Nations, influencemap.org and pewresearch.org to construct a list of potential themes and phrases for each theme. We add new relevant pro-energy themes and corresponding phrases that were not covered by previous work, such as *"Green New Deal would take America back to the dark ages"*

Themes	Phrases
Economy_pro	"Oil and gas will create more jobs", "Without oil and gas, there is no job", "Fracking supports thousands of jobs", "Without fracking, we will be jobless", "Oil and gas help local business", "Without oil and gas, our economy would be at risk", "Oil and gas industries pay high wages", "Jobs would be lower paid without oil and gas", "Local business would suffer without the oil and gas industry", "Don't take jobs away from the coal miners", "Coal is powering economic progress", "Protect our jobs", "Banning fossil fuels will lead to job losses", "Fracking jobs will bring new opportunities to rural areas", "Local communities would suffer due to the loss of tax revenue", "Natural gas ban would kill local jobs", "Oil and gas industries help the community through philanthropic efforts", "Energy industry gives back to communities", "Without the oil and gas industry, there would be less philanthropy".
Identity	"Shifting away from fossil fuels is the loss of our culture", "Destruction of fossil fuel industry feels like the destruction of our identity", "Fossil fuel workers struggle with a loss of identity due to factory shut down", "We should protect our community identity", "Our identities are at stake", "Support the miners", "Coal is not just a Job, it's a way of Life", "Remember the pride that coal mining gave us", "We are fighting for our identity", "Support our families and communities through supporting oil and gas industries".
ClimateSolution	"We support reducing greenhouse gas emissions", "We develop technologies to reduce carbon emission", "We are committing to net-zero emissions", "We are transitioning energy mix away from fossil fuels", "We are moving towards renewables", "Natural gas is the future of clean energy", "Fossil gas is a low carbon energy source", "Natural gas is the perfect partner to renewables", "Natural gas is part of the solution to climate change", "Thanks to natural gas, emissions have reduced", "The oil and gas industry has to be a partner, not a problem", "Renewable natural gas will help us get to net zero carbon emissions as fast as we can".
Pragmatism	"Oil and gas are affordable energy sources", "Without oil and gas, energy would be expensive", "Oil and gas are reliable energy sources", "Oil and gas will keep the lights on no matter what", "Banning fossil fuel would make energy unreliable", "Without oil and gas, energy would be unreliable", "Oil and gas are safe", "Oil and gas power our lives", "Oil and gas are efficient", "Oil and gas meet our essential energy needs", "Oil and gas are resilient", "Oil and gas are abundant", "Oil and gas are secure".
Patriotism	"Shutting down local oil and gas production would force us to increase reliance on unstable foreign oil", "We achieved record-high oil and gas production", "US is leading in oil and gas production", "US is an energy leader", "Without US oil and gas, the world would be forced to use dirtier emissions intensive oil and gas", "Stand up for American energy", "Keep Alaska competitive", "It's not patriotic to shut off American energy", "We don't have to necessarily be reliant on the Middle East", "We are loaded with coal. It's here and it's ours".
AgainstClimatePolicy	"The Build Back Better Act will ruin our economy", "Green New Deal would take America back to the dark ages", "Biden and Democrats own this energy crisis", "Biden's pipeline closure increases gas price", "Government's climate agenda is harmful to our economy", "Democrats' impractical energy policies won't stop climate change", "Government's climate policy is outrageous", "D.C. Socialists are attacking the oil and gas industry", "Biden's climate policy would make energy unaffordable".
GiveAway	"We are giving away free gas", "Collect free coupon for gas".
Economy_clean	"Compared with fossil fuel technologies, which are typically mechanized and capital intensive, the renewable energy industry is more labor intensive", "Fast-growing renewable energy jobs offer higher wages", "Fossil fuels are expensive", "Renewable energy opens up job opportunities", "Clean energy will create jobs boom", "Clean energy can rebuild our economy", "Nuclear energy can bring new clean energy jobs", "Losing nuclear power plants meaning losing jobs", "Make polluters pay to clean up their messes", "Energy companies put profit over people", "Big oil and gas companies are forcing American families to pay more".
HumanHealth	"Climate change is the single biggest health threat facing humanity", "Changing weather patterns are expanding diseases, and extreme weather events increase deaths and make it difficult for health care systems to keep up", "Our communities are facing increased risk of illness, disease, and even death from our changing climate", "Climate impacts are already harming health through air pollution, disease, extreme weather events, forced displacement, pressures on mental health, and increased hunger and poor nutrition in places where people cannot grow or find sufficient food", "Climate crisis is impacting our communities", "Fossil fuels threaten our health", "We need breathable air", "Toxic pollution kills people".
FutureGeneration	"Protect our children, family and future generations", "Climate change is a grave threat to children's survival", "Clean air for healthier kids", "Children's immune systems are still developing, leaving their rapidly growing bodies more sensitive to disease and pollution", "Save the children", "Hotter temperatures, air pollution, and violent storms are leading to immediate, life-threatening dangers for children, including difficulty breathing, malnutrition and higher risk of infectious diseases".
Environmental	"Carbon dioxide and additional greenhouse gas emissions are leading contributors to climate change and global warming", "By slowing the effects of climate change and eventually reversing them, we can expect to see a reduction in extreme weather like droughts, floods, and storms caused by global warming", "Protect our planet", "Changes in the climate and increases in extreme weather events are among the reasons behind a global rise in hunger and poor nutrition", "Changes in snow and ice cover in many Arctic regions have disrupted food supplies from herding, hunting, and fishing", "Destructive storms have become more intense and more frequent in many regions due to climate change", "Climate change is changing water availability, making it scarcer in more regions", "Global warming exacerbates water shortages in already water-stressed regions and is leading to an increased risk of agricultural droughts affecting crops, and ecological droughts increasing the vulnerability of ecosystems", "The rate at which the ocean is warming strongly increased over the past two decades, across all depths of the ocean", "Melting ice sheets cause sea levels to rise, threatening coastal and island communities", "More carbon dioxide makes the ocean more acidic, which endangers marine life and coral reefs", "As greenhouse gas concentrations rise, so does the global surface temperature", "Wildfires start more easily and spread more rapidly when conditions are hotter", "Protect our air", "Protect our ocean", "Climate crisis affects the environment", "The top cause contributing to carbon dioxide emissions is electricity generation from fossil fuel power plants".
Animals	"Climate change poses risks to the survival of species on land and in the ocean", "One million species are at risk of becoming extinct within the next few decades", "Toxic pollution kills animals", "Wildlife is severely affected by the reduction of rainfall and a lack of water", "In the U.S. and Canada, moose are struggling due to an increase in ticks and parasites that are surviving the shorter, milder winters".
AltEnergy	"Transitioning to renewable energy is not only necessary to fight the climate crisis, but also the only way we can quickly and effectively meet rising energy demands", "Alternative energy sources have a much lower carbon footprint than natural gas, coal, and other fossil fuels", "We can diversify our energy supply by implementing the widespread use of large-scale renewable energy technologies and minimizing our imported fuel dependency", "Renewable energy is cheap", "Sustainable energy is the future".
SupportClimatePolicy	"The Build Back Better Act would put $555 billion toward building a clean energy economy in the United States, the largest single investment in combating climate change in American history", "Support clean energy", "Green New Deal is a crucial framework for meeting the climate challenges we face", "Support the Energy Jobs & Justice Act", "Stop corporate polluters", "Big oil and gas industries should be held accountable for climate change", "Join Regional Greenhouse Gas Initiative today", "Support climate policy", "Biden should honor his climate and justice commitments", "We need climate leader", "We need to hold our leaders accountable for climate crisis".
PoliticalAffliation	"Owners of oil and gas companies are the top donors to a political action committee", "Big oil and gas industries spend millions to fight climate bills".

Table 6: Ablation study. FBERT: Fine-tuned pre-trained BERT model, Point_est: Point estimation, thm: Theme, Hyper: Hyperparameter.

which falls under a new theme called '**Against Climate Policy**'. As the initial set of themes contains mostly pro-energy arguments, we add reasons for supporting climate actions which are clean-energy themes, e.g., "*Climate change is a grave threat to children's survival*" ⇒ **Future Generation**. Then, we consult with two researchers in Computational Social Science and finalize the relevant themes with corresponding phrases. The final set of themes can be observed in Table 2. The full list of phrases for each theme can be observed in Table 3.

5.3 Assign Themes

Our main goal is to ground these themes in a set of approximately $25k$ labeled (stance) ads. To map ads to themes, we use the cosine similarity between their fine-tuned sentence BERT embeddings (details of fine-tuning provided in subsection 5.1) of the ad text and the phrases of each theme. To check the quality of the theme label, we annotated around 300 ads with corresponding themes and noticed an accuracy of 38.4% and macro-avg F1 score of 40.2%, which is better than the random (6.6%).

5.4 Bayesian Model Averaging

In this work, we develop a minimally supervised model soup approach by incorporating messaging themes to identify the stances of climate ads on Facebook. We used two approaches for model soup. The first one is uniform soup [57]. We consider a neural network $f(x, \theta)$ with input data x and parameters θ. For uniform soup, we take the average of the fine-tuned model parameters $(f(x, \frac{1}{k}\sum_{i=1}^{k}\theta_i))$ where θ_i can be considered as samples from the Bayesian posterior and the average can be viewed as a cheap approximation to Bayesian model average. The second one is the greedy soup approach [57]. For the greedy soup, we first sort the models in decreasing order of validation set accuracy. The soup is constructed by sequentially adding each model as a potential ingredient in the soup and only keeping the model in the soup if performance on the validation set improves.

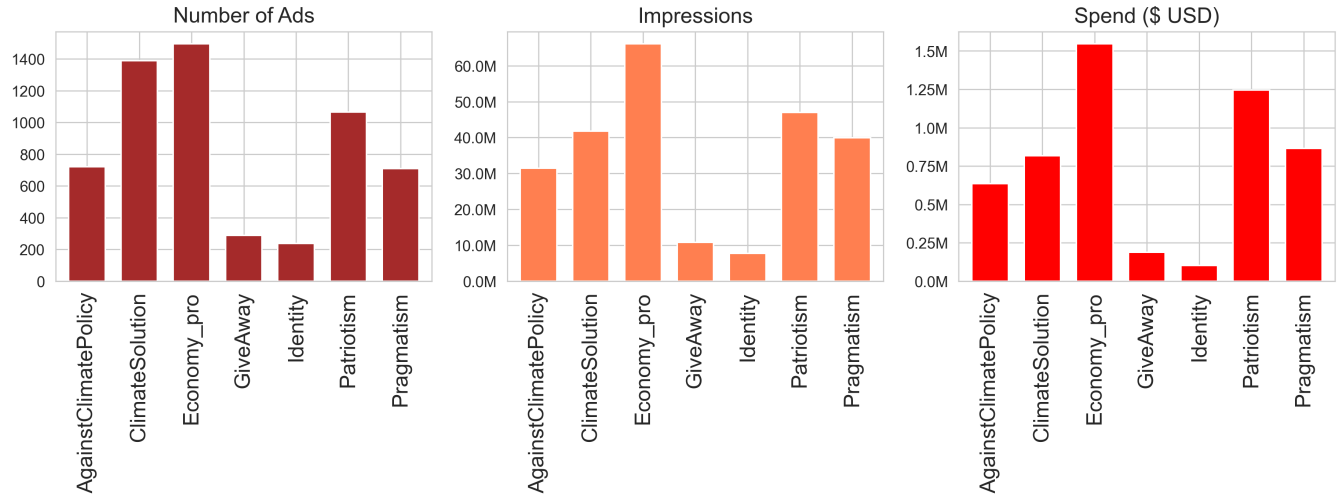
6 EXPERIMENTAL DETAILS

This section presents the experimental details of the stance prediction task on climate change-related ads. We randomly split our data based on the funding entity so that the same ads do not appear in the other splits. At first, we randomly split 20% of the funding entities and keep them as a testing set. Then we randomly split the rest of the data and keep 20% of that as a validation set and the rest as the training set. Details number of funding entities and ads for each split are shown in Table 4. We fine-tune the pre-trained BERT-base-uncased model [16] and run for 10 epochs for each hyperparameter setting, i.e., learning rate and weight decay. We set the maximum text sequence length to 110, batch size 32, and use Adam optimizer [31]. We concatenate the assigned theme with ad text so that our model can leverage the theme information.

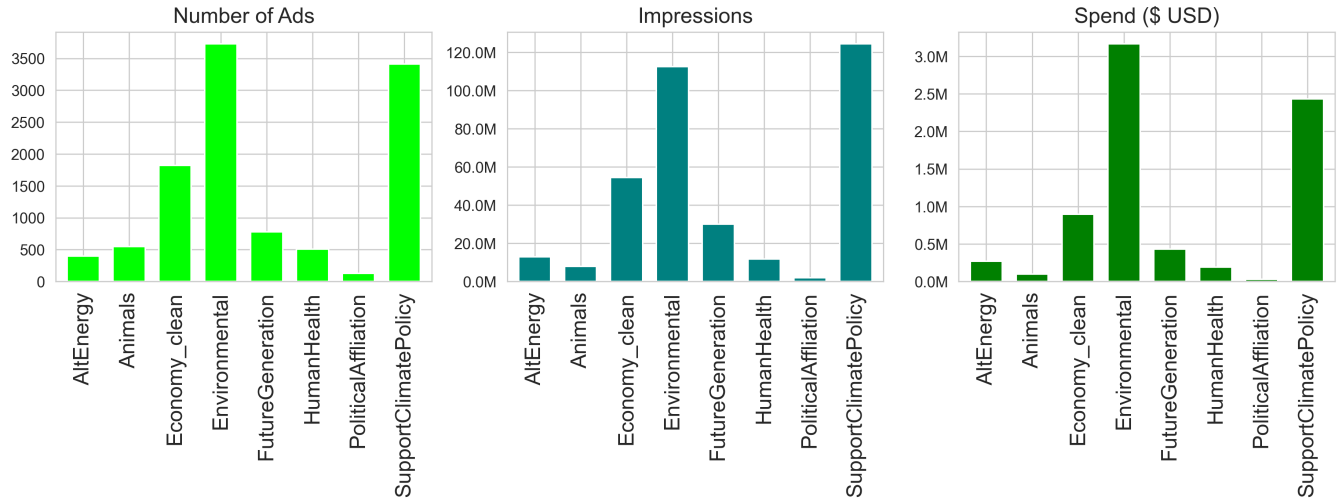
We use pre-trained weights from the Huggingface Transformers library [56]. Evaluation is conducted once at the end of the training, without early stopping. We use a single GPU GeForce GTX 1080 Ti GPU, with 6 Intel Core i5-8400 CPU @ 2.80 GHz processors to run each model, and it takes around 15 minutes to run each model. But averaging several of these models to form a model soup requires no additional training and adds no cost at inference time.

6.1 Results

We provide experimental results in Table 5. For the evaluation metrics, we use accuracy and macro-average F1 score. At first, we compare our approach with simple Logistic Regression (LR) [14] trained on term frequency–inverse document frequency (tf-idf) features baseline (Table 5). Then, to make sure that the model soup being a better hypothesis holds irrespective of the underlying language model (LM) architecture, we test our work on larger pre-trained LM, i.e., RoBERTa [35], T5 [46] besides BERT. Finally, we compare the performance accuracy and macro-average F1 score with the standalone models (best individual model) with respect to the model soup (Table 5). From Table 5, we notice that the uniform model soup



(a) Pro-energy ads



(b) Clean-energy ads

(a) Economy_pro (b) Environmental (c) SupportClimatePolicy

Figure 4: Wordcloud for three messaging themes based on the popularity of ad impressions, expenditure, and the number of sponsored ads for both pro-energy and clean-energy ads.

using ad text + theme (88.8% macro-avg F1 score) outperforms the greedy model soup for text + theme and the best individual model baselines (Answer to **RQ1**).

6.2 Ablation Study

For the ablation study, we run the experiments using only ad text (we **do not** provide any theme information). We notice that the uniform model soup (text + theme) still gives better performance than the uniform model soup (text), greedy model soup (text), and the best single text only models (Table 6).

7 ANALYSES

In this section, we present analyses that address our three research questions (**RQ2**, **RQ3**, and **RQ4**).

In subsection 7.1, we find that various advertisers prioritize distinct themes to promote their narratives that endorse particular stances. In subsection 7.2, we find that advertisers aim their messages at particular demographics and geographic locations to spread their viewpoints. Subsection 7.3 shows that how messaging differs based on the entity type.

7.1 Narrative Analysis

We consider only ads with correct stance prediction and corresponding themes for narrative analysis. To answer **RQ2**, we analyze the messaging strategies used by the advertisers (Fig. 3). By impressions and expenditures, the most popular ***pro-energy*** messaging theme is '**Economy_pro**', accounting for approximately 27% of total impressions and 28.7% of total expenditure (Fig. 3a). Under this theme, narratives promote how *'natural gas and oil industry will drive economic recovery', 'GDP would decline by a cumulative* 700 *billion through 2030 and* 1 *million industry jobs would be lost by 2022 under natural gas and oil leasing and development ban'* (Fig. 4a).

Based on impression, the most popular ***clean-energy*** messaging category is '**SupportClimatePolicy**' (Fig. 3b) (approximately 35%), which features narratives supporting Build Back Better Act[5] to *fight climate change, create clean energy jobs, equitable clean energy future, take bold climate action* (Fig. 4c). Based on spend, the most popular (42%) ***clean-energy*** messaging theme is '**Environmental**' (Fig. 3b). This theme focuses on narratives about *'how dirty fossil fuel industries would harm the indigenous peoples and wildlife', 'why climate scientists agree that climate change causes more extreme droughts, bigger fires and deadlier heat', 'effects of carbon pollution on climate crisis'* etc (Fig. 4b).

7.2 Demographic and Geographics Distribution by Impressions

As Facebook enables its customers to target ads using demographics and geographic information, we further analyze the distribution of the messaging categories to answer **RQ3**. At first, we perform a chi-square test [12] of contingency to calculate the statistical significance of an association between demographic group and their stances. The null hypothesis H_0 assumes that there is no association between the variables, while the alternative hypothesis H_a claims that some association does exist. The chi-square test statistic is computed as follows:

$$\chi^2 = \sum \frac{(observed - expected)^2}{expected}$$

The distribution of the statistic χ^2 is denoted as $\chi^2_{(df)}$, where df is the number of degrees of freedom. $df = (r-1)(c-1)$, where r represents the number of rows and c represents the number of columns in the contingency table. The p-value for the chi-square test is the probability of observing a value at least as extreme as the test statistic for a chi-square distribution with $(r-1)(c-1)$ degrees of freedom. To perform a chi-square test, we take gender distribution over stance and age distribution over stance separately to build contingency tables correspondingly.

The null hypothesis, H_0: whether the demographic group and their stances are independent, i.e., *no relationship.*

The alternative hypothesis H_a: whether the demographic group and their stances are dependent, i.e., $\exists$ *a relationship.*

We choose the value of significance level, $\alpha = 0.05$. The p-value for both cases is < 0.05, which is statistically significant. We reject the null hypothesis H_0, indicating some association between the audience's demographics and their stances on climate change. Fig. 5a shows that *more males than females* view the ***pro-energy*** ads, and *more females than males* watch ***clean-energy*** ads. However, ***pro-energy*** ads are mostly viewed by the *older population (65+)* (Fig. 5b). On the other hand, *young people* from the age range of $25-34$ watch ***clean-energy*** ads (Fig. 5b).

In Fig. 6, we show the distribution of impressions over US states for both stances. To plot the distribution, we use the Choropleth map[6] in Python. ***Pro-energy*** ads receive the most views from Texas which is the energy capital of the world[7] (Fig. 6a). Fig. 6b shows that ***clean-energy*** ads are mostly viewed from California because recently, CA has become one of the loudest voices in the fight against climate change[8].

Type	Entity
Corporation	EXXON MOBIL CORPORATION
Corporation	Shell
Corporation	BP CORPORATION NORTH AMERICA INC.
Corporation	Twin Metals Minnesota
Corporation	Wink to Webster Pipeline LLC
Industry Association	AMERICAN PETROLEUM INSTITUTE
Industry Association	New York Propane Gas Association
Industry Association	Texas Oil & Gas Association
Industry Association	New Mexico Oil and Gas Association
Industry Association	National Propane Gas Association
Advocacy Group	Coloradans for Responsible Energy Development

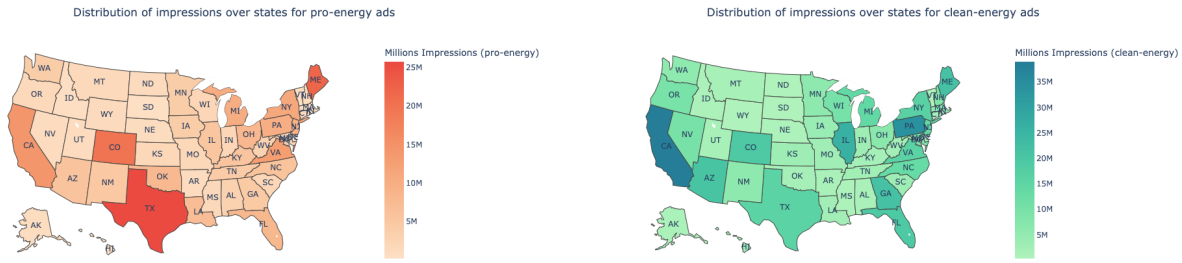
(a) Gender **(b) Age group**

Figure 5: Distribution of impressions over demographic distribution both for pro-energy and clean-energy ads. (a) More males than females watch the pro-energy ads. On the other hand, more females than males view clean-energy ads. (b) The older population (65+) watches the pro-energy ads. In contrast, the younger population (25 − 34) watches clean-energy ads.



(a) pro-energy **(b) clean-energy**

Figure 6: Distribution of impressions over geographic. Pro-energy ads are mostly viewed from Texas (a), whereas clean-energy ads are mostly viewed from California (b).

7.3 Distribution of Messaging by Entity Type

Fig. 7 shows the top 5 funding entities based on expenditure in pro-energy and clean-energy ads. We notice that **Exxon Mobil Corporation**, which is one of the world's largest publicly traded international oil and gas companies[9], spends the most on sponsoring pro-energy ads on Facebook. Clean-energy ads are mostly sponsored by **The Climate Pledge**, which is powered by 378 companies in 34 countries around the globe[10].

To understand how fossil fuel industries and their support groups influence public opinion, we categorize pro-energy funding entities into three types, i.e., Corporations, Industry Associations, and Advocacy Groups. Finally, we select the top 5 pro-energy funding entities based on their expenditure for each category. Table 7 shows the list of pro-energy entities included in our analysis.

The highest spending on '**Economy_pro**' narratives comes from all three entity types (Fig. 8). Corporation entities spend on '**Patriotism**' narratives as their second target. Furthermore, advocacy groups focus on '**Pragmatism**' narratives as their second target. Moreover, industry associations spend almost equally on '**ClimateSolution**' and '**AgainstClimatePolicy**' narratives. Analyzing the messaging themes for different funding entities indicates different groups are fulfilling different messaging roles (Answer to **RQ4**).

8 CONCLUSION

We propose a minimally supervised model soup approach leveraging messaging themes to identify stances of climate related ads on social media. To the best of our knowledge, our work is the first work that uses a probabilistic machine learning approach to analyze climate campaigns. We hope our approach of stance detection and theme analysis will help policymakers to navigate the complex world of energy.

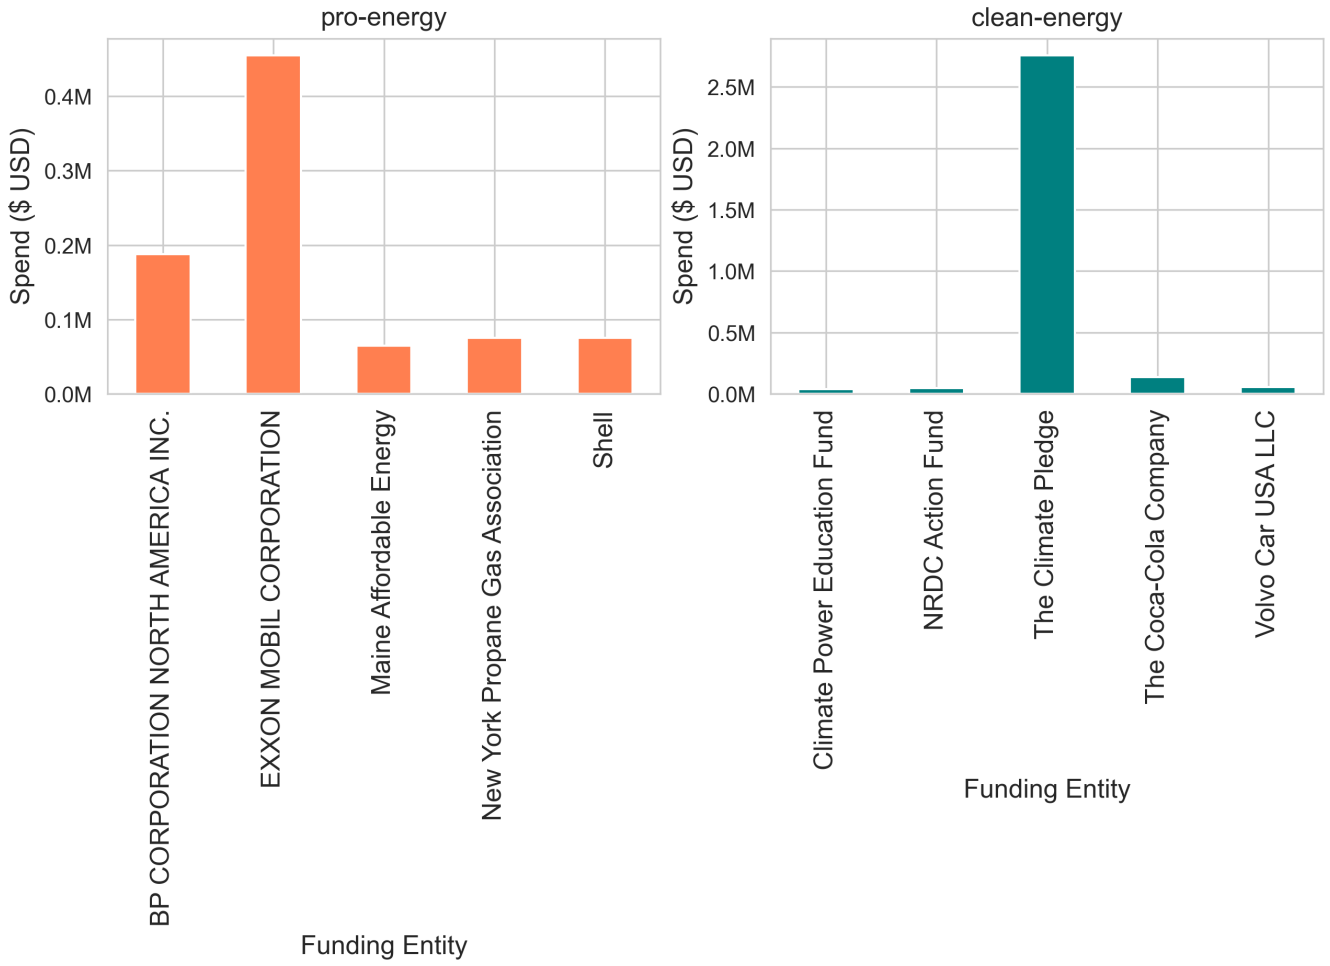

Figure 7: Top 5 funding entities based on expenditure. Orange plot represents pro-energy. Green plot represents clean-energy.

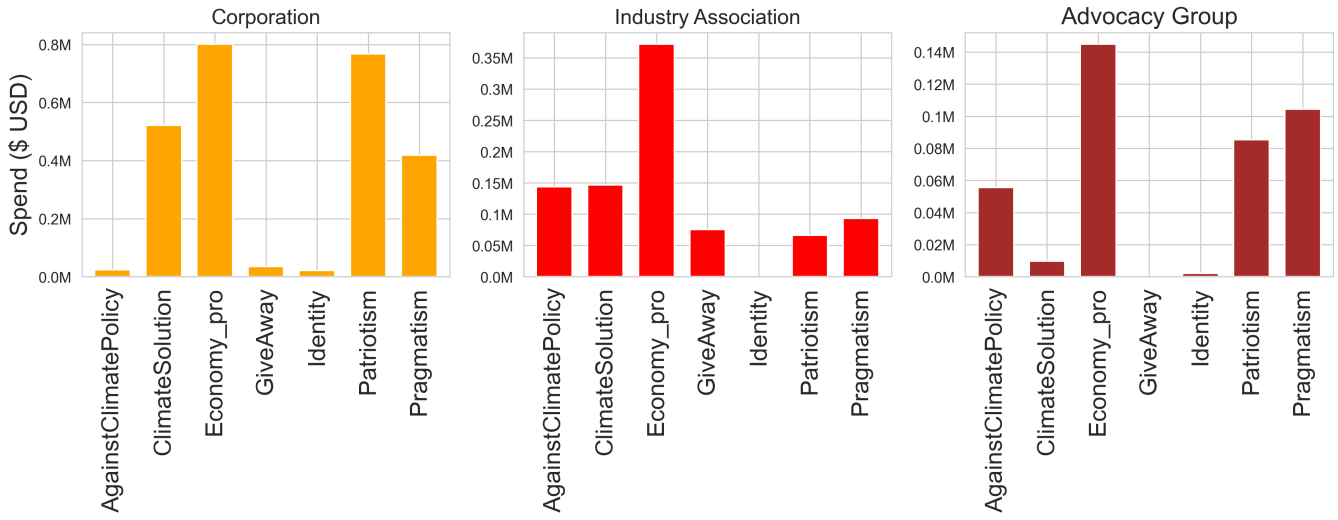

Figure 8: Pro-energy ad themes by funding entity type.

9 LIMITATIONS

In this work, we predict the stances of ads using the theme information. We can further explore other potential tasks, such as moral foundation analysis [23, 24], which will help model the dependencies between the different levels of analysis.

Note that our fine-tuned SBERT based theme assignment model is an unsupervised learning approach and an alternative approach could be zero-shot and/or few-shot classification models [6]. We leave this exploration for future work.

Moreover, our analysis might have an unknown bias as it is based on English written ads on Facebook focusing on the United States only. Another limitation is transparency – some particular aspects of the advertising campaigns are not available to the public through the Facebook Ads Library API, thus limiting our findings.

10 ETHICS STATEMENT

The data collected in this work was made publicly available by Facebook Ads API. The data does not contain any personally identifying information and reports engagement patterns at an aggregate level. The authors' personal views are not represented in any qualitative result we report, as it is solely an outcome derived from a machine learning model.

ACKNOWLEDGMENTS

We are thankful to the anonymous reviewers for their insightful comments. This work was partially supported by Purdue Graduate School Summer Research Grant (to TI) and an NSF CAREER award IIS-2048001.

ABSTRACT

Misinformation in its many forms is a substantial and growing problem for society today. Whether financially or ideologically motivated, purveyors of misinformation do not abide by legal, technical or moral rules. Therefore new, ludic, narrative, gamified and artistic approaches are needed. In this paper we analyse the approaches taken in countering misinformation by 18 AI and machine learning works of art, developed in the MediaFutures project. We examine how these align with existing AI approaches to countering misinformation, and how they address some of the key challenges. We show that AI artists engage with existing debunking and inoculating strategies, including highly technical aspects such as deepfakes, while also utilizing focused strategies of data literacy and collective intelligence. We also find that they are able to integrate hard-to-refute strategies such as narrative and emotion. These findings suggest that data as an art material and AI techniques as art tools are worth of further investigation as to their effectiveness for countering misinformation within society.

CCS CONCEPTS

• **Information systems** → *Social recommendation*; • **Computing methodologies** → **Machine learning**; • **Applied computing** → **Media arts**.

1 INTRODUCTION

Misinformation of various types has been around for centuries, but has grown as the technologies that enable its spread have grown. This matters as misinformation negatively affects the wellbeing of individuals, groups and society in a number of ways. It can undermine democracy [43], reduce climate change consensus [54], exacerbate crises [50] and even lead to death [13]. Further, the proliferation of ways in which misinformation can be encountered also matters, as repeated exposure to a piece of misinformation boosts its likelihood of being believed [35]. Misinformation is also more compelling when it is delivered in emotional language, or designed to be attention-grabbing [35].

Social media is a key forum for misinformation as it enables even those without formal knowledge of the workings of mass media to become content creators, challenging the domain of traditional media [25]. In the run up to the 2016 elections over one quarter of Americans visited a fake news site, visiting an average of 5.5 articles each [37]. Algorithms are a key component of social media, recommending content to users that will keep them engaged with the platform and so provide exposure for adverts [33]. This process is opaque to users and so has been called 'invisible attention engineering' [55]. Misinformation is frequently designed to work with the algorithms to find its way into users' feeds [55].

Art, in the form of cave paintings, predates modern humanity. These paintings and stories shared orally were a way to share knowledge before the existence of written language. The narrative patterns enabled them to be more readily absorbed and remembered by their recipients, who needed the information contained within them to survive. The arts, therefore, are a key way of enabling people to develop the knowledge they need in order to engage effectively with the world around them.

Artists have been working with AI since the 1970s [25]. Algorithms and art are a current topic of much interest, both in popular culture and academia, fueled by the accessibility of algorithmically generated art using large language models such as Dall-E. However, there is also an emerging field of Critical AI art that seeks to engage and comment on society, and with it, attention given to the ethical use of AI tools in this critical art [18].

In this paper we look at art that exposes, refutes or counters various forms of misinformation, by using data science and AI approaches. We describe our use of the term misinformation and some of its key impacts and motivations. The key strategies used

to counter it, media literacy and fact checking, plus algorithmic methods for these, are explored. We show that AI art is used to highlight social tensions in AI itself and as a critique of technology, making it a potential strategy for dealing with misinformation. We identify the strategies used to challenge misinformation online by AI artists through interviews. We find that as well as using current technologies from the computing and journalism sectors, artists incorporate emotion, narrative and explicit ethical appeal in order to counter misinformation.

Our research questions therefore are: 1. What strategic approaches does AI art take to countering misinformation? 2. Which data, tools and techniques are utilized? 3. How does the artistic approach add value to algorithmic approaches to countering misinformation?

This paper makes two key contributions. Firstly, it contributes to the corpus on countering misinformation by analysing a specific and emerging AI approach, and examining how this may support more established approaches. Secondly, it contributes to the growing corpus on AI and the arts by describing the use of AI for artistic creation in a specific context.

2 BACKGROUND LITERATURE

2.1 The challenge of online misinformation

There is no agreed typology of the kinds of incorrect information that is disseminated online both knowingly and unknowingly, although there are some taxonomies created within specific terms [32], [40]. The term 'misinformation is generally understood to mean incorrect information in the sense that it differs from the best available expert information or established fact [57]. 'Disinformation' is seen as more pernicious, and constitutes knowingly incorrect information created for 'public harm or for profit' [28]. Since 2016 these terms have been joined, and possibly superceded in popular imagination by the term 'fake news' [39] which itself includes a number of formulations, including propaganda, trolling, conspiracy theories and satire [53]. Throughout this paper we use employ the term 'misinformation' to represent all forms of incorrect news messaging.

Misinformation in the political sphere has led to "cognitive fallout" where people can continue to believe misinformation even after having been told it is untrue [35]. This "continued influence effect" of misinformation has been demonstrated repeatedly [30], [11]. One of the "fingerprints" of misinformation is its emotional appeal, with high emotionality ensuring virality and hindering analytical explanation [14]. As a consequence, misinformation spreads to up to 1,000 times more people than factual information [56], although some research has shown this is a function of the larger size of some fake news cascades [31].

The growth of large language models has increased the democratic access to content creation online [48], but this very facility presents a threat from machine generated fake news. Another form of machine generated fake news is 'deepfake' videos. These use generative adversarial networks to create believable yet false media [38]. The Korean news channel MBN created a deepfake of its anchor Kim Joo-ha for a bulletin [16], however, the majority of deepfakes are created for the purposes of misinformation. Well-known deepfakes exist of world leaders. such as US film director Jordan Peele's deepfake of Barack Obama discussing deepfakes [44], or more malignly, Vlodymyr Zylynsky suggesting Ukrainian soldiers lay down their weapons [17].

The key motivations for the production and dissemination of misinformation are financial and ideological [7]. Making money via advertising revenue generated by clicks and views on websites is attractive to the fake new media as well as the real news media. An example of this is the far-right conspiracy theory and fake news website InfoWars, which at one point in 2018 made USD800,000 a day. Financially motivated fake news sites often use narrative techniques (clickbait) to appeal to the unwary, such as 'You won't believe what Obama says in this video." [44], [7].

Ideological motivations are more complicated. Propaganda ensures when official bodies spread fake news for ideological reasons. Satire is fake news spread by legitimate bodies for the purpose of entertaining their audience. Trolling is fake news (usually) spread by individuals for' their own entertainment or personal purposes. Largely, these are all driven by requirements for power and influence, albeit in different ways [7].

2.2 Data-driven approaches to countering misinformation

The two key approaches that have been taken to stemming the spread of misinformation online are fact-checking and the development of media literacy within populations (especially youthful ones).

2.2.1 Fact checking. Fact checking is "the systematic publishing assessments of the validity of claims made by public officials and institutions with an explicit attempt to identify whether a claim is factual" [59]. As such it is conducted after the dissemination of misinformation and is colloquially known as 'debunking' [35]. It is performed by both journalistic and non-journalistic bodies such as the Associated Press and FactCheck.org. Both of these organisations use human-led, investigative reporter techniques for fact checking. However, effectiveness of fact-checking as a tool for counteracting misinformation is somewhat undermined by people's unwillingness to accept corrective fact-checking [10]. While "falsehoods" can be corrected, feelings are more challenging [36].

Computationally-oriented approaches are primarily based on knowledge graphs [19]. There are automated approaches that focus on fake news detection, such as Hoaxy [46], which visualise the spread of information on Twitter, and websites that identify how much content around a news story appears to be linked to bots such as Botometer [1]. ClaimBuster flags up claims that appear to be worthy of checking, based on a combination of natural language processing and machine learning [24]. However, this is a very emergent area, and "the potential for automated responses to online misinformation that work at scale and don't require human supervision remains sharply limited today" [24]. With this aim, several automated fake news detection techniques have been developed, based on algorithmic techniques such as random forests (multiple decision trees), content features for classification and neural networks, although they have not necessarily been very successful [26]. One challenge is the variety of types of fake news which has no agreed taxonomy [32].

Further, collecting reliable datasets of fake and trustworthy news on which to train these techniques is not a trivial task and no benchmark dataset exists [36]. Datasets of importance include FEVER, consisting of 185,445 claims generated by altering sentences extracted from Wikipedia and LIAR, based on statements from Politifact.

Approaches to counter machine generated misinformation have been based on identifying the difference between machine and human generated writing. However, they have been less successful in distinguishing legitimate from false machine generated writing, as, unlike humans, machines do not alter their styles between true and false information [45]. Techniques for countering deepfakes include many versions of artifact detection, strict blockchain data provenance for multimedia, and counter attacks [8].

2.2.2 Media Literacy. Media literacy is the development by an individual of a set of skills around critical thinking, evaluation strategies, search skills and knowledge of the news and media industries [12],[20]. Limited research on games and gamification shows that these might also help media literacy. This suggests active engagement with different literacy skills, rather than passive instruction, is important [20]. Media literacy is seen as a 'pre-emptive' approach [35] and has in the past been characterised as an 'psychological inoculation' approach in that it seeks to arm the individual with the skills necessary to critically appraise and identify misinformation when coming into contact with it [36],[12].

A number of studies confirm that media literacy is correlated with the ability to identify misinformation, or engage critically with information online [20]. In one such study a practical test was administered to 63 adults aged 19-24, which showed that critical evaluation behaviours were positively correlated to the correct identification of fake news stories [34]. Unlike debunking, inoculation works equally despite prior attitudes [36].

Computational approaches to media literacy are based on identifying the algorithmic knowledge a media literate public would need to possess, and delivering that through computing education. A key component of this is raising awareness of aspects such as invisible attention engineering, bots/agents, content filtering and tracking [55]. This involves not only creating awareness of the technical capabilities, but their implications. In a post-digital world, in which the digital world and the 'real world' are no longer meaningfully separate, the technical and the political can no longer be separate [29].

The existence of 'big' datasets for training purposes is a key reason AI research is currently flourishing. Hence, the need for a data literacy within media literacy in order to understand the potential impacts of AI, given that the datasets themselves are frequently problematic [29]. Even more specifically, there have been calls for an algorithmic literacy [47].

In addition to these purely educational approaches, a computational approach has arisen that involves automatically notifying readers of the pragmatics of the content, in order to augment their media literacy in context. These could then identify ways that the reader is being manipulated without their awareness, such as by certain tropes being used as narrative frames [9].

Contemporary media literacy tends to organize around five themes: youth participation, teacher training and curricular resources, parental support, policy initiatives, and evidence base construction [12]. However, older adults are particularly susceptible to fake news and consume substantially more than younger people. This may be in part due to not being 'digital natives' and having less facility with the technology on which they encounter fake news [42].

2.3 Critical AI art

According to the World Economic Forum, "Giving people access to data most often leaves them feeling overwhelmed and disconnected, not empowered and poised for action. This is where art can make a difference. Art does not show people what to do, yet engaging with a good work of art can connect you to your senses, body, and mind." [21]. The participation of artists in technological or scientific projects has proven to question technologies, increase citizens' awareness, explore hypothetical paths for progress, enhance and humanize technologies [21].

The first decade of this century saw AI artists exploring natural language processing, computer vision and pattern recognition. In the 2010s deep learning technologies enabled greater expansion [25]. Non-fungible tokens, facilitating a market for digital art, have further brought AI art into the mainstream [25]. High-profile projects such as The Next Rembrandt, which used deep learning to generate a 'typical' Rembrandt painting, tapped into corporate sponsorship as well as industry, public sector and academic partnerships [2].

A specific form of AI artwork is critical AI art – used to address social tensions arising from technology and to enable a sense of critical distance from the technology [51]. A number of artworks, such as Capture (2020) and DataMasks (2014), engage with what has been called "algorithmic anxiety" around the growing ubiquity of facial recognition technologies [58]. DataMasks created masks that, "are shadows of human beings as seen by the minds-eye of the machine-organism" [15]. Projects such as MIT's Crowd-Sourced Intelligence Agency (2015) expose dataveillance practices by allowing visitors to assume the role of security analysts and monitor and analyse their friends' tweets [23]. The well-known ImageNet Roulette (2019) uses classification techniques to illustrate what happens when technical systems are trained on problematic data [3].

As well as being fake news, deepfakes are used as art work to address the dangers of deepfakes themselves. The deepfake In Event of Moon Disaster (2020) purports to show a recording of President Nixon delivering a contingency speech in the event of the Apollo 11 moon mission ending disastrously. It was created by MIT to educate people about the existence of deepfakes and the challenges of identifying them [41]. Artist Bill Posters created a deepfake of Mark Zuckerberg, entitled 'I wish I could…' (2019), which was commissioned for exhibition to raise awareness of how people can be manipulated by social media. This video, showing Zuckerberg boasting that Facebook owns its users, was subsequently posted to Instagram (and was still there at the time of writing). Such works explicitly engage with and critically examine the ethics of AI.

In particular, critical AI art facilitates such aspects as linking "underlying technical systems to structural issues of power", enables experiential learning, and crucially, allows interpretation rather than straightforward explanation [27]. There are a number of projects that aim to use art based on data technologies to interrogate existing structures or create new insights. The British Antarctic Survey Data as Art programme developed a series of artworks using Antarctic data, with the aim of engaging a broad audience with the question

of, 'why is this data important for society?' [4]. RAND Art + Data engaged artists to create visual stories with the aim of challenging the audience to think differently about policy analysis, including topics such as barriers to Covid vaccination and Russian propaganda [5]. The EU S+T+ARTS programme (science plus technology plus the arts) aims to support interdisciplinary teams of artists and technologist to creatively innovate in a host of fields [52]. The project DataStories aimed to investigate data in a "post-truth environment" using a variety of narrative approaches across a number of media including film [6]. There is sufficient volume of artists working in critical AI to provoke the need for a taxonomy of data as a material [22].

Figure 1: Data-Masks Installation in Karlsruhe, 2015 [Public domain], via the artist's website.

3 METHODOLOGY

To investigate the use of fact-checking and media literacy strategies by critical AI artists, we conducted interviews with participants in the Horizon Europe project MediaFutures.

3.1 MediaFutures

MediaFutures is part of the European S+T+Arts programme. It offers grant funding and support for startups and artists, via open calls held in 2020, 2021 and 2022. In MediaFutures, artists are asked to use data as an art material to create works that question the impact of misinformation on individuals and society. The 1st cohort graduated in September 2021, the 2nd cohort graduated in April 2022 and a 3rd cohort started in November 2022 and will graduate in June 2023.

Currently, 10 art pilots have concluded, with a further 5 currently in the third cohort of the programme. A further 8 projects where artists collaborated with startups have also concluded, giving a participant pool of 18 projects. (There are currently 4 more such projects in the programme.) Of the concluded art projects, some are in their final version and have exhibited their work, while others are still pre-exhibition. Of these projects, some use AI to explore and challenge AI, while others use AI/machine learning to explore non-AI contexts. This includes both 'pure' art works and art works with a commercialisation element, developed by artists and startups together. A description of all the art projects in the first two cohorts of the programme can be found in the Appendix.

3.2 Interviews and analysis

We interviewed the artists and startups behind 18 art projects in the MediaFutures programme. These interviews took place after the end of the first and second rounds of the MediaFutures residency and acceleration programme in 2021 and 2022. The interviews were structured, took place remotely and were accompanied by three questions on the data, tools, and techniques used which were sent and answered via email (see Appendix B). The interviews were then transcribed and thematic analysis was conducted. The projects are referred to by ID numbers in the results. Our interview pool was constituted by all the art and artist/start up projects that were selected for the second phase of the MediaFutures project (developing the project to the exhibition/pre-exhibition stage). The interview guide can be found in Appendix 2. We then applied inductive analysis to the interview transcripts, developing codes as we read.

4 RESULTS

4.1 Approaches to media literacy and fact checking

The projects in MediaFutures engaged in both debunking and inoculation strategies. The projects that focused on debunking ([774452], [580713], [504746] amongst others) were aware of the necessity for datasets in combatting fake news, and created new datasets by bringing together multiple different sources. "Specialists cannot combat misinformation if they don't have data to analyse it…we wanted to do is to create a dataset of fake news, which are specific to [a] region, because [it] is highly underrepresented in terms of misinformation…So we talked with all these organisations, and we say, Let's unite all these databases in order to create a big data set for the academic community" [580713]. Artistic engagement was seen as a unique way not only to spread information but also to gather hard to access data. "If you don't understand street stories, you don't understand what's really going on, and you don't get street stories in response to surveys or in response to experts going into interviews or running focus group" [776326]. Those datasets are used in many works for building AI models that allow classifying claims based on their feasibility, auto fact-checking, or fine-tuning pre-existing AI models for a specific context or topic. For instance, Computer-Assisted Recognition of Denial and Skepticism (CARDS) is employed in classifying different types of misinformation on climate change.

Many artists were familiar with and engaged with media literacy theory. "It's very important to understand how to debunk them, how to find a way to raise the resilience and the capacity of people dealing with all this information… and also the creation or the critical thinking of people" [774452]. Artists frequently specified exactly how they believed media literacy creates protection against misinformation. "The main aspects, which we wish to deliver, as an impact to society is strong, critical thinking, super important, as we believe that educated persons can't be influenced by propaganda so easily" [423794.] Others extended the link from critical thinking to behaviour change. "So [engaging with the artwork] as

Figure 2: Epic Sock Puppet Theater uses datasets of right and left wing 'sock puppet' social media accounts, the words of which are then spoken by animatronic sock puppets [Public domain], via MediaFutures.

the foundational of media literacy, of behavioural changes, I guess" [504746].

In terms of data, Twitter was a commonly used source of data in artworks that took a media literacy approach. [984662, 193374]. The GDELT Global Difference Graph (GDG) databases were used to analyze more than 250,000 headlines of Russian-language media publications for fake news identification [774452]. However, artists often created their own datasets for various reasons. One artist ran up against the problem of there simply being no appropriate existing dataset for Eastern Europe [580713]. The LIAR and LIAR+ datasets were used in this project not for their data, but to inform the structuring of the new dataset to address fake news. Another required a very small, specific dataset [859977]. Others sought to collect data that did not otherwise exist, for instance, micro-narratives [776326]. One artwork consisted of a browser plug in that used 11 data sources, including Wikidata and review site TrustPilot, to make visible the underlying ethics of certain websites [504746].

The artists were, overall, very clear on how data-driven art builds media literacy. For instance, "every time disinformation is picked up in the sense of sound or data, there's always this critical approach in revealing mechanisms, but also in the systematic refutation of the disinformation. You see the digital analysis mechanisms and you hear refutations so there's a strong critical thinking here" [831967]. One team believed that debunking approaches were ineffective, and disrupting people's patterns of thinking would be more effective. "I think that there seems to be a dominant view, … that you handle myths by making people more aware of facts, and that's a really bad sign …we think art can provide a line of flight by which people can escape from those dominant patterns" [776326]. One project moved away from either approach to consider less how misinformation is countered, towards, "how do we improve access to accurate information" [859977].

Another focus around data was increasing data literacy, enhancing the ability of the audience to understand aspects of the data, either what it contained or how it was created. This might be simply provoking interest in data, by creating an "immersive experience [that] can become a kind of stepping stone for these people to get curious about" [369215] Some goals were very ambitious, aiming for "people [to] understand better large amounts of data in the making. What is data, how it's done, how you make sense of a database" [758112]. One artist found that collecting data from others, and analysing it, subverted the dominant trope, "as users, companies and governments are analysing us, and in this case we are analysing" [774452].

Educational aspects appear, therefore, to be very present in how the artists are thinking about their artworks and what they want participants, viewers or audiences to take away with them. "Instead of exit through the gift shop, we're thinking it's kind of like exit through the educational aspect of why this exists and kind of details about the process of how these were made, implications for how synthetic media is being used in the world today" [060672]. However, various strategies were employed here. Some were more ludic approaches, "the whole mission of our project is to educate people about what this information is methods of manipulation of their brains, but make it in a gamified way" [423794]. Others explicitly used the base of education to build more concrete behaviour change upon. "I call it an educational art tool. But we have ideas for how it's not just be this kind of individual tool that you use to educate yourself. It's how do we turn you from this individual into collective of individuals. The long objective for this is to use [the artwork] as a form of protest" [504746]. Adding these layers of complexity to simple educational tools also appeared in other ways. One of the artist/startup teams particularly noted that it was important to "educate from within" in terms of the infrastructures worked with, but also that their educational tool needed to "allow for these ambiguities and uncertainties" [758112] surrounding the particular data they worked with.

4.2 Tools and techniques

The artworks created varied widely in form. Some were installations which the audience could experience physically (e.g. 730 Hours of Violence, How many heartbeats to send an email), Critical Climate Change Machine) some were on the web (e.g. Invisible Voices, Social Sandwich) and some in the metaverse (e.g. Time Lapse Migration). Like ImageNet Roulette, many of the works took a hybrid form and can be exhibited in person and on the web. MediaFutures offered technical support to the artists, but the artists involved are often technically highly skilled. "Because I have an interest as an artist, I think that as an artist, we have to be involved in developing our digital tools… You know, that's my art." [758112] "the artists knew more on NFT than us [the startup partner] because they are really into digital art" [748452].

The use of AI and computational methods varied widely across the art works. Some projects were highly complex and used as many as 20 tools or libraries, among them AI models for classifying, predicting or generating content [101362]. A number of the more technically simple projects, such as generating sound or images processing data from social networks, like Twitter, utilized only 4 [984662]. There were also a number of artworks that used data as a source for building the narrative, rather than incorporating it directly in AI, or other computational, models (734815, 859977).

One artist working in the media literacy space described the process as "classical data science pipeline… classical data science

tools" [423794]. Many artists followed this traditional pipeline of data collection, preparation, exploration, visualisation, experimentation and classification. Some of them used visualisation as the end product [774452], and there was the use of supervised classification and regression models (e.g., K-nearest neighbours, DBSCAN or Neural Networks).

One network-based artwork, which had an accompanying commercial product, used knowledge graphs for extracting insights of data. Another work, in the same vein, used network science analysis techniques to achieve perform clustering of networks and in graphs and, ultimately, visualize them.

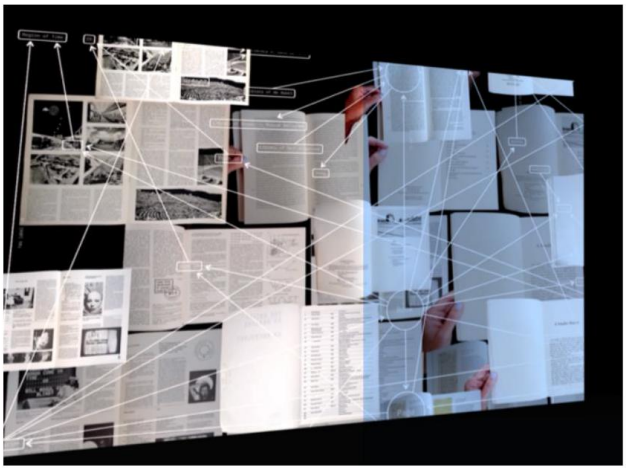

Figure 3: Illustration from Bibliograph, showing how objects in a library are related. [Public domain], via MediaFutures.

One of the most advanced uses of AI in the artwork was for generating synthetic content. Open-source tools like Tools such as the faceswapping framework SimSwap were used by artists addressing deepfakes who also used generative adversarial networks [353266]. Visitors to Oracle Network were introduced to deepfakes by animation of their own images, with First order motion models, which were also used for The Evil Magic Mirror and Soft Evidence. Not all artists developed their work from scratch. One work was based on an existing classifier that had been developed in research. Amongst artists generating,creating and exploring the impacts of deepfakes, existing datasets such as WIDER FACE were used. However, ethical concerns, primarily regarding whether consent for images of real people to be utilized for deepfakes could properly be described as informed, led some of the artists employing deep fake technologies to the creation of their own datasets using generative adversarial networks [353266, 060672].

Most of the artworks developed their work based on open-source tools following the recommendations of mentors in the residency and acceleration programme, however others created their tools from scratch. Consequently, MediaFutures encouraged the publication of datasets and code created by the artists and the algorithms created for an artwork on propaganda are available for others to use in working with propaganda narratives [774452] Again, concern about misuse meant that artists working with deepfake technology were reluctant to do this. [569260].

4.3 Emotion, narrative and ethics in misinformation countering strategies

"Art has a special way, in the way we make sense of things, and we make sense of data. And that art has that kind of level of abstraction that can bridge things" [776326]. The power of art was seen to be facilitative, with art going beyond existing data visualisation techniques and enabling exploration of "much more than representations of the data" [996510]. Others felt the relationship between data and art worked "efficiently" and," the data approach can be enriched with the artistic methods" [774452]. It was believed that, "this interdisciplinary connection between data and art is becoming more and more important and more valid" [758112].

Narrative, or story-telling, was seen as a key aspect of many of the artworks. Simply consumed narratives easily go viral. "So one of the ways that people can find stories, and one of the ways they can discover meaning, is through art, through cartoons. Cartoons are very effective. They go viral" [776326] Another artist described their product as a "storytelling platform" [774452]. Narrative was seen by one team as effective in creating behaviour change. "That's one of the things we do with narrative…So one of the ways you get people to change is ask them a question that they can't answer without thinking or acting differently" [776326].

Emotion is often seen as a tool of misinformation, but the artists frequently engaged with this in their work. One artist used AI emotion analytics to gather information on people interacting with their artwork, and personalised the experience based on that. "There are three emotions, focused, energetic and rage. And for each of those, I create a specific soundtrack. So depending on the emotion when the user is using his mouse, it will say okay, it seems like you're a bit energetic, so it's going to play the energetic track and that way for everybody, the game is going to sound different" [423794]. Emotion was seen as a way to grasp the attention of users. "We need a very strong emotional reaction and engagement in order for people to start understanding how important it is to seek truth, you know, what is truth?" [266713].

Other artists focused on the importance of removing emotion to create neutral ground on which to discuss otherwise emotionally-heightened subjects. Two works explicitly facilitate this platform for dialogue, while others seek to find a way to integrate multiple sides of the story into their artwork. "I need to learn how to look at [a person who is very conditioned to believing misinformation] side of story as well" [266713]. Artists were seen as people who were particularly capable of communicating multiple points of view, "because artists in their worlds express a lot of narrative stories and different points of view" [734815]. Other pieces take what are normally highly-politicised subjects and make them, "purposefully neutral and apolitical. This allows people to engage on neutral ground for conversation about image manipulation and the risk of misinformation posed by such technologies" [060672].

Sound, visuals and touch were viewed as a way of bringing emotions into the misinformation area in a positive way, and combatting potential for attention drift. These emotions might be positive, "because it's something engaging and funny…it would catch their mind as being a different way of explaining and visualising something that before was boring," [201483]. An augmented reality project implemented 'explosions' into their game after discovering

users found it, "satisfying" [580713]. Related to this is art's ability to be multi-sensory and transpose the abstract to the physical. "These abstract concepts, about fake news, . . . this is an enormous amount of data and I think it's very hard to imagine how it looks like, how it sounds like, so we're trying to appeal to the different senses of the audience" [996510]. "Even though I'm using data and binaries, I wanted to make sure that people understand that [misinformation] has a huge material effect on everybody. I'm using a heartbeat, which, when you put your hand on it, you can literally feel the heartbeat" [266713]. This appeal was deemed necessary as an approach by some artists as a deliberate response to the perceived low refutation abilities of current strategies. "We want to create artistic interpretation of fake news, so that people are engaged that find them catchy, visually appealing, we strongly believe that having very strict and boring way of saying, this is fake news...is not engaging people" [774452]. A further art work built on this by segmenting their audience by psychological learning types and developing elements for visual, sound and kinaesthetic individuals [423794].

While all the artists considered the ethical aspects of their artwork as part of the MediaFutures process, some also surfaced ethical questions to their audience. One artist noted that engaging in a project that sought to educate people about harms required a high level of ethicality, especially around transparency, so people engage with the work can trust them. "Ethics has always been at the heart of it..it's about trust. And if we're not doing it right, then then who are we commenting on other people's [ethics]?" [504746]. As noted above, dataset compilation raised many ethical concerns, in particular with regard to deepfakes. "Oftentimes, when you see a deepfake, this many images are scraped from Google without anyone's consent. But we created every single one, so also raising awareness about consent and use of data." [060672].

5 DISCUSSION

Most of the art works in MediaFutures discussed above engage with the key existing strategies for countering misinformation online. They largely adhere to media literacy routes but also develop new, clean verifiable data sets, valuable for fact checking, and many worked with deepfakes to raise awareness of the technology's capabilities and impact. Only one artist rejected the idea that fact-checking would work as an approach. However, an emergent strategy appeared to be focused around collaborative intelligence, essentially a distributed network where each agent contributes autonomously to problem solving. This approach has been used in, for instance, participatory democracy. One of the challenges for traditional counteraction strategies is that they largely attempt to apply considered and direct approaches to mitigating the effects of often highly emotional misinformation. Many of the art works in MediaFutures deal with the challenge of emotion head on, whether by responding emotionally, or neutralizing the emotion in the misinformation. Simply by being art, and sitting outside of the traditional online arenas of media and social media, art is able to create more neutral ground for the discussion of politicised subjects that are vulnerable to post-truth argumentation. This neutral ground is sometimes highly structured, as in Social Sandwich, which reflects other attempts to create less polarised social media online. Similarly, one project used 'standard' classifier, clustering and neural network approaches to the detection of fake news, but added the additional element of using emotion to identify to alert people that they had encountered untrustworthy news.

Deliberately trying to engage an audience or making an intervention 'less boring' has not necessarily been a key goal of media literacy attempts, many of which work with captive audiences. Artists, however, are experienced in the aim of capturing the attention of potential audiences in a world competing for attention, and this has been the driver behind collaborations such as the British Antarctic Survey exhibition. Through the ability to be multi-sensory (even online, through the use of sound) art has an extra dimension through which to communicate with the audience, and be, in the words of one artist, "much more than representations of data". This is key, as it is this appeal which enables virality. Many of the interviewees discussed narrative as a compelling technique for engaging with their audience, or for ensuring their audience engaged with each other. This narrative could then be distributed and consumed via any of the multisensory methods described above, from a brief cartoon to a virtual exhibition of refugee art, but with the ability to appeal to the natural human instinct for storytelling. This reflects the findings that artistic approaches enable interpretation by the audience, requiring engagement, rather than a one-way explanation [4].

Although the types of projects selected into MediaFutures meant that our dataset would not include any artists who were using wholly non-AI approaches to critique misinformation, there was still a vast spectrum across the use of data and technology. While there was standard use of such datasets such as LIAR and techniques such as generative adversarial networks, there was also the utilisation of more unusual software such as translation software and the dataset of the Observatory of Cultural and Linguistic Diversity on the Internet [859977]. Through such approaches, AI art may offer a way to engage more tools in the fight against misinformation. As noted, the major task of debunking fake news is establishing reliable training datasets [10]. For some parts of the world these are simply not available, and the creation of these datasets as part of these artworks is a useful contribution. Artists also promote inclusivity via awareness and addressing of the inherent biases in general datasets) that are focused on claims in majority languages (e.g. English) and the lack of representativity of certain countries.

Projects such as the British Antarctic Survey and those studied in [54] focused on educating audiences. Many of the artists we interviewed engaged specifically with educating their audiences around data, to the point that data literacy, rather than a broader media literacy, was their aim. The artists were sensitive to and responsive to the idea that some groups were excluded from the majority of media literacy approaches, and there was focus on making artworks inclusive and accessible in terms of the amount of digital awareness that was necessary to engage with them, despite their underlying use of AI tools and techniques. This is particularly clear in works such as 730 Hours of Violence, Soft Evidence or How Many Heartbeats to Send a Love Email, where the audience can experience the art works in comparatively familiar ways.

The artworks frequently demonstrated economy of use with multiple aims, but with the audience able to engage with the art at whatever level they felt comfortable. For instance, a number of art works offer tools that allow individuals to simply engage with the art work, but then provide an opportunity to engage further, either with other individuals or by taking knowledge from the artwork into other parts of life. In this way the artwork operates on a number of levels, as a visual, tactile or sonified experience, an educational tool, and then a tool of active choice, or protest against misinformation. This demonstrates the linking of the technical to the power as described in [4]. While the majority of the artists interviewed dealt with ethics mainly in terms of ensuring their own art was ethical, rather than explicitly engaging with the ethics of AI two art projects made highlighting unethical practices the focus of their engagement with misinformation.

This therefore offers a range of considerations to take into account when designing future technologies or interventions against misinformation. The first is that, as data is an established art material, many artists are well-positioned to bring technical as well as artistic skills to their work, creating highly integrated art works. We also find that narrative is a powerful tool that can be exploited through the data/art relationship and resists easy binaries. Integrating emotion into the response to emotionally-heightened misinformation allows for engagement on a more equal footing, which may help reduce the inequity of virality. We also find the idea of engaging with misinformation not prior to or post exposure, but synchronously, via collaborative and participatory opportunities for engagement, to be compelling and worthy of more investigation.

6 CONCLUSION, LIMITATIONS AND FUTURE WORK

6.1 Conclusion

Efforts to counter misinformation online have been hampered by both an age old truism and a very contemporary concept. On the one hand, humans are emotional beings, who respond to storytelling, whether that story is objectively true or not. On the other hand, there is now, in certain circles, a reluctance to accept anything as objective fact, and a mistrust of experts. This creates fertile ground for the most appealing information to be the most widely shared, regardless of veracity, and for there to be little leverage for counter argument.

Countering misinformation with art, however, addresses both of these aspects. Firstly, we have an emotional response to art we find compelling. Secondly, although art can certainly be argued about, it cannot be argued with. After all, "you cannot refute a work of art" [49]. AI-driven artistic interventions allow their creators to use some of the same core techniques of media literacy and fact-checking, based on the same AI approaches, but also utilise multisensory and emotional tools that have the possibility of reaching a wide range of demographics.

6.2 Limitations

The strategies outlined above are from one project. They represent only a subsection of the possible approaches. A number of these artworks are yet to be implemented or exhibited, so the aims are still largely theoretical, rather than user tested for efficacy.

6.3 Future work

As it stands, the variety of strategies available to art and artists, the difficulty in countering a work of art and the fact that art can be understood on many levels mean that this intuitively appears to be a useful addition to other forms of media literacy. In particular, more work needs to be done on understanding the role of data literacy and collective intelligence. However, the effectiveness of current interventions is unclear [38]. Taken together, these suggest that more work is necessary to measure the impacts, both immediate and long term, of artistic approaches. Assessment of this is underway with a number of MediaFutures projects.

APPENDIX A: AI ART PROJECTS IN MEDIAFUTURES 1ST (2021) AND 2ND (2022) COHORTS

Artwork	Brief Description
Soft Evidence	A series of synthetic scenes intended to be as believable as possible. In the exhibition, they mixed synthetic scenes with real scenes to invite the audience to guess which scenes are fake. This interactive guessing encouraged the audience to question the images they see, who created them and for what purpose.
Evil Magic	In this experiment the artists create a deep fake in real time with the face of the user. They demonstrated how, in a few seconds. software can capture the audience's face and body gestures, and turn their images into a deep fake saying words that they would never have said.
Social Sandwich	Offers encounters with anonymous strangers with opposing views or values. The users are invited to collaborate with one another to determine the trustworthiness of the news that appears online. During a 15 minute message-based conversation, they see the world from another perspective, and discover how to keep exchanging when they do not agree with someone's views.
Chanate Machine	Quantifies and reveals the mechanisms of misinformation on global warming. It is composed of two data sets. Fake news stories are categorised and the number of the category is displayed on the artwork. In the exhibition, correspondence is established between values and categories of detected false arguments. Confronted with a landscape of numbers, the visitors are invited to evaluate the quantities of each type of false argument.
730 Hours of Violence	An exhibition using data to explore the new paradigms of violence in the 21st century. Each piece is based on specific data sets, with the aim of engaging the audience with data and encouraging them to understand it rather than ignore it.
Two Truths and a Lie	A multimedia installation exploring the relationship between foreign languages, mother tongues and trustworthiness. In the age of disinformation, distributing credible information is an increasingly complex challenge, but what exactly makes individuals 'deem' an information source trustworthy? Combining experimental documentary, video art, spatial audio, and assemblage, the 100-channel and 100-language installation uses the children's game of 'two truths and a lie' to blend truth and fiction beyond the point of discernibility.
Invisible Voice	A browser plugin that empowers individuals to make informed decisions about the websites and companies that they use. It opens a pop-up, that displays data to enable the user to make informed decisions based on the company's practices, derived from 17 databases.
Edit Wars	The project addresses the use of aggressive narratives in the government-controlled media that isolate public perception from the real state of affairs. Data from large datasets are analysed quantitatively and qualitatively to draw meaningful conclusions for the presentation, and the findings displayed in a multimedia interactive medium.
Synthetic Identity Speculations	A participatory artistic research project that monitors individual synergy effects of social network algorithms and their impact on body images. Transgressing platforms through hyperrealistic ideals and potentially momentous misclassifications, accountability for algorithmic agency is effectively shifted to users.
How Many Heartbeats to	Offers a new narrative about energy consumption and digital data through an interactive experience engaging our own body energy. This artwork intends to create awareness on digital pollution caused by

Send A Love Email	infobesity and fake news, and to question our intimate relationship with online data.
Bibliograph	Bibliograph combines two micro tools for collective linked data aggregation, text annotation and voice recording. The resulting semantic layer allows greater engagement with texts. We are proposing the use of this tools in a non-technical digita environment suited for independent research, autonomy and digital literacy.
HyperViz	This immersive prototype turns hyperspectral data satellite data from a wide variety of sectors including environmental management, agriculture and pandemics into a digital experience for the general public in a way that raw data cannot be experienced.
Fragile Perspectives	A multi-sensory experience of news landscapes, information distortion and the fragility of perspectives formed by unbalanced news consumption. The audience can go further with the tool Ject-ai which was used to analyse news
Ponte	An online tool which allows discussions starting with an illustration. The artwork-based discussion launches the participants into a creative narrative mode. The metaphors and abstractions at the center of arts allow people to contrast perspectives without devaluing an opinion or attributing blame for being wrong. The inputs from those discussions with people around the world are then presented back in illustrations to the participants in an exciting way.
MUMIDIS	The Museum of mis- and disinformation» educates people about methods of brainwashing with disinformation. Using realistic visuals and audio, the audience is engaged in a gamified way to guess false and trusted news. Emotion AI technology, detects emotions & behavior of online visitors and compares the emotions of readers, while they consume news.
The Oracle Network	The Oracle Network is composed of two main parts: urban augmented reality art spread around the city that leads, like a treasure hunt, to the Central Hub of interactive artificial intelligence art installations. The Central Hub is a private space where visitors interact with artificial intelligence art installations. The installations are on three levels of virtualization to gradually introduce the viewer into the abstract tech space of fake media.
Time-lapse Migration	A digital storytelling and exhibitions platform on the web and on the metaverse to disseminate first hand forced migration narratives and to give visibility and new market opportunities to refugee artist's artwork. This counters misinformation and disinformation on refugee phenomenon in Europe, by giving a wider context and different lights on the migration fluxes, their motivations, problems but also past episodes of forced migration in Europe and their contributions to European culture.
Doppelganger	Doppelgänger aims to educate the audience on understanding of the laws and practices surrounding CCTV and draw into question the neutrality and trustworthiness of images recorded by a machine in an age where deep fake technology is widespread.

APPENDIX B: INTERVIEW GUIDE

The first line in each question is the main question, with the following questions used as prompts or followups as necessary.

1. Can you give us a brief overview of what you set out to do in the MediaFutures support programme (MediaFutures for short), and what you ended up doing?

How is your project connected to misinformation?

2.What were your expectations going into MediaFutures?

What did you hope to learn?

What did you think are going to be the biggest challenges?

3.What was your actual experience of participating in MediaFutures?

What challenges did you face during your work in MediaFutures? Did you use any of the MediaFutures resources, like datasets, infrastructure, tools, or the toolkit?

4.What types of support did you seek outside of MediaFutures? Were there types of support that you could not find either within or outside of MediaFutures?

5. What role did citizens/users engagement play in your project? Did you engage citizens/users in the design or testing of your product/artwork?

Did you support interaction among citizens/users? How would you describe that interaction and their effect on participants?

Did you change or improve your citizen engagement practices as a result of MediaFutures, for example in terms of ethics?

6. What do you think is the impact of your project on your users?

Do you think it improved or is able to improve their knowledge on a specific subject?

Did or could it have an impact on their media literacy, how they understand, access, use media?

Did you notice or do you think it could improve users' soft skills such as interpersonal communication, collaboration, problem solving and critical thinking?

7. Do you think that MediaFutures had an impact on your visibility and recognition in your sector? How?

Did you observe an increase in your followers and/or interactions on social media?

8. How has participating in MediaFutures changed your use of data? Did you use new or different data sources? Which?

Did you change your data management practices? How?

What were your biggest challenges around use of data?

9. How relevant was interdisciplinarity and/or an intersectoral approach for your project? How did that surface?

10. (Start up/Artist only)

What do you think is the value of start-up/artist collaborations?

11. What was it like to work with artists/start-ups on this project?

12. Will you continue working with this artist/start-up after MediaFutures?

13. How did the physical distance impact the co-creation process? AI Art and Misinformation

14. What would you recommend to others attempting such collaborations?

(Artists only)

10. Have you consulted or collaborated with scientists or technologists (internal or external) to carry out the project?

11. What were the fields of expertise that you needed to carry out the project?

12. How did you establish that collaboration? Has MediaFutures helped you to do that? Why not?

14. Which are the main challenges and opportunities of scientist/technologist and artist collaboration?

15. Which are the crucial elements of a successful artist / scientist /technologist partnership

16. What have you learned during MediaFutures? Have you changed the way you work? What is your most important takeaway? What do you wish you had known before starting in MediaFutures? What did you learn about misinformation during your project?

17. What was your biggest success within MediaFutures and what did this mean for your project and for you as an artist/entrepreneur?

18. What are your plans after the end of MediaFutures?

(Follow-up questions via email)

1. What data set did you use? Please provide links to open, or a brief description for closed datasets. If the datasets are associated with a project or paper, references would be great.

2.What data tools did you use? Please provide a list of any tools you used during the project, and a brief description of what you used them for (where appropriate). This could include high-level tools for data processing (cleaning, modelling, visualization, etc.), but also data science frameworks, libraries, and models. We are especially interested in models that deal with disinformation or other core applications of projects (metaverse, community detection, cascade effects, XAI or algorithmic fairness techniques, etc.).

3. What data, code, or other outputs of your project did you or would like to publish? Please provide a link to any published resources, and some details about any you would like to publish, including whether you would like our support in doing so.

From Preference Elicitation to Participatory ML: A Critical Survey & Guidelines for Future Research

ABSTRACT

The AI Ethics community faces an imperative to empower stakeholders and impacted community members so that they can scrutinize and influence the design, development, and use of AI systems in high-stakes domains. While a growing chorus of recent papers has kindled interest in so-called "participatory ML" methods, precisely what form participation ought to take and how to operationalize these ambitions are seldom addressed. Our survey of the relevant literature shows that in many papers, participation is reduced to highly structured, computational mechanisms designed to elicit mathematically tractable approximations of narrowly-defined moral values. Of papers that actually engage with real people, these engagements typically consist of one-time interactions with individuals that are often unrepresentative of the relevant stakeholders. Motivated by these clear limitations, we introduce a consolidated set of axes to evaluate and improve participatory approaches. We use these axes to analyze contemporary work in this space and outline future AI research directions that could meaningfully contribute to operationalizing the ideal of participation.

KEYWORDS

Participation, elicitation, value-alignment

1 INTRODUCTION

With the proliferation of data-driven algorithms automating or assisting high-stakes decisions in diverse societal domains [3, 60], the project of ensuring that these algorithms align with stakeholder values has taken on new urgency. As scholarly work on Fairness, Accountability, Transparency, and Ethics (FATE) has matured, a growing chorus of voices within the research community has called for centering issues of power, agency, equity, and participation [8, 9, 50, 71, 79]. For example, in addressing the goal of achieving *fairness*, scholars have highlighted the importance of determining precisely whose judgments about what constitutes fairness should be prioritized and how those values should be operationalized [67]. Offering appropriate responses to these critical questions requires the research community to design effective processes and mechanisms to involve stakeholders in the ideation, design, development, and use of ML systems in order to make sure these systems reflect their values and make deliberate, morally acceptable trade-offs when those values conflict with one another. Beyond a mechanism for value alignment, *participation* has been hailed as an end on its own and an essential ingredient of broader justice-related ideals, such as procedural fairness and democratic governance [77].

To heed these calls and include non-expert stakeholders in the process of designing, evaluating, and deploying ML-based decision-making systems, a recent line of work in AI/ML has supplied computationally feasible mechanisms to elicit stakeholders' moral preferences and values. For example, one early and influential study of this kind was the Moral Machine study, which went viral and attracted millions of internet users [6]. As described in Section 4, participants were posed pairwise comparison questions in the form of "trolley problems" [73]. In each scenario, they were asked to choose whose lives to prioritize, e.g., passengers' or pedestrians', in the face of an unavoidable accident. In follow-up work, Noothigattu et al. [59] used the data from the study to propose an algorithm to model and aggregate participants' *moral preferences* by estimating and averaging linear utility models in the hopes of reflecting all participants' preferences. Structured, computationally efficient mechanisms of this type are frequently designed to elicit mathematically tractable approximations of narrowly-defined values, and they have sometimes been referred to as *"Participatory ML"*. The rationale behind these methods is to provide the precision, formality, and scalability needed to model and capture moral values in ways that enable ML experts to translate them directly into measures and objective functions for developing and evaluating ML systems.

*These authors contributed equally.

AIES '23, August 08–10, 2023, Montréal, QC, Canada

While the intention behind the above line of work is noble and prior work in the area has provided several intriguing observations [44, 64, 71], we contend that there are fundamental limitations to these so-called "participatory ML" approaches. In particular, we critically examine the leap from structured preference elicitation to participatory design for value alignment. Through an extensive literature review and comparative analysis of several existing methods, we outline ten axes along which participation (by non-technical stakeholders) should be evaluated:

(1) Is the target stakeholder group **represented** appropriately?
(2) At what **stage** of the ML lifecycle is their participation sought?
(3) Is the appropriate **setting** for effective participation provided?
(4) Are adequate **resources** available to facilitate participation?
(5) Are there **communication** channels between participants and researchers to discuss the participatory task and the significance of its outcomes?
(6) Are the affordances and limitations of the **elicitation** mechanism adequately scrutinized, understood, and addressed?
(7) What are the mechanisms for **conflict resolution**?
(8) Do participants get to review and provide **feedback** about the process and outcomes of their participation?
(9) Does the participation benefit and **empower** the target stakeholder group?
(10) And finally, have the researchers properly **evaluated** their proposed approach?

To illustrate the utility of our proposed guidelines, we selected five influential participatory ML articles published in recent years and critically evaluated their contributions through the lens of our ten criteria. While the majority of these contributions required little in the way of resources, they all lacked adequate representation of stakeholder groups. Additionally, four of the five had mixed or unsatisfactory results along half of our axes, notably empowerment and communication channels. These findings suggest that while preference elicitation may pose an interesting computational problem, the corresponding methods are insufficient for addressing stakeholders' needs around participation.

In conclusion, as issues of empowerment, control, and agency take center stage in the AI ethics discourse, the research community must strive to provide real avenues of participation to marginalized stakeholders and impacted community members. We hope that the critique put forward here motivates future research toward closing major gaps and shortcomings of existing approaches and identifies new directions for impactful contributions, including considering participatory methods beyond traditional preference elicitation, increasing the representation of members of target communities in ML research and development teams, and acknowledging the fundamental limitations of ML as a tool to address complex sociotechnical challenges on its own.

2 RELATED WORK

In this section, we provide a brief overview of participatory design, its general critiques, and similar approaches in the context of AI/ML. We also highlight notable recent surveys of participatory design for AI and data practices that, while different in scope and scale from the current contribution, are recommended to the interested reader. We end this section with a brief overview of preference elicitation mechanisms proposed recently in CS venues.

2.1 An Overview of Participatory Design

Participatory design (PD) can be described as an approach to design that centers users in the design process [18, 45, 70]. While it originated in Scandinavian workplaces as a way to empower workers in light of technological changes [70], it has also been deployed in areas of governance and sustainable development as a way to empower citizens, particularly in the Global South [39, 45]. More recently, some have proposed that machine learning and automation can help increase participation in governmental processes, for example, by using natural language processing (NLP) to help citizens audit their government [65] or aid stakeholders in negotiating proposals and peace talks [4, 5].

However, others have argued that due to the large impacts that algorithms can have on people's lives (e.g., [3, 60]), participation in design of *the algorithms themselves* should be prioritized [2]. In line with this argument, researchers have employed qualitative participatory approaches to build algorithmic systems across a range of domains, including but not limited to Wikipedia content moderation [30, 69, 81, 83], teacher assistance tools [37], feminicide news and data collection [23, 72], and legal document review [19]. While our survey centers works that utilize quantitative/computational approaches to preference elicitation to build value-aligned models, it is important to highlight the qualitative work around PD as they share similar goals and are, at least for some design choices, more appropriate for achieving the goals of participation.

2.2 Critiques of Participatory Design

In spite of the general excitement around PD, it is not without its share of critics. In particular, Cooke and Kothari [17] and Mohan [55] criticize participatory approaches to government and development as they have been applied in the Global South. They argue that local practices may not always stem from culture but rather from necessity (i.e., due to scarcity of resources). They also critique homogenizing participants as a single group (resulting in participation benefiting certain subgroups more than others), and assuming norms and communication are similar (enough) to Western counterparts. In response, Kesby [46] concedes that *"[these] are important criticisms"* but nevertheless counters [17]. Using the author's prior work studying gender relations and HIV in Zimbabwe, Kesby highlights that blind resistance to participation on account of it involving power dynamics and domination is dangerous, and argues that well-utilized participation can actually lead to beneficial societal changes.

Focusing on participatory approaches to AI/ML design, Bratteteig and Verne [12] argue that various aspects of AI, including lack of transparency, possibility of biased data, and the need to adapt to new situations through constant training, can make it difficult for AI and PD to work together. Additionally, Delgado et al. [20] note that even though various practitioners are in favor of greater stakeholder participation in algorithm design, what constitutes *participation* in this sense is actually not clearly defined. Robertson and Salehi [63] and Sloane et al. [68] take their criticism a step further,

positing that participation can actually prevent progress or promote exploitation—depending on the choices available to participants.

There are various answers to the above critiques. For instance, recent work has proposed participatory frameworks for handling difficulties posed by PD and AI alike. Martin Jr et al. [53] put forward *Community-Based System Dynamics* (CBSD), which involves engaging stakeholders via causal loop diagrams and simulations to learn and include their viewpoints. Hossain and Ahmed [38] directly respond to Bratteteig and Verne [12] with a different approach they denote as *agile PD*. Drawing parallels with both agile software development and political activism, agile PD centers marginalized voices by leveraging stakeholders' spokespeople, alliances between practitioners and stakeholders, and stakeholder involvement in engineering processes. Hossain and Ahmed note that it is not a panacea to all of the issues raised in Bratteteig and Verne [12]. Nevertheless, they believe that *"agile PD is a first major step towards having a design method used with marginalized people that may be transferable to the design of AI technologies, but also revamped so that it does not encounter and contain the issues that exist with present-day PD."* Bondi et al. [10] respond to Sloane et al. [68]'s concerns of *participation-washing* with another framework called *Participatory Approach to enable Capabilities in communiTies* (PACT). PACT centers stakeholder participation in building AI for social good by inviting stakeholders to evaluate how resulting AI systems distribute and expand human capabilities. We draw from these critiques and responses in formulating our guidelines for participatory ML.

Addressing qualitative participatory approaches to AI algorithms, Birhane et al. [8] perform three case studies. The first involves participatory building of NLP-based translation tools for low-resourced languages in Africa. The second discusses an indigenous community's participatory shaping of data usage agreements. The third details a framework for participatory approaches to dataset documentation. Each of these case studies employs analysis in terms of benefits and shortcomings via priorities and related work similar to ones used here (e.g., [45]). What distinguishes our work is our focus on *quantitative* approaches proposed by AI/ML researchers and our critique structured around a set of axes along which such participatory approaches can be assessed.

2.3 A Survey of Preference Elicitation for ML

To gather papers for our literature review, we employed several approaches. We primarily consulted the proceedings of top conferences and journals that were likely to publish contributions that fit our definition of participatory ML. These venues included but were not limited to AAAI, FAccT, CHI, CSCW, AIES, and EAMMO. We also followed citation trails to and from widely cited papers in our repository, and used searches across Google Scholar and Arxiv to find additional related work.

The results of this review are summarized below. We grouped the articles retrieved by this search into one of two categories based on the goals the participation aimed to achieve: **use cases of moral preference elicitation** or **performance metric elicitation**.

Use cases of moral preference elicitation. Numerous participatory ML approaches have sought to create value-aligned algorithms for certain use cases through *moral preference* elicitation. Awad et al. [6] introduce the Moral Machine experiment, a study in which participants from various countries were posed questions that probed their beliefs about autonomous vehicles. Based on the results of that study, Noothigattu et al. [59] propose a method to construct a utility model to reflect the collective preferences of the participants, which in turn could quickly navigate ethical quandaries in a deployed system. Lee et al. [52] use similar techniques as [59] in conjunction with interview and workshop sessions. They do so to build a donor-recipient matching prioritization algorithm for a food delivery nonprofit based on participatory input from relevant volunteers and stakeholders. Kahng et al. [43] generalize the framework proposed in [52] to motivate algorithms that model participants' beliefs in order to facilitate democratic voting processes via automation. Kahng et al. [43] indirectly builds on earlier work by Lee et al. [51] to motivate participatory democracy via voting rules such as Borda count and Condorcet winner voting. Outside of the algorithmic governance space, Freedman et al. [27] demonstrate how to use participatory input to build kidney exchange algorithms that reflect stakeholders' beliefs. Johnston et al. [41] utilize preference elicitation in the medical resource allocation space, but their application domain is COVID-19 resource triage.

Performance metric elicitation. Another branch of participatory ML work involves building metrics to assess algorithms based on what is most important to participants. Ilvento [40], Jung et al. [42], Mukherjee et al. [58], and Bechavod et al. [7] propose methods to estimate individual-level definitions of fairness (as described in [24]) based on participant queries. Yaghini et al. [78] use Equality of Opportunity, as opposed to individual definitions of fairness, for metric elicitation. Hiranandani et al. [33, 34, 35, 36] apply metric elicitation to derive metrics that pertain to performance or group-level fairness. While these works have sought to build new metrics based on stakeholder input, others have explored which existing notions of fairness and feature selection most align with stakeholders' values. Saha et al. [64], Saxena et al. [66], Srivastava et al. [71], and Harrison et al. [31] assess participants' understanding of different fairness metrics and observe conditions under which they prefer some metrics over others. They do so based on crowdsourced responses to online surveys. In comparison, Cheng et al. [14] propose an interview protocol and user interface to help stakeholders weigh tradeoffs between metrics and gauge responses. Instead of gathering participants' thoughts on metrics, Grgic-Hlaca et al. [29] and Van Berkel et al. [75] explore what feature usage participants consider "fair" to use. Kasinidou et al. [44] further researches subtleties regarding *what participants consider agreeable* versus *what they consider fair* in decisions made by automated systems.

In Section 4, we offer further details and critical evaluations for a small selection of the above quantitative elicitation methods [27, 40, 52, 59, 71]. As we will argue shortly, our focus on these contributions is motivated by the attention they have garnered and is meant to illustrate evaluation via our axes (proposed in Section 3) through several concrete case studies.

3 TEN AXES FOR EFFECTIVE PARTICIPATION

Drawing on our extensive literature review and our sustained direct experience working with impacted community members, we provide a necessary set of axes for a quantitative approach to contribute

to the meaningful involvement of non-technical stakeholders in the design and use of ML systems. Table 1 summarizes our guidelines, and the rest of this section elaborates on each in more detail.

Representation. Our first axis concerns the representation of stakeholders in the participatory activity. We argue that *stakeholder groups should be represented commensurate to their need for/claim to empowerment* and that participants should be *generally representative of their respective stakeholder population.* These considerations serve to center marginalized voices in the activity. As noted by Cooke and Kothari [17] and Mohan [56], failing to do so may result in benefits of participation being enjoyed solely by those with prior privilege(s) and/or good social standing. Ideally, a representative individual or committee should also be placed in the research and development team.

Stage. The next axis pertains to how participants are involved in the ML lifecycle; namely, it concerns which part(s) of the ML pipeline (e.g., ideation, design, development, deployment, or maintenance) participants can affect. Our guidelines stipulate that participation generally requires *engagement as early as possible and at multiple stages of the ML lifecycle* as opposed to a one-time engagement after the system is already built and deployed. For instance, issues could arise if participants were involved in how the model performance was assessed but excluded from the data selection phase. Additionally, given that cultural norms and values evolve and that knowledge of a system's shortcomings accumulates over time, a one-time interaction may not suffice to decide how (or whether) the ML system should be maintained or discontinued.

Setting. The setting in which participation takes place is the next crucial component of our guidelines. Specifically, we contend that participation should be *conducted in an environment that is comfortable, familiar, and beneficial to participants.* If participation takes place in an unfamiliar or uncomfortable setting (e.g., research lab or company headquarters as opposed to one's own neighborhood), processes may not elicit true, underlying views of the participant (e.g., due to pressure or coercion, etc.). Moreover, a beneficial setting guarantees *fair compensation for participants (relative to that earned by the system's researchers and developers)* regardless of outcomes of the participation itself. Sloane et al. [68] argue for *"recogniz[ing] participation as work,"* and one way of doing so is to provide proportionate compensation, especially in cases where downstream deployed systems can yield nontrivial financial benefits for its designers and practitioners.

Resources. We argue that the participatory activity should be designed to be compatible with realistic resource constraints. This axis promotes forms of participation that *require minimal participant resources for effective engagement.* For example, the meaningful participation should not assume background knowledge that the stakeholder group does not possess.

Communication. As argued by Kelty [45], *"The experience of participation must include the sense not only of having spoken, but of* having been heard.*"*[1] To take this into consideration, we recommend that *there should be open-ended communication channels between practitioners and participants to discuss the activity.* In addition, we suggest that practitioners should *provide adequate background information to participants* and should *communicate outcomes of the activity to participants in a way they can understand and probe.* If participants are not provided requisite information on the problem the ML system is trying to solve (e.g., use cases and auditing metrics are obfuscated by technical jargon) and there are no ways to clarify misunderstandings, their participation may not reflect their true beliefs. Additionally, if results are not disclosed or understood, participants may rightfully feel exploited.

Elicitation. The specific mechanism and interface used for eliciting participants' judgements and values can have a significant impact on the the outcomes and perceptions of the activity. We suggest that elicitation should be done in a *multifaceted manner* that requires *reasonable effort* from participants while accounting for *realistic human conditions* (e.g., psychological tendencies and biases). This is in contrast to approaches that may utilize one form of elicitation (such as structured elicitation through pairwise comparisons), saddle participants with cognitive burdens, or assume rational agent models. As Vaughan [76] and Koppol et al. [48] indicate, humans are not oracles and can get tired, make mistakes, or even lie under certain circumstances. Therefore, participatory approaches that assume away these possibilities may fail in practice.

Conflict resolution. Aside from channels of communication between researchers/practitioners and participants, participants *should be empowered to communicate with one another, especially to deliberate and resolve disagreements.* Handling differences solely by crude enforcing mechanisms (such as majority rule) may quash a key aspect of participation and lead to unacceptable outcomes [49, 61, 63].

Feedback. Participatory approaches should allow participants to provide continual feedback to researchers and practitioners about every aspect of the activity, not just the specific question(s) of interest to researchers. For example, participants should be able to voice their concerns about the project generally or about the nature of their participation in particular. Our guidelines support participation that offers *multiple channels for continual feedback.* Failure to provide these channels may result in participants feeling undervalued, unheard, and exploited.

Empowerment. One of the most important axes considered by our guidelines is how participation actually affects the target population and their relevant outcomes. We emphasize that the target stakeholder group *should benefit from participation* beyond adequate compensation for their effort. Participants *should gain better control over the design process and outcomes as well as the benefits the activity produces.* The former is in line with existing human participant research practices (e.g., the Belmont Report, as summarized in [54]). For example, if the participants' involvement leads to significant research insights or accuracy gains, they should be acknowledged as co-authors and co-creators of the resulting artifact.

Evaluation. Lastly, our guidelines encourage researchers and developers of participatory mechanisms to critically evaluate their proposal. We emphasize the need to *verify the efficacy and validate* with people (as opposed to relying on simulations or mathematical proofs). Testing with actual human participants could uncover

[1] Emphasis added by Kelty.

Axis	Sample Prompts	Satisfactory Examples	Unsatisfactory Examples
Representation	*Are all stakeholder groups represented commensurate to their need for/claim to empowerment? Are participants representative of their respective stakeholder population?*	Stakeholder groups are adequately represented; marginalized voices are centered; a representative stakeholder has a long-standing voice in the broader research/development project.	Inadequate representation of key stakeholder groups; marginalized voices remain marginalized and disempowered.
Stage	*At what stage(s) of the ML lifecycle are participants engaged? What is/are the specific choice(s) for which participants can provide input?*	Engagement at multiple stages; providing input on impactful choices in each stage	One-time engagement; focus on unimpactful choices
Setting	*What are the conditions under which participation takes place? Is the setting familiar, comfortable, and beneficial to participants?*	Face-to-face human interactions; familiar location; adequate time and compensation	Virtual interactions; unfamiliar location; insufficient time and compensation
Resources	*What participant resources (e.g., time, money, background knowledge and expertise) are required for meaningful participation?*	Minimal resources needed for practical usage	Nontrivial resources and time investment required
Communication	*Can participants and practitioners communicate about the task? What background information is provided to participants about the ML system and the participation activity? How is the outcome of the activity communicated with them?*	Open-ended communication channels exist; participants are provided enough information accounting for their prior knowledge; results disclosed to participants in an understandable manner	No communication channels exist; participants lack the context required to understand the task; results not disclosed; disclosure is too high-level or technical.
Elicitation	*How are values elicited? What kinds of assumptions are made to capture those values?*	Multiple methods and user interfaces to elicit the same value; accounting for psychological effects	(Only) structured elicitation mechanism; Unrealistic agent models
Conflict resolution	*How are the conflicts of opinion among participants brought forward and handled?*	Channels to handle disagreement and deliberation among participants	(Only) crude voting mechanisms used to handle disagreements
Feedback	*Do participants have effective channels to provide continual feedback and voice concerns both about the participation outcome and the process?*	Feedback channels outside of elicitation	No feedback channels exist
Empowerment	*Does the participation empower/benefit the target population? How much control does it afford to participants? Can participants prevent technologies from being built or suggest entirely new routes?*	Participation provides great control over development and future benefits	Participants have little control over the process/product and little or no access to benefits
Evaluation	*How are participatory mechanisms/frameworks evaluated/validated? Have the findings been reproduced under various conditions?*	Co-design and testing with real human participants	(Only) verification with simulations and mathematical proofs

Table 1: Ten axes to evaluate participatory ML proposals.

practical challenges and limitations that proofs or simulations can never identify.

4 CASE STUDIES

While interest in this area has exploded in recent years, some works in particular have been highly influential. Specifically, they have been widely cited (e.g., on the order of 100 to 1000 times) and have inspired numerous follow-ups. As such, many of the other works in this field utilize similar ideas and fare similarly with respect to our axes. The review and critique in this section consist of in-depth case analyses of a handful of influential works in participatory ML, as a concrete illustration of the utility of our axes. Our assessments of these works are summarized in Table 2.

4.1 Moral Machine Voting

Description. Awad et al. [6] study the Moral Machine experiment in which people from around the world were queried about their personal ethics regarding autonomous vehicles. Specifically, users were posed questions similar to the Trolley Problem [73] in that in the face of an unavoidable accident between a self-driving car and pedestrians, they were asked to answer *whose lives should be prioritized: those of the pedestrians or those of the vehicle's passengers?* under varying conditions (e.g., young passengers, elderly pedestrians, etc.). Noothigattu et al. [59] subsequently use data collected from this experiment as an example and proposes a method to learn linear utility models based on Thurston-Mosteller (TM) processes [57, 74] that approximate individuals' beliefs, after which these models can be averaged together to obtain an overall model that

	Cases				
Axis	Noothigattu et al. [59]	Ilvento [40]	Srivastava et al. [71]	Lee et al. [52]	Freedman et al. [27]
Representation	Unclear target population, possible selection bias, mismatch of norms	Unexplored, no human involvement, left to implementers	Slight deviations from US Census	Selection bias through self-selection and volunteer-based sampling	Utilization of crowdworkers with awareness of divergence from target population
Stage	One-time engagement; at data collection stage	One-time engagement during model evaluation	One-time engagement during model evaluation stage	Interactions at multiple points in process, including model-building, aggregation, and result interpretation	Model training stage
Setting	Clear problem context, minimal language requirements, comfortable environment	Unexplored, left to implementers	Clear problem context, basic language requirements, and comfortable environment	Clear problem context and comfortable environment through in-person meetings	Clear problem context, basic language requirements, and comfortable environment
Resources	Access to internet; social media access	Unspecified, assumes knowledge of problem and access to querying system	Internet access; access to MTurk	Nontrivial time and effort required from participants	Internet access; access to MTurk
Communication	Information communicated through structured UI; No unstructured communication with researchers	Unspecified, left to implementers	Information communicated through structured UI	Frequent, free-form communication through interviews and workshops	Information communicated through structured UI; No unstructured communication with researchers
Elicitation	Structured elicitation via pairwise comparisons	Structured elicitation via pairwise comparisons	Structured elicitation via pairwise comparisons	Structured and unstructured elicitation via pairwise comparisons and interviews	Structured elicitation via pairwise comparisons
Conflict resolution	Aggregation of preferences via voting	None; assumes individual agent or body capable of coming to consensus	None; assumes individual agent or body capable of coming to consensus	Channels for deliberation during discussions and workshops	Aggregation of preferences via BT models
Feedback	None	None	Comment submission form which seemed to have no results on downstream experiments	Channels for feedback during discussions and workshops	None
Empowerment	Unclear	Unclear	Unclear	Control over parts of development, and understanding of results	Unclear
Evaluation	Evaluation via simulation on both synthetic and real-world pair-wise comparison data	Theoretical vetting via proofs of convergence	Human evaluation via MTurk workers	Human evaluation by participants and researchers	Human evaluation via MTurk workers of approach, not outcomes

Table 2: Details of case study assessments across each axis of participation. Green indicates relative satisfaction, orange indicates relative unsatisfaction, and yellow indicates mixed results.

ideally reflects the preferences of all participants. The authors conclude that the resulting model could be deployed at runtime and quickly decide the best alternative (in terms of utility maximization) that should be in line with the population's norms.

Evaluation. Based on Awad et al. [6]'s setup, given the scope and scale of the experiment, the target population is unclear. However, selection bias through requiring interest and internet access to participate may affect stakeholder representation. In particular, a *"[w]orld map highlighting locations of Moral Machine visitors"* in [6] illustrates noticeable sparsity in areas of the Global South, including but not limited to large swaths of Africa, South America, and east and central Asia. Given that existing literature also suggests that Western norms may not cleanly map to non-Western societies [9, 32], the experiment may not have truly elicited global values. Additionally, as described, Noothigattu et al. [59]'s model only allows for a one-time engagement of stakeholders. Pairwise comparison queries were posed via image comparisons to eliminate language barriers (see [6]) and participants could participate in their environment of choice, so the setting is reasonable. Provided participants have access to Internet and social media, resource requirements would also be minimal, as these are the only resources required by this framework. However, the protocol in [59] does not involve communication between participants and practitioners, and there is also only one structured elicitation mechanism through voting that

does not allow for conflict resolution between participants. Moreover, the protocol does not provide feedback channels or empower participants in the process, and simulations and [6]'s dataset were used to evaluate the approach. Beyond our guidelines, Chan et al. [13] highlights that stakeholder identity in terms of gender and perspective (i.e., passenger versus pedestrian) may affect elicited preferences, and El-Mhamdi et al. [25] and Feffer et al. [26] prove that the averaging approach employed here is not robust in the case that participants vote strategically.

4.2 Metric Learning for Fairness

Description. In light of existing work highlighting how various definitions of fairness may be mutually unsatisfiable under certain conditions (e.g., Chouldechova [15], Kleinberg et al. [47]), Ilvento [40] describes mathematically how to elicit metrics of fairness from people. The author does so by introducing an algorithm to obtain a metric grounded in an individual-based definition of fairness (such as the one described at length in [24]) from an agent by posing questions about the distance metric to use for the definition. Specifically, there are two types of queries posed to the agent:

(1) *real-valued distance queries*: questions inquiring about the distance between two individuals (e.g., $\mathcal{D}(u, v)$ for individuals u, v), and
(2) *triplet queries*: questions inquiring about whether one individual in a set of three is closer to one versus the remaining individual in the set (e.g., $\mathcal{D}(a, b) < \mathcal{D}(a, c)$ versus $\mathcal{D}(a, c) \leq \mathcal{D}(a, b)$ for individuals (a, b, c)).

Given these types of queries, the rest of the paper describes how to learn an individual-level fairness metric from these queries based on a finite set of N individuals and proves that their methods of doing so, specifically by choosing a set R of representative individuals and comparing them to other members of the set while using properties of a distance metric to order everyone, converge with total numbers of queries polynomial in $O(|R|N)$.[2] The work assumes that the agent is a single person or body of people "free from explicit biases or arbitrary preferences" but does not perform any analyses with actual human participants.

Evaluation. Participant representation is unconstrained and therefore determined by the researcher(s) or practitioner(s). Given that this method elicits preferences regarding performance metrics, any participants are only involved at a single point of the ML pipeline (the evaluation phase) and only have power over determining the output metric. Setting, communication, and participant resources are also unconstrained beyond assumptions of ample problem context and access to the querying system. The approach uses structured elicitation and utilizes a rational agent model. It also assumes that if the agent is actually a body of people, they should be able to come to consensus and resolve any disagreements amongst themselves. Therefore, there are no methods to handle disagreements between participants.[3] As described, there are also no feedback channels. Evaluations were performed via proofs of convergence and not with live participants.

4.3 Eliciting Perceptions of Fairness

Description. An alternative approach to eliciting value-aligned models or metrics is to determine which type(s) of performance people generally prefer or may want to prioritize for a given situation. To that end, Srivastava et al. [71] conduct three experiments with Amazon Mechanical Turk (MTurk) workers to explore conditions under which stakeholders may want to prioritize a certain definition of fairness as opposed to predictive accuracy or vice-versa. The first two experiments posed pairwise comparison queries to participants that asked which one of two algorithms was more discriminatory based on output of the algorithms in terms of predictions, ground-truth values, and demographics of people affected (namely their race and gender). One experiment involved algorithms to predict criminal recidivism while the second discussed algorithms to predict skin cancer likelihood. The researchers used the Equivalence Class Edge-Cutting (EC^2) algorithm [28] to simultaneously limit the number of queries to ask participants and estimate the mathematical definition of fairness that aligned with participants' responses. They found that demographic parity agreed with participants' answers the most often in both of these experiments, contrary to their hypotheses that equality of false positive or negative rates would be prioritized in the criminal recidivism setting while equality of accuracy would be prioritized in the skin cancer setting. In their last experiment, participants were asked to decide which of three algorithms with different fairness-accuracy tradeoffs should be used in a given setting. For instance, one of these algorithms had high accuracy for both men and women but at different rates while another algorithm with overall lower accuracy had equal accuracy across demographic subgroups. There were four settings in question that varied both the domain and stakes of the decisions being made:

(1) Skin cancer prediction (medical domain, high-stakes),
(2) Flu virus prediction (medical domain, low-stakes),
(3) Jail time prediction (criminal justice domain, high-stakes),
(4) Bail amount prediction (criminal justice domain, low-stakes).

In the end, they found that participants preferred accurate algorithms when the setting involved high-stakes decisions and fair algorithms when the setting involved low-stakes decisions, regardless of the setting's domain. The authors conclude by specifying limitations of their work (such as that they only considered algorithms with similar levels of accuracy, but larger differences in accuracy may have yielded other results) and suggesting future directions, arguing in particular that *"Algorithmic decisions will ultimately impact human subjects' lives, and it is, therefore, critical to involve them in the process of choosing the right notion of fairness,"* and that their work is *"an initial step"* in this direction.

Evaluation. In terms of representation, the sample of participants contained slight deviations from the US Census. While this work involves more than one interaction with participants, all experiments

[2] The bounds reported by Ilvento [40] take the form $O(|R|N)$ multiplied by a logarithmic factor and range from $O(|R|N \log N)$ to $O\left(|R|N \log \frac{1}{\alpha_L}\right)$ depending on the assumptions and querying algorithm provided, where α_L is "the minimum precision with which the arbiter can distinguish elements or distances."

[3] Ilvento [40] explicitly states "When human fairness arbiters strongly disagree, we consider this to be a situation where discussion between the human fairness arbiters, and perhaps additional external parties, is needed."

are limited to determining the fairness notion that most cleanly maps to their intuition. This in turn only relates to one part of the ML pipeline . Even though ample context about each problem was provided to the participants in their place of choice and resource requirements only involved access to MTurk, this work uses structured elicitation via MTurk as opposed to face-to-face interactions. The approach also lacked communication protocols, strategies for resolving conflicts between participants, and participant empowerment. While there were feedback channels for providing additional comments on the experiments, this input seemed to have no effect on determining the flow of the overall study. This being the case, evaluation of the approach still involved humans, in addition to quantitative and qualitative result analysis.

4.4 WeBuildAI

Description. In [52], Lee et al. summarize their work with a local nonprofit food delivery organization. Their goal was to improve the matching algorithm used to connect establishments with leftover food to recipient groups that could use it. As modifications to this algorithm involve a number of stakeholders with different preferences, the researchers believed a participatory approach would work well. The resulting format consisted of three phases. The first involved individual belief elicitation by creating models through pairwise questions (based on TM processes, similar to Noothigattu et al. [59]) or optionally via manual specification of scoring rules. The next used Borda count voting aggregate recommendations from these individual models and involved asking stakeholders *who, if any of you, should be prioritized in this voting process?* (in this case, they almost unanimously chose to prioritize the food delivery organization over donors and recipients). Lastly, the research team built and presented an interface to stakeholders in order to communicate effects of their participation on future decisions, namely in terms of explanations, preference rankings, and vote counts of various outputs. Each part of this process was conducted via in-person workshop and study sessions, and participants were compensated for their time and effort. However, participants were mostly a homogeneous group based on demographics (primarily white female), which the authors attribute to volunteer-based sampling.

Evaluation. While selection bias yielded a participant group that was not very diverse, the resulting participants were involved at multiple points in the algorithmic development process during face-to-face meetings. Sessions were conducted at participants' convenience and for which they were paid, and each provided participants with appropriate context. This being said, this method of participation was resource-intensive for the participants due to the time and effort needed to interact with the researchers. Results of these sessions were communicated to stakeholders during follow-up sessions and the built interface, and even though structured elicitation approaches were used at various points, participants had the ability to modify inputs to these approaches (such as by making individual models through explicit rules or altering Borda count voting power). Stakeholders had channels for feedback and deliberation and were also empowered by having control over several parts of the development process. Researchers' methods were evaluated based on these in-person workshop sessions.

4.5 Value-aligned Kidney Exchange Algorithm

Description. Freedman et al. [27] build on a long line of research on kidney exchanges (e.g., Abraham et al. [1], Dickerson et al. [21, 22]). The authors do so by reasoning about how to incorporate moral preferences into their clearing algorithm (e.g., the belief nonsmoking individuals should be prioritized to receive kidneys over smoking individuals). The work illustrates a proof-of-concept approach in this regard via two experiments in which MTurk workers were used as participants. The first experiment ascertained MTurk workers' thoughts on which patient attributes should be relevant to decisions about prioritization. The next involved asking another set of MTurk participants a number of pairwise comparison questions to learn how they prioritized donating kidneys. Specifically, each comparison involved answering a hypothetical question, namely *based on their patient profiles, which of these two individuals requiring a transplant should receive a kidney?*. Attributes included in these patient profiles were age, general health, and drinking behavior (e.g., young, healthy, rare drinking patient versus old, cancerous, frequently drinking patient) which were in-turn determined based on the results of the first experiment. With the resulting pairwise comparison data, the researchers built Bradley-Terry (BT) models [11] to approximate how the average participant made decisions. They subsequently used the corresponding BT scores for each patient profile to configure tie-breaking behavior of their clearing algorithm such that patients matching profiles with higher scores received kidneys over patients with lower scores if both were otherwise equally prioritized recipients. Finally, they compared this modified algorithm to their original algorithms without participant input through a number of simulation experiments and showed that the new algorithm behaved as expected (i.e., patients with profiles corresponding to higher BT scores received kidneys more often). Overall, they demonstrated that there were no technical barriers to implementing this algorithm.

Evaluation. While this work relies on crowdsourcing via MTurk, the authors clearly state that actually building a model for use in practice would involve working with a number of stakeholders closely related to the problem. There were two engagements with the participants, but both were related to one stage of the model development process through MTurk tasks with no other forms of engagement. However, using MTurk allowed researchers to provide problem context and allow participation in a setting where the participants were comfortable. While their method imposes few resource requirements on participants (primarily access to MTurk), the utilization of (only) structured elicitation means it lacks communication with participants, conflict resolution strategies between participants, channels for feedback, and participant empowerment. Lastly, it allowed them to evaluate their approach through human participation to prove that their method was technically sound, but they were not able to evaluate results in a practical setting.

5 DISCUSSION OF FUTURE DIRECTIONS

Drawing on the limitations of prior work, we conclude this work by outlining several important avenues through which AI/ML researchers and practitioners can effectively contribute to participatory frameworks.

Choosing and justifying the target population. Beginning any participatory project by strongly considering the appropriate target population can facilitate downstream parts of the process. This determination is not necessarily trivial, as questions like *why this group?* and *why this sampling approach?* may not be easy to answer. However, choosing a target population makes it possible to assess whether the sample of stakeholders is conducive to the end goals of the project or not (perhaps due to bias). For instance, Srivastava et al. [71] note that their sample of MTurk workers deviates slightly from the US population. But is this the appropriate target group of stakeholders to include in the process of determining the definition of fairness?

Identifying which choices in the ML lifecycle impact stakeholders' outcomes the most. By being aware of which parts of an ML project have the largest effects on outcomes relevant to stakeholders, AI experts can prioritize engagement with stakeholders on those choices. This prioritization, in turn, can empower participants by improving their control and agency over their subsequent outcomes. Along the same lines, by scrutinizing and potentially relaxing unrealistic assumptions (e.g., participants are rational or oracles of objective truth, preferences are stable and acyclic, etc.), experts can better ensure that proposed participatory approaches can capture the genuine opinions and preferences of the target stakeholder groups.

Acknowledging resource requirements and how they bias the sample. Research protocols that require participant resources, such as time and background knowledge, can hinder or prevent the participation of stakeholders that may otherwise be representative of the target population. This drawback happened to Lee et al. [52] as several participants could only partake in the first sessions due to time and job constraints. Participant barring and dropout can further bias the sample. While such issues may be unavoidable, delineating them as limitations and/or reducing them to the extent possible can promote participation and inform future research.

Meeting participants where they are. Using technical jargon, complicated interfaces, and unfamiliar environments to interact with stakeholders may not produce results in line with what they actually believe or want. In contrast, conducting exercises in a way that makes participants feel at ease can yield more faithful responses. To this end, researchers and practitioners can utilize everyday speech and writing where possible, pilot technical UIs before sharing them with participants, and host their participatory tasks in places stakeholders frequent in their daily lives.

Supplementing elicitation with deliberation. As evidenced by our review, quantitative approaches to preference elicitation have major limitations when used as standalone participatory activities. However, Lee et al. [52] demonstrate the utility of such techniques in conjunction with other forms of engagement and deliberation with stakeholders. Building systems via co-design as exhibited by works in Section 2 (e.g., [30, 37]) and developing new technology and interfaces to handle communications and richer forms of elicitation (e.g., [80, 82]) are among promising paths forward to promote deliberation.

Being receptive to feedback. Many of the works explored here either did not have channels for participants to share their thoughts on the activity with the researchers or did not appear to use input from participants in downstream processes. For instance, Ilvento [40] did not account for feedback in the protocol described, and while the UIs utilized by Srivastava et al. [71] featured open-ended comment boxes, crowd worker input did not appear to influence future experiments. Further work that receives and utilizes feedback can reduce feelings of exploitation, foster goodwill and collaboration, and ameliorate the sense of being heard.

Employing a wider range of frameworks to include non-technical stakeholders. The tacit assumption that experts should lead and execute research and reap its benefits has been challenged in other arenas (e.g., Participatory Design [18, 45, 70]). Research and tech development teams can diversify expertise and include relevant stakeholders as equal team members to incorporate their voices and expertise at various stages of their projects. This level of integration can prevent critical errors, reduce bias, and improve trust between researchers and stakeholder communities.

Conducting contextual, human-centered evaluation with representative participants. Most works referenced here rely on evaluation via simulations, mathematical proofs, or structured interactions with non-representative crowd workers. While these approaches are acceptable for early testing of new proposals, we join Freedman et al. [27] to strongly advocate for further validation studies on these systems (e.g., via usability testing with real stakeholders).[4] Additionally, as argued by Conitzer et al. [16] and Kelty [45], effective evaluation of a participatory activity with actual stakeholders requires both context and locality. As an example of context, garnering effective participation may require establishing long-term relationships with community advocates, representatives, and domain experts. Regarding locality, as we pointed out in Section 4, Western norms may not map well to all societies. For instance, Pugnetti and Schläpfer [62] note that even Swiss citizens (who presumably follow Western norms) have opinions that, on average, differ from those of the average respondent of the Moral Machine study [6].

Understanding the limits of what problems ML expertise can and cannot address. Last but not least, AI experts must avoid using elicitation methods as a way of participation-washing [68]–without empowering or benefiting participants, and to solely make outcomes appear more democratic. AI experts and practitioners must acknowledge that a wide range of skills beyond AI is needed to develop the necessary relationships with community stakeholders, gain their trust, and effectively moderate deliberations and resolve conflicts. ML expertise alone is not the solution to highly complex socio-technical challenges, and "participatory ML" is no exception.

ABSTRACT

This paper explores the impact of value similarity between humans and AI on human reliance in the context of AI-assisted ethical decision-making. Using kidney allocation as a case study, we conducted a randomized human-subject experiment where workers were presented with ethical dilemmas in various conditions, including no AI recommendations, recommendations from a similar AI, and recommendations from a dissimilar AI. We found that recommendations provided by a dissimilar AI had a higher overall effect on human decisions than recommendations from a similar AI. However, when humans and AI disagreed, participants were more likely to change their decisions when provided with recommendations from a similar AI. The effect was not due to humans' perceptions of the AI being similar, but rather due to the AI displaying similar ethical values through its recommendations. We also conduct a preliminary analysis on the relationship between value similarity and trust, and potential shifts in ethical preferences at the population-level.

1 INTRODUCTION

Making ethical decisions is challenging, because they often lack clear right or wrong answers. For example, during the early stage of a pandemic, local governments must decide who to vaccinate first when there are not enough vaccines available for everyone. In emergency rooms, doctors must decide how to prioritize patients who need treatments with limited amount of time and medical resources. Social workers also encounter tough choices when allocating limited resources to prevent homelessness. In these situations, decision-makers must weigh various ethical values and principles, making it difficult to find universally acceptable solutions.

In the meantime, artificial intelligence (AI) has gained significant progress in the past decade, and naturally, has been increasingly involved in decision making in our daily life, including decisions in ethically-sensitive domains. While some may fight against the implementation of AI systems being involved in real-world ethical decisions, proponents argue that AI could potentially lead to more equitable outcomes for marginalized communities by minimizing human biases [27]. In addition, the automated nature of AI can substantially speed up decision making to a level that is much faster than what humans can achieve. To leverage the benefits of AI in decision making while alleviating the concerns of having AI making ethical decisions autonomously, one approach which is getting increasing attention is to adopt the paradigm of AI-assisted decision making, where human decision makers receive recommendations from AI, which assist humans to form their final decisions.

While AI-assisted ethical decision making holds promise, incorporating AI recommendations in decision making could also lead to unintended consequences. In particular, AI algorithms exhibit their own ethical values, realized through recommendations they provide to human decision makers. Furthermore, the ethical values exhibited by AI could propagate to final decisions in different ways, depending on whether and when human decision makers decide to adopt AI recommendations. Without more research on the impacts of AI recommendations to humans in ethical decision making, we run the risk of real-world systems outpacing our understanding of these systems, potentially causing real-world harm. For example, if human decision makers always tend to accept recommendations from AI exhibiting similar ethical values and reject recommendations from AI exhibiting different ethical values, we run the risk of creating a more *polarized* decision making environment where human tend to make more extreme decisions.

In this paper, we aim to advance our understanding of incorporating AI recommendations in ethical decision making. Specifically, we investigate the research question of how value similarity between humans and AI affects the human decision makers' reliance on AI recommendations in the context of AI-assisted ethical decision making. Additionally, given the *value* exhibited by an AI is not directly observable, we are also interested in understanding whether the effect of value similarity to human reliance is influenced more by the value the AI *claims* to exhibit or the value that is demonstrated by the recommendations the AI provides.

To answer the above research questions, we have conducted a randomized human-subject experiment on Amazon Mechanical Turk (MTurk). Using the domain of kidney transplants as a case study, we first ask recruited workers to solve a series of ethical dilemmas without AI recommendation to measure their own ethical preference, which is our operationalization of the participant's "value". We then randomly assign workers into two treatments which differ on whether the AI model used in the treatment is similar or dissimilar from the participant's own ethical preference. We compare participants' decision alignment with the AI recommendation across the two treatments to understand how human-AI value similarity impacts human reliance on AI.

We find that recommendations provided by a dissimilar AI has a larger effect on human decisions than recommendations from a similar AI. However, this result is generally due to the high levels of agreement between the similar AI and user, creating less opportunities to "change their mind". If we limit our analysis to the subset of scenarios where humans and AI disagree, humans are more likely to change their decision when provided with recommendations from a similar AI than recommendations from a dissimilar AI. In addition, we find no evidence that this effect is due to humans' perceptions of the AI being similar. Instead, we find that this effect is largely due to the AI actually displaying similar ethical values through recommendations. Finally, we perform an explorative analysis that investigates potential shifts in polarization at the population-level, and find preliminary evidence that personalized AI assistants could lead to a more radicalized decision-making population.

2 RELATED WORK

There has been extensive recent work in understanding how humans rely on their AI teammates in AI-assisted decision making, and this has been studied both in domains with objectively correct decisions to be made, and domains where decisions are made according to subjective ethical practices. Our paper draws from prior work in three categories: how humans rely on AI advice, how humans trust AI advice, and how humans perceive AI values.

In studies of humans' reliance on AI advice, there have been mixed results on whether humans rely more on human advice or AI advice. Many papers have shown evidence of algorithmic aversion, which is the notion that humans tend to relatively distrust AI advice, and prefer to receive advice from other humans [7, 29, 34]. This aversion extends to second and third parties, who may prefer decision-makers to use no advice, rather than AI advice [36, 43]. On the other hand, despite the evidence that decision-makers tend to subjectively prefer human advice over AI advice, Logg et al. [28] found that human-decision makers tend to rely more on AI advice in practice. This finding has been validated not only in objective domains, but ethical decision-making domains where there are no correct answers [32, 41]. One potential explanation is that humans perceive AI to be more rational and unbiased [8]. Human decision-makers may also want to shift the cognitive burden of ethical decision making off of them [25], as society tends to hold humans to higher standards of being unbiased than AI [4].

One aspect which affects human reliance on AI is trust, or more generally, the level of confidence that humans have in AI outputs. Bansal et al. [3] investigated the mental models that humans have in AI behavior, and found that when model outputs are more understandable, humans are better able to incorporate these outputs into their own decision-making strategies, leading to better team performance. Yin et al. [45] looked at the relationship between model accuracy and trust, and found that humans tend to both trust and rely on advice with a higher stated accuracy more than advice with a lower stated accuracy. Schmitt et al. [35] found that when humans are exposed to AI advice and later shown that the prior advice was incorrect, their trust in the AI actually increases. Zhang et al. [47] looked at methods for calibrating human trust in AI, and found that confidence scores improve trust calibration, though this doesn't necessarily improve overall decision making performance.

Our work focuses on the effects of value similarity to human reliance in AI-assisted ethical decision making. There is a rich body of sociological work understanding the effects of value similarity on humans. For example, Sitkin and Roth [38] found that improving reliability is insufficient for restoring trust in interpersonal relationships or inter-organizational mechanisms, and a better method for improving trust is to show value similarity. Siegrist et al. [37] analyzed the effects of value similarity in risk management, and found that increased value similarity leads to increased trust and is a significant predictive factor in the outcome of risk-benefit analysis for new technology.

In the last few years, more work has begun on understanding how value similarity affects interactions between humans and AI assistants. One of the closest work to ours is by Grgić-Hlača et al. [18]. They focused on objective (non-ethical) domains and measured AI similarity by comparing model output with human decisions. Similar to our observations, they found that advice from similar AIs is more likely to change the mind of a human decision maker, but dissimilar AIs have more opportunities to change minds, giving them a bigger overall impact. Mehrotra et al. [31] and Yokoi and Nakayachi [46] both analyzed the effects of value similarity on AI trust in various ethical decision-making domains, and found that AI assistants with a higher value similarity lead to higher levels of trust in the AI assistant. However, the latter two papers only look at subjective measures of trust in these ethical decision-making domains, without empirically validating changes in user reliance. We have already seen paradoxical results when looking at reliance on human and AI advice, where decision-makers prefer and trust human advice more, but rely on AI advice more. As such, we aim to fill this research gap in AI-assisted ethical decision-making, by showing that value similarity in AI recommendations leads to both increased reliance and increased trust.

In this work, we perform experiments in the area of medical resource allocation, specifically, kidney transplant allocation, as a case study. There has been a rich body of literature which has looked

at the ethics of medical resource allocation [12, 13, 17, 33]. Taking from this literature, there have been a few algorithmic experiments understanding human values for kidney allocation. Freedman et al. [16] created a methodology for estimating human values for kidney allocation, and proposed kidney exchange algorithmic improvements which better take into account human values. Narayanan et al. [32] expanded on this research by incorporating both verifiable information and predictive information into the solicitation of human ethical preferences. Research on ethics on scarce allocation actually informs real-world kidney exchange algorithms. For example, the United Network for Organ Sharing published a report detailing changes they made to their kidney algorithm in the last year, and showed that outcomes are now more equitable for racial minorities and other vulnerable groups [15].

3 EXPERIMENT

The aim of our experiment is to investigate the influence of value similarity between humans and artificial intelligence (AI) on human reliance on AI for ethical decision-making. In pursuit of this objective, we present scenarios involving ethical dilemmas to recruited participants and measure their ethical preferences in varying conditions. These conditions include instances where participants are provided with no AI recommendations, recommendations from AI with similar ethical preferences (similar AI), and recommendations from AI with dissimilar ethical preferences (dissimilar AI). We pose two main research questions, and design our experiment to validate the following hypotheses.

Research Question 1: How does value similarity affect reliance on AI recommendations?

- **H1:** Recommendations made by a dissimilar AI will create a greater change in alignment than recommendations made by a similar AI.
- **H2:** When considering scenarios where humans originally disagreed with the AI, recommendations made by a similar AI will cause a greater change in alignment than recommendations made by a dissimilar AI.

Research Question 2: Are the effects of value similarity on reliance caused by claims of value similarity or because the recommendations actually align with human values?

- **H3:** The effect of value similarity is primarily due to humans relying on AI recommendations which claim to share similar values, and it is less important for humans reliance that AI actually follows its claimed values.

3.1 Experiment Task

To test the aforementioned hypotheses, we conduct a case study in which we recruit participants to make a series of ethical decisions pertaining to the allocation of kidneys. Each decision presents participants with a hypothetical scenario where two patient candidates are in need of a kidney transplant, but only one kidney is available. Participants are required to evaluate the information provided about both candidates and express their preference for which candidate should receive the kidney first.

To align our task design with well-established ethical preference frameworks, we follow the extensive literature on the ethical principles in allocating scarce medical interventions [12, 13, 17, 32, 33]. In particular, we adopt the ethical preference framework proposed by Persad et al. [33], which describes four categories of ethical values: Treating People Equally, Favoring the Worst-Off, Promoting Social Usefulness, and Maximizing Total Benefits. Narayanan et al. [32] differentiated between the first three categories and the last, denoting the first three as *verifiable* and the last as *predictive*. They found that this predictive category can have an out-sized effect on the verifiable categories, especially when the prediction is considered to be AI-determined. To avoid these effects, we only display the three verifiable categories in our experiments, and select the following factors to represent these categories.

- *Kidney Donor Status (Promoting Social Usefulness)*: If the candidate has donated a kidney of their own in their past. This is a binary feature, with possible values of {Not prior donor, Prior Donor}.
- *Wait Time (Treating People Equally)*: How long the candidate has been waiting to receive a kidney. This feature has possible values of {Less than 1 year, 1 year, 2 years, 3 years, 4 years, 5 years}.
- *Kidney Disease Stage (Favoring the Worst-Off)*: How severe the candidate's kidney disease is. This is a binary feature, with possible values of {Stage 4 (Severe kidney damage), Stage 5 (Kidney failure or near-failure)}.

It is worth noting that in the ethical principle framework proposed by Persad et al. [33], each factor has a default preference ordering in cases where all other factors are equal. If one candidate is a prior donor, and the other isn't, then the default ordering prioritizes the prior donor. If one candidate has been waiting for a longer period than the other, the default ordering prioritizes this candidate. If one candidate's kidney disease is at a higher stage than the other, the default ordering prioritizes this candidate. In our study, we presented various scenarios to online workers to investigate how individuals make trade-offs between these three factors, which correspond to the stated ethical principles.

3.1.1 Scenario construction. In our experiment, workers are asked to make a series of ethical decisions. Specifically, we generate scenarios with two candidates, and workers are asked to express their ethical preference on which candidate should receive a kidney transplant first. When eliciting workers' ethical preferences, these scenarios can be split into three categories.

The first category includes scenarios where the two candidates differ in only one factor, and share the same values for the other two factors. For example, in one scenario, Candidate A may be a prior donor, while Candidate B is not; both candidates have been waiting for 3 years and have Stage 4 Kidney Disease. The primary objective of this category is to elicit workers' baseline preferences for each of the factors individually (in this case, *Donor Status*). The second category consists of scenarios to understand workers trade-offs between two factors. In this category, the two candidates share the same value for one factor, one factor should prioritize the first candidate, and the remaining factor should prioritize the second candidate (according to the default preference ordering). For example, Candidate A may be a prior donor, while Candidate B is not, Candidate A may have been waiting for 2 years, while

Candidate B has been waiting for 4 years, and both candidates have Stage 5 Kidney Disease. This category enables us to isolate the trade-offs between pairs of factors (in this case, *Donor Status* and *Wait Time*). The third category involves scenarios where the two candidates have different values in all three factors. One candidate is prioritized in one factor, while the other candidate is prioritized by the other two factors. For example, Candidate A may be a prior donor, while Candidate B is not, Candidate A may have been waiting for 2 years, while Candidate B has been waiting for 4 years, and Candidate A may have Stage 4 Kidney Disease, while Candidate B has Stage 5 Kidney Disease. This category enables us to represent more complex interactions between the factors.

In each of these categories, there are three unique scenarios, giving us a total of nine scenarios. For each user, we realize each scenario with random values that preserve the preference order. For instance, if the disease stage needs to be equal, we may display both patients as "Stage 4" or "Stage 5". We also limit wait time differences between candidates to be no more than 2 years.

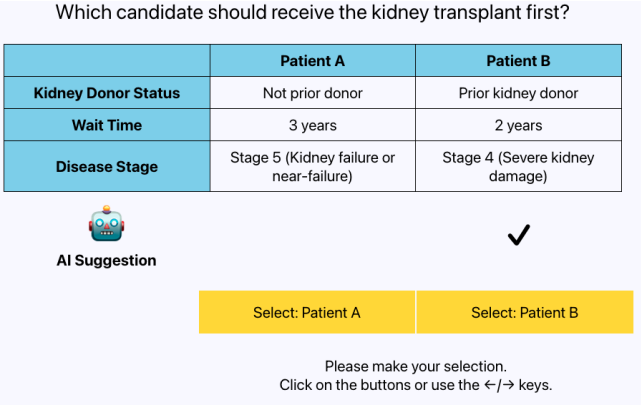

Figure 1: An example of the task interface for our experiment. This interface corresponds to the task of Stage 2 in our experiment design as described in Section 3.2.

3.1.2 Creating AI with Similar/Dissimilar Ethical Preferences. The goal of this work is to investigate the influence of value similarity between humans and AI on human reliance for ethical decision-making. Given our domain application, we use the similarity of ethical preferences to represent the value similarity. We now describe how we create AI with similar or dissimilar ethical preferences with a given worker.

For a worker's ethical preference, we can measure their answers on a set of given scenarios, i.e., their choices on who to receive a kidney first among several pairs of candidates, when they are not provided AI recommendations. Using their answers, we can compute their (prior) ethical preferences without seeing AI recommendations. A worker's ethical preference is represented by three values, each indicating how often workers' answers align with the default ethical ordering of each factor. This alignment is measured separately for each factor, and indicates how often the worker chooses the preferred factor value (e.g. "Prior Donor" over "Not Prior Donor" for the "Donor Status" factor), across all scenarios. For example, in the scenario presented in Figure 1, if the worker selected Patient A, then their answer aligns with the preferred factor for the "Wait Time" and "Disease Stage" factors, but not the "Donor Status" factor. We would then average the number of times the worker aligns with each preferred factor across all scenarios to generate the alignment values for each factor.

Using these values, we use the $A > B > C$ notation to denote a worker's value ordering in their ethical preferences over factors A, B, and C. For example, if a worker aligns with the "Donor Status" factor in 30% of scenarios, with the "Wait Time" factor 80% of the time, and the "Disease Stage" factor in 50% of scenarios, then their prior ethical preference ordering would be "Wait Time">"Disease Stage">"Donor Status".

Based on a worker's value ordering in the prior ethical preference, we can design a similar AI and a dissimilar AI that share similar and dissimilar ethical preferences with the worker. In particular, if a worker's value ordering is $A > B > C$, the ethical preferences for the similar/dissimilar AI for that worker are specified below:

- Similar AI: The ethical preference order for a similar AI is chosen uniformly at random to be either $A > B > C$ or $A > C > B$, i.e., the top factor of the similar AI is the same as the top factor of the worker.
- Dissimilar AI: The ethical preference order for a dissimilar AI is chosen uniformly at random to be either $C > A > B$ or $C > B > A$, i.e., the top factor of the dissimilar AI is the same as the bottom factor of the worker.

Our second research question aims to understand how the claim of similarity affects human reliance on AI recommendations. We therefore need to be able to distinguish between cases where AI is truly following its value preferences, and cases where the AI is only claiming to follow its value preferences, but no more. To create this distinction, we instruct our AI to act as follows:

- Deterministic AI: The AI will deterministically follow its ethical preference ordering. If the AI's top ethical preference has different values for the two candidates, then the AI will pick the candidate whose factor value aligns with its preference. If the values are tied, then the AI will move to the second preference, and then the third if necessary.
- Random AI: The AI chooses the recommendation entirely randomly, without any regard for the candidate attributes.

Using this design, we can distinguish between cases where user reliance is affected by both the value similarity claim and similar recommendations (Deterministic), and cases where user reliance is affected only by the value similarity claim (Random). When we describe the AI to workers in our experiment, we explicitly inform workers of the AI's ethical preferences and that the AI makes stochastic recommendations.

3.2 Experiment Design

To understand the effect of AI similarity on the usage of AI recommendations in ethical decision making, we conducted a two-stage, two-treatment randomized behavioral experiment. A general schematic of our experiment design can be found in Figure 2.

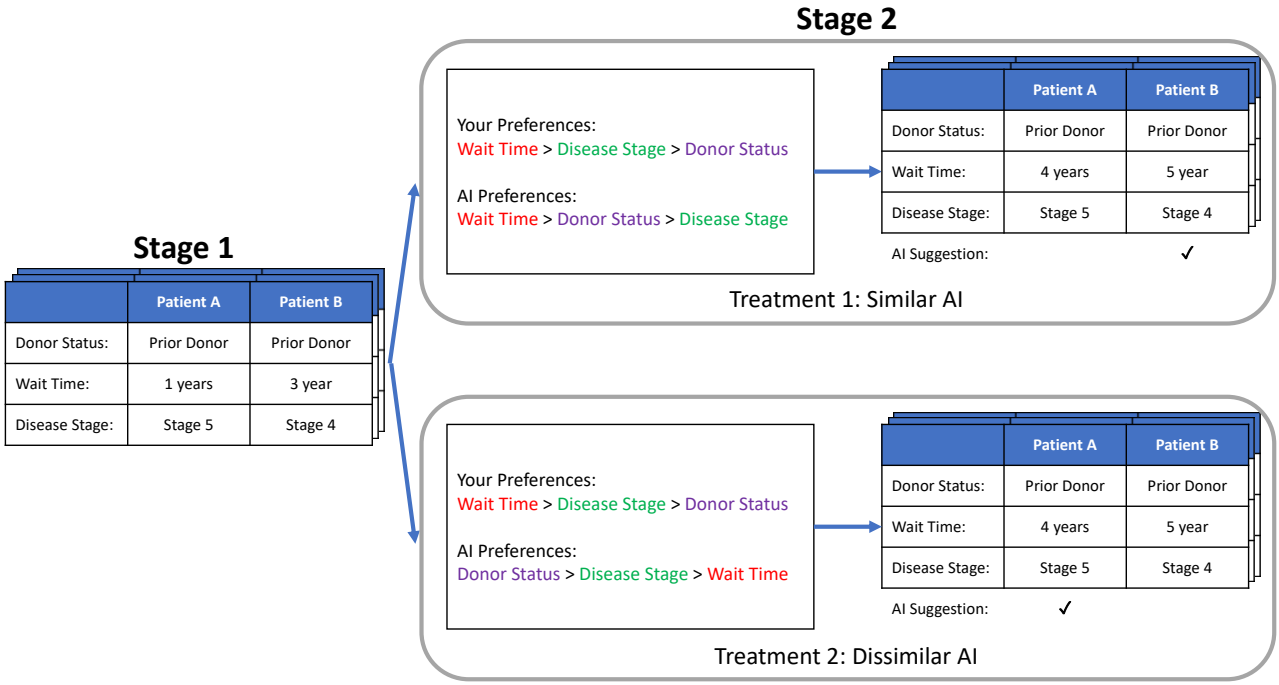

Figure 2: A general illustration of our experiment design. In the first phase, we present the user with a series of scenarios, and use this data to understand the user's ethical preferences. Using this, we create similar and dissimilar AI assistants in the second phase, and display them to the user. We then present the user additional scenarios, with the AI recommendation visible.

In our experiment, each recruited worker begins with the first stage, where they are asked to express their ethical preferences in 9 scenarios, generated using the approach described in Section 3.1.1. After eliciting workers' prior ethical preferences, we then randomly assign workers to two treatments:

- **Treatment 1 (Similar AI)**: In the second stage, each worker in this treatment group are shown recommendations from AI with similar ethical preferences to their own ethical preferences.
- **Treatment 2 (Dissimilar AI)**: In the second stage, each worker in this treatment group are shown recommendations from AI with dissimilar ethical preferences to their own ethical preferences.

After the first stage, workers are presented with a summary of their own ethical preferences and the ethical preference of the AI that will make recommendations during their decision-making during the second stage. Workers are also asked three survey questions — how confident they are in their own answers, if they think our estimation of their preferences is accurate, and how much trust they would have in an AI which behaves according to the displayed preferences. Each of these is graded on a 5-point Likert scale.

In the second stage, workers are presented with 18 additional scenarios where they make their decisions with the assistance of the provided AI. An illustration of our experiment scenario layout in the second stage is shown in Figure 1. The scenarios are generated the same way as in the first stage, but the number of scenarios are doubled and the realizations of the factor values might not be the same. In both treatments, workers will encounter a deterministic AI in 9 scenarios, and a random AI in the other 9 scenarios. These are shuffled so workers don't know whether recommendations are deterministic or random. Because the Random AI could still pick the patient according to its original value preference ordering by chance, the combined AI (Deterministic+Random) follows its stated value preference ordering stochastically, about 75% of the time.

Once the worker finishes the second stage of the experiment, they fill out an additional survey where we ask workers for a general demographic description, and two more questions about their experience — which dimension (Prior Donor, Wait Time, Disease Stage) most impacted their decision making without the AI, and how much did they think they relied on the AI when making decisions in the second stage.

4 RESULTS

We recruited a total of 303 workers, with 160 workers being assigned to the first treatment, and 143 workers being assigned to the second treatment. 67% of participants were male, and 33% were female. 86% of participants were white. 81% of participants had a bachelor's or higher. Median pay for workers was approximately $10 per hour. This study was approved by our institution's IRB.

4.1 Effect of Value Similarity on AI Reliance

We start by answering our first research question, which analyzes how value similarity affects reliance on AI recommendations. We measure reliance in two different ways. First, we express reliance as the overall change in alignment between the human and AI between the first and second stages. Then, we express reliance as the change in decision-making behavior, computed only on the subset of scenarios where the human and AI differ in the first stage. We present results for both of these metrics in Figure 3. We report the statistical significance values using a t-test and the effect sizes using Cohen's d. Error bars in plots represent standard errors.

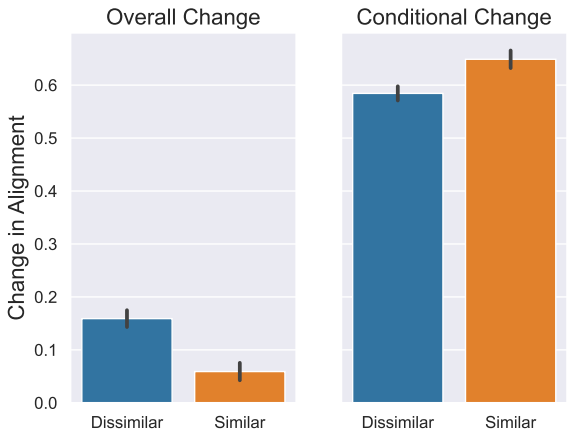

Figure 3: The effect of value similarity on alignment change between Stages 1 and 2. In the left figure, we find across all scenarios, the dissimilar AI has a significantly larger change in alignment ($p < .001$). In the right figure, we find that in scenarios where the human and AI disagree, the similar AI has a significantly larger change in alignment ($p = 0.003$).

4.1.1 Overall Change in Alignment. In order to measure the overall change in alignment, we compare the rate at which users match with the (unseen) AI in the first stage with the matching rate in the second stage. We find that adding a recommendation from a similar AI significantly increases alignment by 5.9% ($t(1286) = 3.58, p < .001, d = 0.10$), while adding a recommendation from a dissimilar AI significantly increases alignment by 15.9% ($t(1439) = 9.98, p < .001, d = 0.26$). The difference between the two increases is also significant with $t(2705) = 4.35, p < .001, d = 0.17$. **Overall, we find that dissimilar AIs have a bigger overall impact on overall alignment, confirming our first hypothesis.**

While this result may seem unintuitive, it can be explained by the fact that users tend to agree more with a similar AI than a dissimilar AI, so there is less room to increase agreement for a similar AI in the second stage.

4.1.2 Conditional Change in Alignment. As a perhaps more useful measure of reliance, we can choose to consider only scenarios where the AI gives recommendations which go against the decision that the user made in the first stage. This comparison is possible because our experiment design guarantees that each of the nine possible scenarios appear once in the first stage, and twice in the second stage.

We find that when the AI gives a recommendation which goes against the user's Stage 1 decision, alignment with a similar AI increases by 64.9%[1], while alignment with a dissimilar AI increases by 58.4%. This difference is significant with $t(1302) = -3.00, p = 0.003, d = 0.17$. **Overall, we find that similar AIs have a bigger impact on human alignment when the AI goes against human prior preferences, confirming our second hypothesis.**

4.2 Effect of Value Similarity *Claims* on Alignment Change

For our second research question, we try to understand why we see effects of value similarity on AI reliance. Specifically, we want to see if the increases in AI alignment caused by value similarity in Sections 4.1 can be explained by the workers' belief that the AI shares a similar set of values to the workers, or if the increase in AI alignment is due to the actual similarity in values exposed in AI recommendations reinforcing the workers' own preferences.

In our experiment design, half of the AI recommendations in the second stage are generated deterministically according to the claimed ethical preference, and half of the AI recommendations are generated randomly. When the AI is random, any alignment increase is only due to the perception of the AI having similar or dissimilar values. When the AI is deterministic, alignment increases are explained by both user perception of AI similarity and the effect of the AI actually acting according to its preferences. As a result, we can compare these two to find the isolated effect of AI claims.

We measure the effect of value similarity on conditional AI alignment (as in Section 4.1.2), and break this data down by AI Behavior — whether the AI is deterministic or random. These results are presented in Figure 4. In this experiment, we have two independent variables (deterministic vs random AI, and similar vs dissimilar AI). The dependent variable is the conditional alignment. To examine the significance of the results, we first conduct a two-way ANOVA test and find a significant interaction effect between the two independent variables ($F(1) = 6.86, p = 0.009$). We then conduct post-hoc Tukey's HSD tests. We find that when the AI is deterministic, there is a significant difference in the conditional AI alignment between similar and dissimilar AI ($p < 0.001$). However, when the AI is random, we see no significance in the conditional AI alignment between similar and dissimilar AI ($p = 0.58$). The results suggest that workers' reliance on AI is influenced by the realized AI recommendation instead of the value AI claims to exhibit. **With this result, we find no evidence to support our third hypothesis, as we see no effect from AI similarity claims alone on reliance.**

4.3 Exploratory Analysis

Now that we have answered our main research questions, we perform a few follow-up investigations of our data to shed further

[1]Because we are only examining scenarios where the human originally disagreed with the AI, these increases can be interpreted as total alignment in the second phase. E.g., in this subset of scenarios, workers choose to follow similar AI recommendations 0% of the time in the first stage, and 64.9% of the time in the second phase.

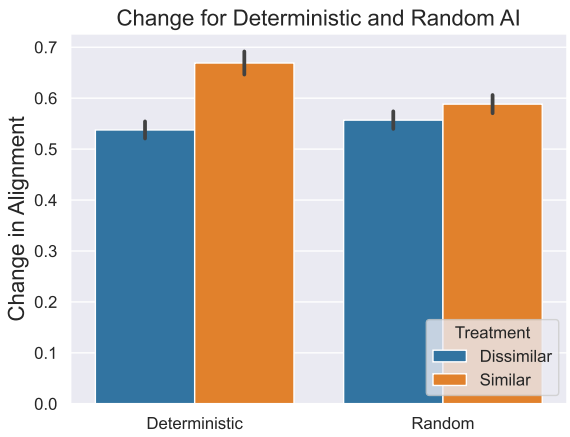

Figure 4: The effect of value similarity on alignment change between Stages 1 and 2, across combinations of Deterministic/Random and Similar/Dissimilar. When the AI is Deterministic, the Similar AI leads to a significantly larger change in conditional alignment ($p < .001$). However, when the AI is Random, there is no significant difference between Similar and Dissimilar AI ($p = .58$).

light on the effects and implications of using AI recommendations in problems of ethical decision making. We note these analysis is intended to be exploratory and hope that this additional analysis provides a starting point for future work to study these topics in more depth.

First, we look at the relationship between AI similarity and people's subjective beliefs of self-confidence, trust in AI, and perceived usage of AI with the type of AI they used (similar/dissimilar). This can be considered an extension of Mehrotra et al. [31], which investigated the relationship between people's subjective beliefs of AI trust and AI similarity. In addition, we broaden the scope of our results in Section 4.1 to understand not only the individual-level effects of AI assistance on reliance, but population-level shifts which personalized AI recommendations can create.

4.3.1 Subjective Perceptions. In our experiment, we asked users three subjective questions which relate to their perceptions of their own decisions or the AI's decisions: How confident were they in their own decisions made in the first stage (Self-Confidence), how much they trust AI to make decisions on its own (AI-Trust), and how much they believed they relied on the AI in the second stage (AI-Reliance). Each of these questions were asked on a 5-point Likert scale, where "1" represents strongly confident, strongly trust, and strongly reliant, respectively.

We compare the results of these questions across the two experiment treatments - whether they were presented with similar or dissimilar AI recommendations. It should be noted that the first two subjective questions, on Self-Confidence and AI-Trust, were asked directly after we presented them with a summary of their own values (calculated using their responses from the first stage) and the values of the AI assistant assigned to them. The third question, on AI-Reliance, was asked after the second stage.

We find that users shown a similar AI had a Self-Confidence score of 1.82, an AI-Reliance score of 2.01, and an AI-Trust score of 2.02. Users assigned to a dissimilar AI had a Self-Confidence score of 1.88, an AI-Reliance score of 2.14, and an AI-Trust score of 2.18. However, none of these differences across treatments are significant, with p-values of 0.41, 0.23, and 0.41, respectively.

We highlight this last result specifically, as it is similar to the analysis done by Mehrotra et al. [31]. However, they found a significant correlation between value similarity and trust in a smaller study (89 users), while we were not able to replicate this finding in a larger experiment (303 users). We speculate that this lack of replication is due to the choice of ethical values used for determining similarity. In Mehrotra et al. [31], they described their AI assistants to workers using a generic set of ethical values, only some of which were actually relevant to their ethical decision-making problem. This could have lead workers to have high trust in AI recommendations based on values relevant to the problem, and low trust in AI recommendations based on values irrelevant to the problem. In contrast, we exclusively present values which are relevant to our ethical problem; this may cause a smaller effect when comparing the values against each other.

4.3.2 Population-Level Shifts. In this section, we investigate potential population-level shifts in user behavior as a result of using personalized (similar or dissimilar) AI recommendations. Specifically, we aim to understand if populations become more divided in their ethical preference strengths, and potential implications on population polarization.

First, we discuss the metric ΔP, introduced by Awad et al. [2], which represents a worker's ethical preference in a single factor (e.g. Prior Donor Status). We can calculate ΔP on this factor by taking all decisions where the factor is unequal across candidates, and computing the difference in preferences across options. For example, if a worker views four scenarios where one candidate is a prior donor and the other candidate is not, and the worker selects the prior donor three times, their ΔP for the Prior Donor factor is $0.75 - 0.25 = 0.5$. For each worker, we generate a vector of ΔP values (or $\boldsymbol{\Delta P}$ for short) to represent the worker's ethical preferences across the three factors.

Using $\boldsymbol{\Delta P}$, we can then generate our population-level metric, the normalized stated preference (or stated preference). Recall that we asked workers to express the dimension they care about the most in the post-experiment survey (we call this dimension "preferred factor"). To generate the normalized stated preference, we normalize each worker's $\boldsymbol{\Delta P}$ to be length one and select the value in the dimension of the workers' preferred factor. For example, if a user's normalized $\boldsymbol{\Delta P} = (0.8, 0.6, 0)$, and the user's preferred factor is the Prior Donor factor (the first dimension of the vector), then their normalized stated preference value would be 0.8. The reason we normalize $\boldsymbol{\Delta P}$ before selecting this preferred factor is to better measure the relative preferences between a user's stated preference and the other two preferences, without giving extra weight to users with a higher overall ethical preference strength.

The intuition of using this normalized stated preference as a metric is to measure how divided a population is. For example, people

generally have varying priorities on what government should focus on (e.g. the economy, health care, climate change, security) [23]. If a population has a relatively low stated preference, then this can be interpreted as the population having relatively weak preferences towards their highest priority over the other policy options. If the population has a high stated preference, this means that people strongly believe in their top policy over the others.

We analyze the average stated preference of the two stages. We find an average stated preference of 0.151 in the first stage, and an average stated preference of 0.173 in the second stage. This increase is not significant ($t(895) = -0.52, p = 0.60, d = 0.04$). However, if we compare the increase in the average stated preference with similar AI and the increase with dissimilar AI, We see that a similar AI increases stated preference to 0.226, and a dissimilar AI decreases stated preference to 0.125. This difference is statistical significant, with $t(595) = -2.09, p = 0.037, d = 0.17$. Overall, the results suggest that the use of similar AI recommendations leads to higher stated preferences than using dissimilar recommendations.

5 DISCUSSION

In this section, we discuss the limitations, implications, and future work of our study.

Limitations and generalization. We discuss the limitations of this study. First, we have conducted our experiments using crowdsourcing with users recruited from Amazon Mechanical Turk. While crowdsourcing is getting increasing popularity in conducting user studies, the nature of distributed work of the platform raises questions about the engagement of workers and the quality of their responses. The common approaches to improve the quality of crowdsourced data collection include post-hoc aggregation [6, 19, 20, 42, 48], designing proper incentives [21, 22, 24, 30, 44], and improving the task design [1, 9–11, 14, 40]. However, the subjective nature of our task makes it challenging to ensure data quality as we cannot evaluate whether the workers are providing truthful answers. Moreover, the hypothetical nature of the presentation of the moral dilemma, although being a standard practice for academic studies [2, 16], may not reflect human ethical preferences in real-life scenarios. Additionally, the study surveyed ethical preferences from a general population of laypeople, who may interpret the moral dilemma differently from relevant domain stakeholders. Therefore, surveying preferences from stakeholders such as medical doctors or policymakers could provide valuable insights on how these results could inform real-world implementation of AI-assisted human decision making on kidney allocation.

Second, we have conducted a case study in the domain of kidney allocation to investigates the effects of value similarity to human reliance in the context of AI-assisted ethical decision making. Given the nature of case study, we cannot guarantee that the results and findings carry over to other domains. However, kidney allocation is an example of a general family of problem in scarce resource allocation. Therefore, we conjecture that our results could translate to other domains in this family of problems, such as vaccine distribution or homelessness resource allocation. However, it is important to carefully study applications in other domains before using these results to inform implementation in real-world systems.

Implications. In this work, we find that human reliance on AI is influenced by the value similarity between humans and AI. This result showcases the complexity of understanding the impacts of incorporating AI recommendations in ethical decision making, as the final decisions made by human-AI teams would depend on not only the ethical values exhibited by humans and AI algorithms but also the similarity between them. For example, if workers' ethical preferences are reinforced by AI with similar ethical preference, in the sense that they put more focus on the top factor in making ethical decisions, when we provide personalized assistive AI (with similar values to decision makers) in AI-assisted ethical decision making, it could create an effect similar to the *echo chamber* effect [5] that make the ethical decisions made by AI-assisted decision making more polarized, focusing on more extreme factors.

Moreover, the fact that human decisions are influenced by AI assistance also creates potential concerns of manipulation. For example, through leveraging the techniques from the literature on information design [26, 39], the advantageous party (e.g., the party that provides the AI assistance, usually the party with more power and information advantage) might strategically choose the assistance to lead human decision makers to take certain decisions. Therefore, as the growing prevalence of AI involvements in decision making in high-stake domains, having more studies on how humans reliance on AI evolves and whether it is possible to be manipulated are important to ensure the introduction of AI in decision making creates positive impacts to the society.

Future work. Our work has presented interesting findings on the effect of value similarity to human reliance in AI-assisted ethical decision making. There are still a lot of open questions that deserve future study. First, it is worth exploring the other factors that might impact human reliance on AI in the domain of ethical decision making. For example, if we provide explanations on why the AI recommendations exhibit certain ethical values, are human decision makers more likely to follow the recommendations? Moreover, as brought up by the above discussion on the limitations and implications, investigating the impact of AI assistance in different problem domains and with different stakeholder populations would help us understand the generalizability of the results. It is also important to study how the overall ethical preferences evolve when introducing AI to help humans make decisions in ethically-sensitive domains.

6 CONCLUSION

We investigate the impact of value similarity to human reliance in AI-assisted ethical decision making. We find that recommendations provided by a dissimilar AI have a higher impact on human decision-making than those given by a similar AI. However, this result is primarily due to the fact that a similar AI typically has a higher level of agreement with the human decision maker, leaving fewer opportunities for persuasion. When we focus on scenarios where humans and AI disagree, we have observed that humans are more likely to change their decision when given recommendations from a similar AI rather than a dissimilar one. We have found no evidence to suggest that this effect is a result of humans perceiving the AI as being similar. Instead, our findings indicate that this effect is mainly due to the AI's ability to display similar ethical values through its recommendations.

ABSTRACT

In this paper, we introduce new formal methods and provide empirical evidence to highlight a unique safety concern prevalent in reinforcement learning (RL)-based recommendation algorithms – 'user tampering.' User tampering is a situation where an RL-based recommender system may manipulate a media user's opinions through its suggestions as part of a policy to maximize long-term user engagement. We use formal techniques from causal modeling to critically analyze prevailing solutions proposed in the literature for implementing scalable RL-based recommendation systems, and we observe that these methods do not adequately prevent user tampering. Moreover, we evaluate existing mitigation strategies for reward tampering issues, and show that these methods are insufficient in addressing the distinct phenomenon of user tampering within the context of recommendations. We further reinforce our findings with a simulation study of an RL-based recommendation system focused on the dissemination of political content. Our study shows that a Q-learning algorithm consistently learns to exploit its opportunities to polarize simulated users with its early recommendations in order to have more consistent success with subsequent recommendations that align with this induced polarization. Our findings emphasize the necessity for developing safer RL-based recommendation systems and suggest that achieving such safety would require a fundamental shift in the design away from the approaches we have seen in the recent literature.

1 INTRODUCTION

Recommender systems, also known as recommendation systems, are algorithms designed to sift through vast collections of data to identify and suggest entities that are particularly relevant to a specific user or group [7]. These systems have been extensively deployed in a variety of domains, including entertainment, retail, and social media, where they curate suggestions for movies, music, and merchandise, as exemplified by platforms such as Netflix, YouTube, and Twitter. A particularly significant application of these systems is in news and social media platforms where they curate relevant content for users. In the context of this paper, we focus on these as *media recommender systems*.

A popular approach to deploying recommender systems is to treat the recommendation problem as a Markov Decision Process (MDP) and applying reinforcement learning (RL) to the recommendation task. Although the potential of this approach was recognized theoretically two decades ago [29, 31, 32], the more recent emergence of 'Deep RL' – notably, its ability to handle larger, more complex recommendation problems – has reignited applied interest [19, 36, 37]. In response, researchers have begun exploring the applicability of Deep RL-based recommendations within the news and social media sector [28, 38]. This body of work has shown a significant increase in user engagement compared to the deployment of the recommendation problem using two other prominent methods: (i) 'static' machine learning approaches [3, 7, 12, 20, 22] and (ii) contextual Multi-Armed Bandit approaches [18, 33–35].

Advancements in RL techniques have enabled the large-scale implementation of RL-based recommender systems. Major social media platforms, such as Facebook, have already begun integrating these systems into their frameworks [13, 21]. This integration raises crucial safety and ethical question: How can we identify potential harms arising from the use of RL-based recommender systems, and what measures can we take to mitigate them?

The social implications of media recommender systems have received significant attention in recent years [1, 16, 23, 24, 30]. A comprehensive review of the topic identifies six key areas of concern: biased/unfair recommendations, encroachment on individual autonomy and identity, opacity, questionable content, privacy, and social manipulability and polarization [23]. This paper focuses on the last of these concerns: social manipulability and polarization. In particular, we elucidate the potential harms and risks of social manipulation and polarization posed by RL-based media recommendation systems. Given the growing ubiquity of RL-based social media in our daily lives, we argue that these concerns necessitate immediate scrutiny. We begin our discussion with a review of the primary literature on this subject.

Russell [26, 27] suggests that a specific issue of social manipulation and polarization can arise when the recommendation problem is viewed as an MDP, and an RL approach is used to resolve it. The primary concern here is that an RL-based recommender system might learn to make recommendations based not solely on the user's current interests and beliefs, but also on the long-term influence these recommendations could have on the user. This approach could result in altering the user's interests and beliefs over time. Various recent studies have investigated this issue from different angles

Krueger et al. [17] connect this problem to a concrete probabilistic concept known as auto-induced distributional shift (ADS). ADS pertains to the capacity of an RL agent to learn independently how to shift the opinion distribution among users to its own objective advantage. Such a shift might involve (i) enticing a larger proportion of users who are simpler to provide recommendations for, or (ii) modifying the preferences and behaviors of the current user base. Krueger et al. [17] explore methods to mitigate such unwanted manipulation in example problems including media recommendation systems. However, the learning algorithms employed in their studies are not reflective of the current state-of-the-art algorithms with which this study is concerned, as they consider the emergence of ADS in the context of population-based training with multilayer perceptrons, rather than deep RL. Our paper attempts to address this gap.

Carroll et al. [8] examine the dangers of RL-based recommenders insofar as the inducement of opinion shifts – or ADS – is concerned. The authors formulate mitigation strategies against these dangers by revising the optimization objective of the RL agent. Farquhar et al. [11] also examine the media recommendation problem and explore a different set of mitigation strategies, relying upon a novel extension of the classic MDP model and Causal Inference theory to limit the RL agent's ability to identify opportunities for manipulating users. Our paper differs from these two works in that, while the previous authors focus on principles for how safer RL-based recommenders *could* be developed, we delve deeper into the question of *why they must* be urgently developed with urgency. We substantiate our point through both mathematical and computational demonstrations.

In this paper, we make two core contributions to the literature on safe and ethical media recommender systems. Our first contribution is the formalization of the concept of 'user tampering' as a potential safety issue that could arise in RL-based media recommenders. User tampering reflects the concern that a recommender system may learn that manipulation of a user's preferences, opinions, and beliefs via the recommendation of certain content has beneficial outcomes for its ability to maximize its reward function in the longer term.[1]

User tampering is formalized using the Causal Influence Diagram techniques, proposed by Everitt et al. [9], to extract the specific mechanisms enabling RL-based recommenders to learn such manipulating strategies. Unlike previous research, our formalization directly engages with the state-of-the-art algorithmic designs featured in recent RL-based recommendation literature. Our second contribution is an experimental demonstration of user tampering in recommender systems. In particular, we design a simulation study capturing a simple media recommendation problem. We show that a standard Q-learning algorithm can learn to exploit user tampering by developing a policy for making recommendations that affect our simulated users' content preferences. While our simulation occurs on a significantly smaller scale than a real recommendation problem scenario, its novelty is relevant because it aims to replicate a known cause of opinion shift in social media users. Thus, our simulation study computationally affirms that user tampering is a crucial ethical and safety concern which must be taken seriously when designing and deploying RL-based media recommender systems.

The rest of this paper is structured as follows. In Section 2, we formulate the media recommendation problem as a Markov Decision Process. We then introduce a causal model of the recommendation problem, which we think can be representative of a large subset of current leading recommender systems. Section 3 introduces user tampering formally. We draw on Casual Influence Diagram techniques to identify problematic behavioural incentives in our proposed problem formulation. We then use these techniques to articulate why mitigation strategies applicable to similar tampering problems cannot apply successfully to user tampering. Section 4 introduces our simulation study and its results. Finally, Section 5 concludes the paper.

2 MODELLING THE MEDIA RECOMMENDATION PROBLEM

In this section, we achieve two goals. First, we present a formulation of the media recommendation problem as a Markov Decision Process (MDP).[2] Second, we employ Causal Influence Diagrams (CIDs) to identify relevant causal relationships among specific variables within this model. Our formulation aims to maintain the MDP as general as possible, while integrating design insights from recent developments in the implementation of RL-based media recommender systems [28, 38].

2.1 The MDP formulation of the media recommendation problem

We begin by constructing an MDP model that represents the media recommendation problem, one that aligns with those commonly employed in recent RL-based recommendation literature. This approach is informed by a recent survey, which outlines the cutting-edge of research into RL-based recommendation algorithms, as detailed by Afsar et al. [2]. Our proposed MDP formulation $\langle S, A, R, T, \gamma \rangle$ includes a series of well-founded assertions, specifically relevant to a reasonable MDP formulation of a media recommendation problem. These assertions are as follows:

- S denotes a set of states. A state $s \in S$ can represent a variety of structures, but primarily, it encodes information about the performance of recent recommendations from the recommender. As noted in Afsar et al. [2], this form of state representation is broadly applicable to the various methods of modeling media recommendation problems in recent literature. Dominant approaches since the mid-2000s tend to represent the state based on recent positive user-content

[1] In the rest of this paper, we use the terms 'preferences', 'opinions', 'beliefs, and 'interests' interchangeably.

[2] For an introduction to Markov Decision Processes, see Puterman [25].

interactions [31, 32]. This approach to representation is also observed in the Deep RL literature that has gained attention over the past five years [2]. As a concrete example among many, consider the state represented by a collection of $|n \times m|$ data points, which capture users' aggregate clicks on recommended items across n categories and through m different time frames of recent history (e.g. the last 1 hour, 6 hours, 1 day, etc.).[3] The inclusion of user-behavioral information is crucial in state representation; without it, the theoretical advantages of using RL could be compromised. In order to develop policies that not only capture current opportunities for reward but also anticipate future ones, it is necessary to incorporate user-behavioral information in the state representation.

- A denotes a set of actions. As Afsar et al. [2] observe, recent studies show a substantial consistency in how actions are modeled, with an action signifying either a single item or a collection of items recommended to a user. Practically speaking, actions could manifest as an n-dimensional vector, representing the properties of a piece of content (e.g., an article) across n dimensions for user recommendation. This concept can be broadened to interpret an action as the recommendation of a fixed-size bundle of content (e.g., a set of articles) to a user, since the individual content units can be integrated into the vector.
- R denotes a reward function. R maps an agent's activity to numerical values indicative of the 'goodness' of these activities. Typically, recommender systems use observable engagement metrics, such as a clicks or 'likes', as a basis for these rewards. The form of the function R may vary based on the specific implementation and the definition of actions and the state space. It can be represented in several ways, including $R : S \to \mathbb{R}$ or $R : S \times A \to \mathbb{R}$. In the case of recommender systems, as engagement is included in the state representation and will be updated at each step, a function of the form $R : S \to \mathbb{R}$ is generally sufficient.
- T denotes a transition function. T calculates the probability of an agent arriving at a specific 'successor state' s' after taking a specific action a from its current state s. Typically, a transition function is formulated as $T : S \times A \times S \to [0, 1]$.
- $\gamma \in \mathbb{R}$ denotes a discount factor for future rewards. γ encapsulates the balance between the value assigned to immediate rewards and those expected in the future.

Given these five types of assertion, a media recommendation problem can be modeled as follows: An agent takes an action a_t ($a_t \in A$) at time t. This action transitions the system from the current state s_t ($s_t \in S$) to a subsequent state s_{t+1} ($s_{t+1} \in S$), with the probability $T(s_t, a_t, s_{t+1})$. Following this transition, the agent receives a reward, denoted as $R(s_t)$. Subsequently, another action is chosen at time $t + 1$, and the process continues. During this sequence of actions and rewards, the influence of the discount factor γ is consistently factored in.

[3]This example is very similar to the approach taken by Zheng et al. [38] to represent states.

2.2 Extracting a CID from the MDP

The Causal Influence Diagram (CID) is a modeling technique central to our formalization of user tampering [9, 14]. This technique has recently seen increased application in analyzing the potential incentives driving RL agents' behaviour [4, 9, 10]. We start by briefly describing the basic building blocks of CIDs and then will provide an illustration of CIDs within the context of the media recommendation problem (Figure 1).

CIDs are structured as directed acyclic graphs. CIDs are specified by three node types, representing different variables within the problem at hand. These nodes are (i) Decision Nodes, (ii) Structural Nodes, and (iii) Utility Nodes. As depicted in Figure 1, Decision Nodes are shown as squares, Structural Nodes as circles, and Utility Nodes as diamonds. The Decision Nodes stand for variables that receive an assigned value at the point of decision.

Both Structural Nodes and Utility Nodes symbolize probability distributions over the possible values a variable might take. However, they do this in different ways: Structural Nodes represent distributions over possible state variable values, whereas Utility Nodes represent distributions over possible rewards. A directed edge from a node X to a node Y can be interpreted as follows. If Y is a Utility or Structural Node, then the value of the random variable Y is conditional on the value of X. In such instances, a solid line depicts the edge. If Y is a Decision Node, then the value of X represents the information available to the agent at the decision-time of Y. The edge, in this case, is illustrated with a dashed line.[4]

In the context of RL-based media recommendation, using a CID-based analysis for agent incentives offers several advantages when compared to alternative methods like purely statistical analyses. Firstly, CIDs, and the notion of an instrumental goal in these graphs (as introduced in Section 3), are uniquely equipped to handle *causation*, not just *mere correlation* between variables. This is pivotal in media recommendation, where the causal dependency relations are crucial: We can show recommenders' ability to cause increased user engagement via their actions' causal effects on users' preferences and opinions. Secondly, CIDs allow us to abstract from extraneous information about the specifics of RL algorithm implementations and instead focus on the core causal mechanisms shared among them. This abstraction is particularly beneficial in providing a space for formally discussing causal properties of various potential implementations simultaneously, as opposed to a statistically analysis of the results achieved by each unique implementation.

Note that throughout this paper, for the given CIDs, our figures only depict a subgraph of three time steps from the entire diagram. This simplification is intended to capture the main structure of CIDs, without overly complicating the visualization. Consequently, these results can be readily generalized to scenarios involving more than three time steps.

Let us begin with a simplified model of a media recommendation problem. If we were to naively model an MDP's causal structure as a CID, without additional considerations, we would end up with a representation akin to that shown in Figure 1. At a specific time step x, the distribution over possible current states is represented by S_x. The actual value of the state at time x is the only piece of

[4]The reader is encouraged to refer to Everitt et al. [9] for a more comprehensive understanding of the CID modeling technique.

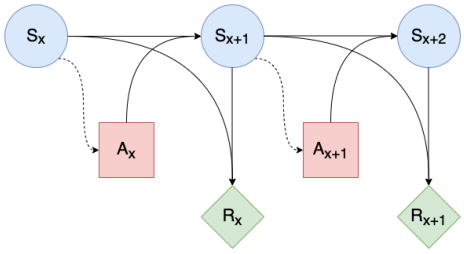

Figure 1: A naive CID of the media recommendation problem.

information available to the agent for its action selection at A_x. The distribution of possible states in S_{x+1} is subsequently determined by T, given S_x and A_x. Finally, R_x denotes the distribution over the reward value achieved from the action taken at A_x. We have assumed an interpretation of the reward function as $R : S \times S \to \mathbb{R}$, wherein the reward is determined by comparing two successive states. This arrangement offers adequate information to infer the success of the most recent action or recommendation.

A simple thought experiment demonstrates that this naive CID underspecifies the causal relationships in the actual problem due to neglecting key variables external to the MDP. Consider the following scenario. Alice and Bob are two university students who recently created accounts on a media platform. Thus far, both have been recommended the same three articles about student politics at their university and both have clicked on the three articles. Within our problem specification, it is quite plausible that the states of the system have been identical thus far from the recommender agent's perspective. Yet, suppose Bob clicks on the articles because his friends feature in the cover photos of the three articles, whereas Alice's clicks stem from a genuine interest in politics, including student politics. If the next recommendation for both Alice and Bob – denoted as A_{x+1} – is an article on federal politics, the distribution over possible states at S_{x+1} is the same. In this state, Alice is more likely to be observed engaging with this content.

This thought experiment illustrates the need for an exogenous random variable to the MDP to model any external causal effects potentially introducing media recommendations. We think this variable can capture the relevance of a specific user's hidden impactful opinions to whom the agent recommends media content. We represent this exogenous variable by θ^T for considering it in our causal modeling framework.

That is to say, the exogenous variable that is the user's interests not captured by her observed behavior (such a click or like) at time x, is represented as θ^T_x.[5] The key point is the potential causal relationship between θ^T_x and S_{x+1}.

As the simple example above demonstrates, an appropriate explanation for the distribution over states S_{x+1} cannot be achieved without considering the possible effect of θ^T_x.

This potential link cannot be easily removed by any practical redesign of the state space. Moreover, it is crucial to recognize that an influence link also exists between A_x and θ^T_{x+1}. This reflects the intuitive idea that a user's information consumption may modify

[5]We do not enforce any Markov assumptions on θ^T_x: it may depend on the values of the variable at multiple, or even all, previous time steps.

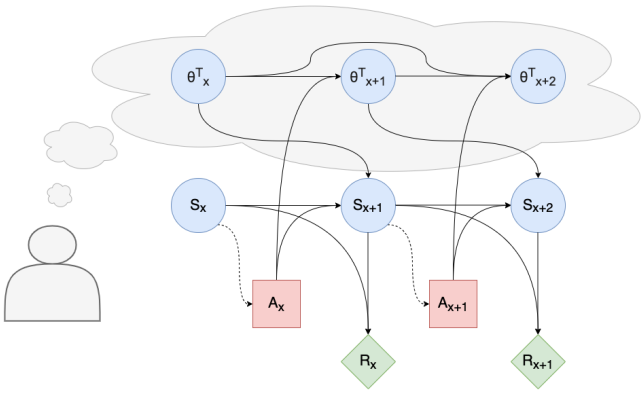

Figure 2: A CID of the media recommendation problem, extended to include the exogenous variable affecting state transitions.

their interests over time. Although θ^T is exogenous, we are not proposing a precise model that explains *how* A_x affects the distribution over possible values of θ^T_{x+1}. Rather, we are acknowledging the potential for a causal dependency via this influence link.

By incorporating the exogenous variable θ^T in our model of media recommendation, we can revise Figure 1 to the CID depicted in Figure 2. We believe that this better captures the actual causal dynamics at play in the media recommendation MDP. We would like to note that similar causal structures for the recommendation process have been suggested in previous work [15]. Nonetheless, these were not framed within the CID context. Our approach, in contrast, not only integrates these structures into the CID framework, but also facilitates in-depth graphical analysis of the media recommendation systems, which we will elaborate on in the following section.

The exact design of the MDP can lead to variations in the CID formulated here; for one such variants see Appendix A.[6] However, these variations do no impact the role or influence of θ^T and its links from the preceding action to the succeeding state remains part of the model's causal structure. As our forthcoming analysis will specifically focus on these causal relationships, the CID depicted in Figure 2 offers a sufficiently general representation for our needs going forward.

3 USER TAMPERING

In this section, we use the CID outlined in the previous section (Figure 2) to examine a primary safety concern related to RL-based media recommendation systems: the potential for user manipulation and polarization. In particular, we introduce and formalize the phenomenon of user tampering. This refers to the possibility of an RL-based recommender system strategically manipulating a user's opinions via its suggestions, aiming to maximize long-term user engagement.

After introducing the concepts of 'instrumental goals' and 'instrumental control incentives,' we demonstrate within the CID

[6]In this Appendix, we provide an example of the implied causal structure when the designer opts to broaden the reward function to incorporate observations not captured in the state representation.

framework that an instrumental goal exists for the agent to manipulate the expected value of the exogenous variable, θ^T. This provides a concrete and formal interpretation of the user tampering safety concern.

3.1 Instrumental Goals and Control Incentives

According to Everitt et al. [9], an 'instrumental goal' is conceptualized as an outcome that serves as a means to achieve the ultimate goal of obtaining a reward. Speaking in causal terms, an agent possesses an instrumental goal to cause an event if: (1) the agent is able to cause the event and (2) the event, in turn, results in an increase in the agent's expected observed reward. One of the key benefits of using CIDs in the modeling of media recommendation systems is that CIDs provide us with conceptual tools for the examination of instrumental goals. RL agents often harbor such instrumental goals, which assist in increasing their observed rewards.

An 'instrumental control incentive' (ICI) is a property displayed in the graphical models of CIDs, as introduced by Everitt et al. [9]. An ICI is said to be present on a Structural Node X if it is located along a path in the CID that originates at a Decision Node and concludes at a Utility Node. This essentially implies that the choice of action at the Decision Node can alter the expected utility at the Utility Node *through* affecting the distribution over values at X.

ICIs bear significant implications for user tampering due to their capacity to graphically indicate either the possible presence or the categorical absence of an *instrumental goal* in certain events within a RL problem [10]. An RL agent is said to possess an instrumental goal to influence the distribution at a Structural Node X in a certain way if it has an ICI on X and that particular influence increases the expected reward accumulated by the agent. Essentially, the agent must have both the ability and a motive to influence the distribution at X.

3.2 Formalizing User Tampering

In the CID presented in Figure 3, there is a subset of Structural Nodes upon which instrumental goals are *desirable*. These nodes represent the set of random state variables, denoted as $\{S_t | t \in \mathbb{N}\}$. The term 'desirable' here means that we, as the problem's designers or framers, 'want' the RL agent to shift the probability distribution at these nodes towards 'good' states which maximize reward. In our problem, these are states where many of recent recommendations have been favorably received by the user. As such, any path in the CID from a Decision Node to a Utility Node passing exclusively through random state variables (e.g. $[A_x \rightarrow S_{x+1} \rightarrow R_x]$, or $[A_x \rightarrow S_{x+1} \rightarrow S_{x+2} \rightarrow R_{x+1}]$) only involves intended and safe instrumental goals.

However, in the CID, there exist additional paths from Decision to Utility Nodes. Specifically, there are paths which involve the exogenous random variables – for example, $[A_x \rightarrow \theta^T_{x+1} \rightarrow S_{x+2} \rightarrow R_{x+1}]$. This pathway is illustrated in Figure 3. An ICI is clearly present on θ^T_{x+1} or on any other variable in $\{\theta^T_t | t \in \mathbb{N}\}$ appearing in similar pathways.[7]

[7]Page size constraints prevent us from displaying larger CID subgraphs, but note that longer paths can also be identified containing similar instrumental goals. For example, paths of the form $[A_x \rightarrow \theta^T_{x+1} \rightarrow \theta^T_{x+2} \rightarrow \ldots \rightarrow \theta^T_{x+n} \rightarrow S_{x+n+1} \rightarrow R_{x+n}]$, or $[A_x \rightarrow \theta^T_{x+1} \rightarrow S_{x+2} \rightarrow S_{x+3} \rightarrow \ldots \rightarrow S_{x+n} \rightarrow R_{x+n-1}]$ are feasible.

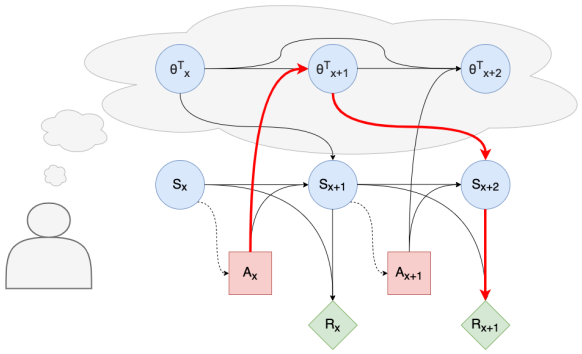

Figure 3: An annotated version of the media recommendation CID for state-based rewards. An example of an undesirable causal path introducing an instrumental control incentive on θ^T_{x+1} is shown in bolded red.

Given these conditions, if an agent can secure higher rewards by tailoring recommendations to a user with particular interests (represented by θ^T), then the agent may have an instrumental goal to influence θ^T accordingly, potentially leading to greater long-term expected rewards. Essentially, the presence of an ICI on at least one node in $\{\theta^T_t | t \in \mathbb{N}\}$ in the CID establishes the graphical prerequisite for user manipulation to emerge as an instrumental goal for an RL agent. If such an instrumental goal is attainable – meaning the agent can boost its expected reward by influencing users' interests – then we can expect that an advanced RL agent would likely learn to exploit this instrumental goal, rendering user tampering a 'learnable' phenomenon. We can thus define user tampering as follows.

Definition 1*. User tampering is a 'learnable' phenomenon for an RL-based media recommendation algorithm iff it has an instrumental goal to affect at least one of the variables in* $\{\theta^T_t | t \in \mathbb{N}\}$.

Importantly, however, an instrumental goal affecting some variable in $\{\theta^T_t | t \in \mathbb{N}\}$ does not inherently mean that a given RL agent will necessarily learn to affect the user in a way that increases its expected reward. It simply means that the agent *has the potential* to learn this behavior. So, the learnability of user tampering in a certain model is a necessary, but not a sufficient, condition for user tampering to actually occur in an RL agent's learned policy. To clarify this distinction, it is beneficial to introduce a second definition of user tampering that separates our discussion of its theoretical learnability from the examination of its practical manifestations in a specific recommender's policy.

Definition 2*. An RL-based media recommendation algorithm 'exploits' user tampering iff there exists a state* s_t *such that* $\pi(s_t) = a_t$ *and* $\pi'(s_t) \neq a_t$*, for the algorithm's actual learned policy* π*, and the hypothetical policy* π' *that the same learning process would have produced in a world where each action has no causal link to the user's subsequent preferences, i.e.,* $A_t \perp\!\!\!\perp \theta^T_{t+1}$.

Informally, this is to say that the learned policy makes a different recommendation in some possible state of the problem than what

it would make in a hypothetical scenario where recommendations had no causal impact upon the user's preferences.

In the rest of this section, we contrast our proposal to a different form of 'tampering' in RL, known as 'Reward Function (RF)-tampering.' Despite some apparent similarities, the RF-tampering is quite distinct from a causal perspective. This distinction rules out the transfer of promising solutions in the literature – particularly those proposed by Everitt et al. [10] – from the context of RF-tampering to that of user tampering.

3.3 User Tampering's Differences from RF-tampering

Reward function (RF)-tampering refers to a specific safety issue where an RL agent has one or several undesirable instrumental goal(s) to affect variables *within* its own reward function. This aims to alter the way in which certain states are evaluated by the function [4, 10]. Detailed analysis on this issue is scant, but it is suggested that the high-level concerns of social manipulation and polarization might be classified under the category of RF-tampering [10]. At a certain level, this assertion seems intuitive – the user and their behavior often mirror a 'reward function' for the recommendation system, since the user's response ultimately decides whether a recommendation is rewarded. Hence, one might expect that tampering with the user would constitute a kind of 'reward' tampering. However, our earlier discussion reveals that this assumption is inaccurate.

In the media recommendation problem, the reward function is an explicitly defined function that maps concrete outcomes within the state space, such as clicks or likes, to numerical rewards. Here, the user essentially forms part of the problem environment, with their behavior contributing to the environment's dynamics. Our earlier definition of 'user tampering' is not a form of 'reward tampering.' Instead, it more accurately represents 'transition tampering.' This perspective is acknowledged by Everitt et al. [10], but not dealt with nearly as extensively as their work on reward tampering.

To situate our argument, we begin with a brief synopsis of the characteristics of any problem in which RF-tampering (and its associated CID) may occur. In such a problem:

- The reward function can be expressed as $R(S;\theta) : S \times \mathbb{R}^N \rightarrow \mathbb{R}$, where θ represents some 'parameters' of the reward function other than states or actions. These parameters are distinct from the states or actions in the model, and should not be confused with θ^T from our model; we use θ here to be consistent with the notation of Everitt et al. [10].
- A specific 'intended' value of θ exists, represented as θ_*. This value remains static unless a change is introduced to it at some point by an external process. In other words, its value is independent of any actions undertaken by the RL agent.
- The agent models θ_* and updates that model based on its experiences. At each time step t, the agent's distribution over possible values of θ_* is represented as θ_t.
- The agent is able to influence the distribution θ_{t+1} with its action a_t.
- The rewards observed by the agent at time step t are defined as $R(S_t;\theta_t)$, rather than $R(S_t;\theta_*)$.

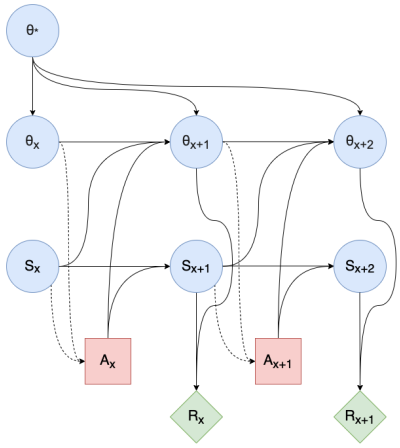

Figure 4: CID Representation of an RF-Tampering-susceptible problem.

The crux of the RF-tampering problem is that the agent has an instrumental goal to alter its own model of the reward parameters such that it rewards certain states more positively than what θ_* would actually generate.

Note, however, that the MDP and associated CID representation of the media recommendation do not conform to this description on several points. Particularly, in the media recommendation problem:

- θ^T is not a hidden parameter to the *reward* function, but instead to the *transition* function.
- θ^T is *not* independent of the agent's actions. While it fulfils a similar conceptual role as θ_* in RF-tampering in that it represents an 'intended' parameter, it is nonetheless subject to the effects of the agent's recommendations. This is why there is a causal link from A_t to θ^T_{t+1}.
- In the problem of media recommendation, it is generally not attempted to estimate the distribution θ^T_t at a given time step t. Rather, the state space contains an implicit estimation of the intended parameters in the form of recorded user behavior. This contributes to the causal link between θ^T_t and S_{t+1}. This does not imply that there *cannot* be an attempt to model this aspect explicitly. For example, Carroll et al. [8] attempt this explicit modeling in their work aimed at mitigating user manipulation. However, as the current industry standards and R&D trends outlined by Afsar et al. [2], it is standard not to do so.

It may help the reader to consult and compare the diagram in Figure 4, where we have recreated the CID given in Everitt et al. [10] to represent an RF-tampering-susceptible model, with the recommendation CID we constructed in Section 2 (i.e. Figure 2).

Several solutions to RF-tampering have been proposed by Armstrong et al. [4] and Everitt et al. [10]. However, some of their underlying assumptions cannot be transferred to our case of transition tampering. Although one proposed solution could be adapted theoretically, its implementation demands a resolution to as-of-yet unresolved questions in the literature, as we elaborate on below.

The solutions that cannot transfer to transition tampering are what Everitt et al. [10] refer to as Time-inconsistency-considering, Direct learning, and Counterfactual agents.[8] At their core, these solutions aim to eliminate the agent's instrumental goals to tamper with its own model of the reward function through hidden parameters.

For our purposes, it is important to understand that these solutions are predicated on the assumption of 'uninformativity.' This means that no causal links can exist between the ground truth hidden parameters at one time step, and the distribution over the state space at the next time step (meaning graphically, in our model, no directed arrows $\theta_t^T \rightarrow S_{t+1}$). As we have discussed, this is an unattainable quality in the media recommendation problem, because it undermines the entire purpose of approaching recommendation with RL. To reiterate, if the state representation contains any measure of previous recommendation successes, 'uninformativity' is not achieved. Conversely, if it does not, an RL algorithm fails to learn as it becomes incapable of drawing associations between its recommendations and their respective impacts on overall reward. Consequently, we must disregard this set of RF-tampering solutions as a feasible transfer of ideas to the user tampering problem.

Another solution proposed is the concept of a time-inconsistency-ignoring agent, which does not necessitate uninformativity, thus providing potentially more promise. The basic premise of this solution – as it would apply to user tampering – is to initially model the user's content preferences explicitly, and subsequently rewarding the agent based on the engagement we would *expect* its recommendations to receive according to this model, rather than the user's actual engagement. This idea was proposed by Everitt et al. [9], who believed that this approach eliminates the ICI, and the instrumental goal, to manipulate user preferences.

However, this solution reveals complex, unresolved problems: How can we learn a sufficiently detailed model of a user's content preferences? How can we simulate organic evolution in these preferences without making the model dependent on the user's actual behavior? For example, if a user of their own volition develops an interest in politics, resulting in increased engagement with political content when occasionally recommended, it would be a poor service if the system continued to seldom recommend such content due to its reliance on an outdated preference model.

A deeper understanding of how and why preferences shift 'naturally' apart from content consumption, and how to distinguish this from changes induced by tampering, is essential. Although recent work by Carroll et al. [8] makes progress in this area, further research is required.

The takeaway for us, in this paper, is that there is no 'quick fix' to tackle user tampering issues, extrapolated from other research on RL tampering problems. Coupling this with our prior discussions about the surge in popularity of RL recommenders and the dominance of a problem framework that significantly enables learnable user tampering, a disconcerting image of the current safety of RL media recommendation starts to surface. To further illustrate this, we will present computational results in the next section, showing exploitation of user tampering in simulated scenarios.

[8]Readers may refer to their work for further details about each of these concepts.

4 COMPUTATIONAL EXPERIMENTS

In this section, we empirically analyze the user tampering phenomenon formalized in the previous section. First, we introduce a simple media recommendation problem, which involves simulated users and a user tampering incentive, derived from recent empirical findings concerning polarization on social media. Second, we present a Q-learning agent designed to mimic the Deep Q-learning algorithms employed in recent media recommendation research, training it within this environment [28, 38]. Our findings show that the policy it learns significantly exploits user tampering to maximize rewards.

4.1 Problem Formulation and Environment Setup

Consider the following scenario where a recommender agent sequentially offers h 'political post/article' recommendations to a user. At each time step t ($0 \leq t \leq h$), the agent can select one of three available 'sources' for recommendation. The first source present consistently left-wing in its perspective, the second offers consistently a centrist viewpoint, and the third consistently showcases a right-wing stance.

Furthermore, we assume the definition of the exogenous parameter θ^T introduced in Section 2. Recall that the agent does not explicitly model this variable (θ^T is an exogenous variable). We define θ_t^T as a tuple of three probabilities as of time t, i.e. $\Theta^T = \{(\theta^{T^L}, \theta^{T^C}, \theta^{T^R}) \in \mathbb{R}^3 \mid \forall x \in \{L, R, C\}.\theta^{T^x} \in [0, 1]\}$. For some arbitrary user, their probability θ^{T^L} represents their probability of clicking an article from the left-wing source *if it is recommended*; the same can be said of θ^{T^C} for the centrist source, and θ^{T^R} for the right-wing source. We say that a user is initially (t=0) 'right-wing' iff $\theta_0^{T^R} > \theta_0^{T^C} \wedge \theta_0^{T^R} > \theta_0^{T^L}$, and 'left-wing' iff $\theta_0^{T^L} > \theta_0^{T^C} \wedge \theta_0^{T^L} > \theta_0^{T^R}$. Finally, we include a simple environmental dynamic whereby users who are recommended content from a source that is politically opposed to their viewpoint gradually become more polarized in favor of their own political bias. This concept is underpinned by recent studies exploring user polarization on social media. These studies provide evidence that exposure to a high volume of content from the politically opposite side can often amplify user polarization [5, 6].

We would like to emphasize that our model of polarization is greatly simplified and is not intended to model the intricate details of the polarization phenomenon described in applied social media in the previously cited works. Indeed, our primary goal is not to simulate the effects of polarization in painstaking detail, but rather to construct an environment which allows the hypothesized effect of user tampering to be tested given the potential for polarization. In order to accomplish this, we consider potential causal effect an agent could use as part of their instrumental goal. Even though our model is simplified, its dynamics remain rooted in authentic sociological findings.

The detailed definition $\langle S, A, T, R, \gamma \rangle$ of the media recommendation MDP, as well as the precise implementation of the 'polarization' effect we have just described, is provided in Appendix B. Next, we train a Q-learning agent in this environment and show that it learns to perform user tampering on our simulated users.

4.2 Recommender Simulation

To computationally operationalize the model described previously, we need to establish some additional specifications. We assign a value of 30 to h, while the probabilities that define the exogenous variable θ^T are restricted to a maximum value of 0.75.[9] We then introduce p, defined as the 'polarization factor.' The polarization factor represents a user's subsequent likelihood of engaging with content from their aligned source, after having a post from an opposing source recommended to them.

In the context of our experiment, a population of five 'users' with varying preference profiles. This include:

- A 'strong left' user with θ_0^T = (0.4, 0.1, 0.1)
- A 'moderate left' user with θ_0^T = (0.3, 0.25, 0.1)
- A 'centrist' user with θ_0^T = (0.2, 0.4, 0.2)
- A 'moderate right' user with θ_0^T = (0.1, 0.25, 0.3)
- A 'strong right' user with θ_0^T = (0.1, 0.1, 0.4)

We train a Q-learning agent in this environment. Each episode starts with the selection of a user at random from the population to provide the initial θ^T value.[10] Non-deep Q-learning was used for training, in spite of deep Q-learning being the more viable approach at industrial scales; this was a deliberate choice, because unlike deep Q-learning, non-deep Q-learning provably converges towards the optimal policy for the problem.[11] Nonetheless, to maintain alignment with practical Deep RL application, we modeled the state space in a parameterized manner suitable for such algorithms.

For each of the five users in our population, we provide two plots based on 10000 evaluation episodes with the user, using the policy learned from the aforementioned training process.

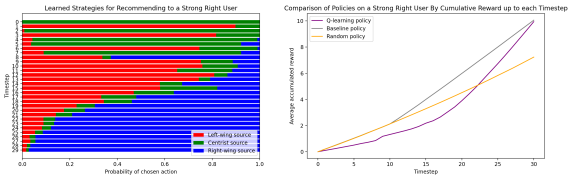
Respectively, these two plots estimate the following. (i) The probability of the learned policy selecting each action at every problem time-step. This is determined by taking the per-episode average frequency of each choice. (ii) The expected reward accumulated up to and including each time step t, $0 \leq t \leq h$. To provide context, we plot this scenario against the expected reward accumulated by two different kinds of recommenders.

(a) The first recommender makes uniformly random recommendations at each time step. (b) The second recommender follows a simple multi-armed bandit-esque policy, which provides a 'baseline' of a good policy. This policy makes random recommendations for the first third of the episode, but then operates like a multi-armed bandit, always recommending from the source that has the highest mean reward in the episode thus far.

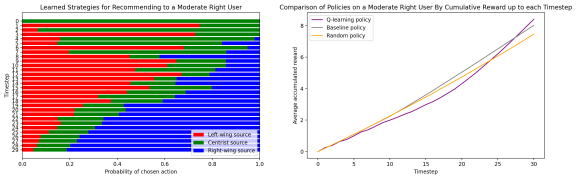
Figure 5 illustrates the plots for each of the simulated users as specified earlier. These results exhibit multiple interesting properties.

First, the exploitation of user tampering by the learned policy is apparent for all users, with the exception of the Centrist. Directing attention to the strategy plots of the two 'left-wing' users reveals a particularly dominant strategy that evolves as follows:

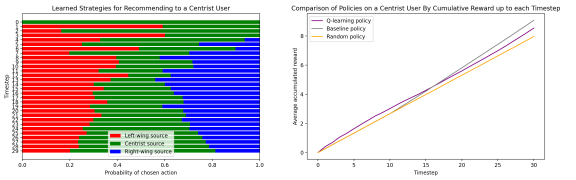
- The recommender attempts to profile the user and their preferences. This is achieved by assessing their response to centrist and left-wing content – predominantly during the first quarter of the episode.
- The recommender primarily recommends right-wing content *in spite of* its low expected reward. This will tamper



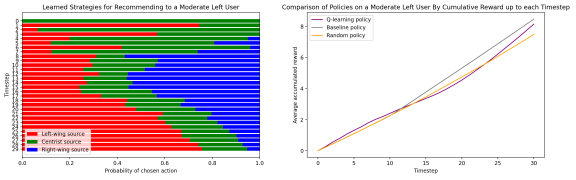
(a) **The 'Strong Right' user.**



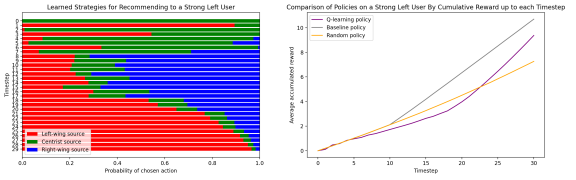
(b) **The 'Moderate Right' user.**



(c) **The 'Centrist' user.**



(d) **The 'Moderate Left' user.**



(e) **The 'Strong Left' user.**

Figure 5: Evaluation of the policy learned with Q-learning for each member of our sample user population.

[9]The authors imposed this arbitrary limitation to prevent users from becoming so 'polarized' that they would engage with every post from a source that mirrors their viewpoints. This seemed an extreme, and thus unrealistic, outcome that could undermine the plausibility of our simulation.

[10]Our implementation, including a pre-trained recommender agent, is available on GitHub: https://github.com/chevans-lab/user-tampering.

[11]Since we wanted to test whether the agent was able to find a *better* policy by exploiting user tampering than it could otherwise achieve, Deep Q-learning was an inappropriate choice for the experiment as there was no way to guarantee that it would not converge on a good, safe policy even when a better, user tampering policy was available.

with the user's preferences and increase the expected reward from subsequent left-wing recommendations – mainly during the second quarter of the episode.
- The recommender predominantly recommends left-wing content to the (now more) left-wing leaning user. This maximizes the high expected rewards that action will now offer – mainly during the second half of the episode.

Despite the low expected rewards associated with right-wing content and the learnability of user tampering in this context, the recommender system is observed to strongly favor right-wing content initially, only to later shift to left-wing recommendations for the rest of the episode. This apparent exploitation of user tampering is noteworthy. Moreover, the inverse behavior is learned for right-wing users – it suggests that the model is not merely attempting to polarize all users towards the left, but is instead crafting a nuanced policy to identify and exploit the causal link between its actions and the user's exogenous variable. This inference is further supported by the policy observed for 'centrist' users.

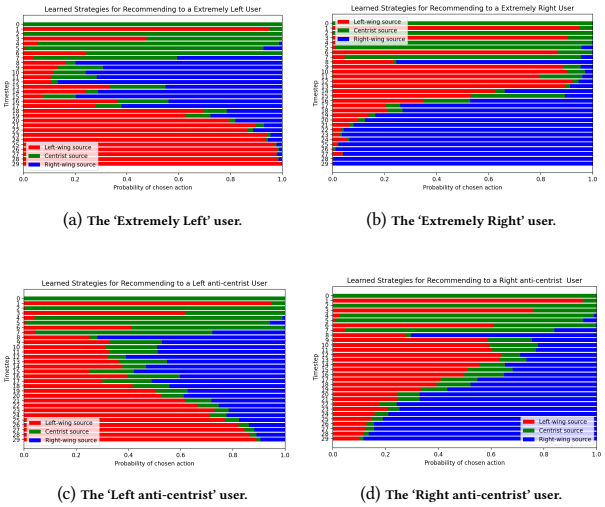
Further evidence to this effect is given by the policy for the 'centrist' user – here, the data clearly indicates that the recommender recognizes its actions hold no discernible causal influence over these users, preventing any feasible user tampering. Consequently, the system's recommendations align closely with the initial preferences of these users.

Second, the agent heavily exploits user tampering even though we were able to generate similar cumulative rewards with our crude 'baseline' policy. This adds weight to the safety concerns with respect to user tampering. It indicates that there exist other policies which do not exploit user tampering (although they may make a handful of 'polarizing' recommendations by chance) and which offer similar rewards to the one that the recommender learned; nonetheless, over several iterations of retraining, the policy consistently converged to the policy we have presented here (with small natural variations). This implies that in this environment, the unsafe policy is not only learned occasionally, but presents a likely direction of convergence for the learning algorithm.

It is also worth establishing that the exploitation of user tampering in the learned policy was robust to simulated users not encountered during training. We generated the same policy plots for the recommender over 10000 evaluation episodes spent recommending to each user in a new, 'unseen' population: an 'extremely left' user with θ_0^T = (0.5, 0.05, 0.05), an 'extremely right' user with θ_0^T = (0.05, 0.05, 0.5), a 'left anti-centrist' user with θ_0^T = (0.35, 0.05, 0.2), and a 'right anti-centrist' user with θ_0^T = (0.2, 0.05, 0.35).

These results are shown in Figure 6. Although these specific users were never encountered during training, the same unsafe strategies appear here; the three phases of user profiling, then polarization, and finally preference satisfaction are clearly visible.

These results support the previous section's claims that user tampering is learnable for commercially dominant methods of designing RL media recommender systems, and strengthen the implications of this by showing that it is, at least according to our small-scale simulation, very much exploitable. Taken in combination with the lack of immediately available remedies, this should raise significant safety concerns about the use of the current state of the art in RL recommendation on pubic media platforms.



(a) **The 'Extremely Left' user.** (b) **The 'Extremely Right' user.**

(c) **The 'Left anti-centrist' user.** (d) **The 'Right anti-centrist' user.**

5 DISCUSSION AND CONCLUSION

This paper has substantiated concerns about the risks of emergent RL-based recommender systems with respect to user manipulation and polarization. We have formalized these concerns as a causal property – user tampering. We have demonstrated the possibility of isolating and identifying user tampering within a formalization of a recommendation system's implicit causal model. We have discussed why the learnability of user tampering is practically uniformly present amongst leading RL recommender systems, and why research into similar RL tampering problems cannot easily be adapted to redesign RL recommendation systems to be safer. Moreover, we have demonstrated computational results for a simple simulation environment which we designed inspired by recent research on social manipulation and polarization. We have shown that a Q-Learning-based recommendation algorithm can consistently learn a policy of exploiting user tampering – which, in our discussion, took the form of the algorithm explicitly polarizing our simulated users. We argued that our demonstration of user tampering phenomenon points to the potential unethical and troubling problems in real-world media recommendation systems. Due to a combination of technical and pragmatic limitations on what could be done differently in RL-based recommender design, we urge significant caution in the deployment of RL media recommendation systems until commercially and computationally viable adaptations of these algorithms that explicitly protect against the possibility of user tampering have emerged.

To this end, the findings in this paper motivate further work in two distinct areas; increasing understanding of the possibilities of the user tampering phenomenon in practice, and identifying positive directions for advancement in research & development of safer algorithms.

While this paper has formalized user tampering and demonstrated its exploitation by an RL algorithm in a simulated environment, that environment was highly abstracted relative to an

industrial-scale recommendation problem. So, while it was valuable in showing that user tampering *can* be exploited by an RL-based recommender system, it contributed less to our understanding of how it would manifest in a real context. While experimenting with actual users would obviously raise ethical questions, there is room for progress by simply reducing the level of abstraction present in the simulation. For example, future work can consider simulating the following scenarios:

- Recommendations from a wider range of sources, which may or may not be political.
- Users with more complex preference profiles, and users whose preference profiles shift as a result of effects external to the recommendation environment during a recommendation episode.
- Causal effects of recommendations on simulated users which more authentically replicate empirically demonstrated effects on real users.
- Recommending content over longer episodes.

On a related note, it would also be valuable to show that results similar to ours can be replicated with a Deep Q-learning-based algorithm, given that this may more closely replicate the learning process of industrial-scale RL-based recommendation (which is predominantly done with Deep Q-learning). Extending our results with this or any of the above suggestions would further substantiate our concerns by closing the abstraction gap between these simulations and the real-world system being simulated.

With respect to identifying positive directions for recommendation research, we believe that the combination of (a) a recommender algorithm capable of learning to estimate a recommendation's effect on the success of subsequent recommendations and (b) defining success in terms of user engagement poses inevitable risks in the form of user tampering. Note, however, that this does not invalidate the premise that algorithms which have a temporally sophisticated approach of the kind described in the first point above *do model the recommendation problem more effectively than static approaches*; where possible, then, this remains an attractive property to include in recommendation algorithms' implementation. We suggest that these observations could be interestingly combined with recent discussions on the notion of 'multistakeholder' recommendation [1, 24, 30]. This discourse, to summarize, has pushed for a more 'value-aligned' approach to recommender system design that – without disregarding the (primary, from a business perspective) goal of user engagement – recommendations should also reflect the interests of other stakeholders such as the creators of the content being recommended, and even society at large. For us, this raises the question; could we create a multi-stakeholder recommendation system in which the interests of the non-user stakeholders, at least, benefit from a more temporally sophisticated approach?

We suggest that approaching multi-stakeholder recommendation with an ensemble model, where each sub-model represents the interests of a (group of) stakeholder(s) and all sub-models *except* for the 'user-representing' sub-model are RL-based may be an exciting direction for future research. This would allow the potential benefits of the RL approach to be maximized as far as possible without introducing learnable user tampering. Without violating the pragmatic requirement that maximizing user engagement is a primary driver of the ensemble's recommendation decision, such an approach may allow us to create systems which use RL's potential in recommendation not as an enabler for user manipulation and polarization, but instead as a positive force for achieving multi-stakeholder value alignment.

ACKNOWLEDGMENTS

We thank the *Humanising Machine Intelligence* grand challenge and its members at ANU for support and feedback throughout this research, as well as attendees of the 4th FAccTRec Workshop on Responsible Recommendation at RecSys 2021, members of the Causal Incentives Working Group at DeepMind, and the anonymous reviewers for their respective feedback. Special thanks are given to Lexing Xie, Tom Everitt, Sebastian Farquhar and Micah Carroll for their comments and discussion. Significant portions of this paper were written while Atoosa Kasirzadeh was at the Australian National University.

A EXAMPLE VARIATION ON THE MEDIA RECOMMENDATION MDP AND CID

The MDP representation of the media recommendation problem may be expanded relative to our characterization in Section 2, if the designer wishes to expand the reward function to account for observations that are not captured in the state representation. This would be a reasonable design choice – for example, the state representation may only record some user behaviors such as clicks, whereas we may want to reward the agent based not only on clicks, but also on the 'dwell time' of the user on the article (the time spent on the article after clicking). For generality, we demonstrate how the CID could be extended to represent this.

This firstly requires some changes and introductions to our MDP definition:

- A set of observations O. An observation consists of some collection of metrics representing how a user observably responded to some recommendation.
- An observation probability function $Z : S \times A \times O \to [0, 1]$. This models the probability of making a particular observation (for example a click, but no comment) after making a certain recommendation in a certain state.
- An altered definition of the Reward function as $R : O \to \mathbb{R}$. This simply corresponds to the fact that the information on which rewards are predicated – the observable user response to the content – has now been concentrated into the one variable $o \in O$.

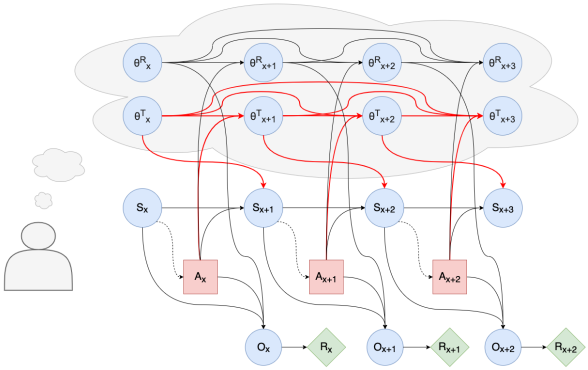

Figure 7: A CID of the media recommendation problem, extended to include an observation space and more complicated definitions of reward.

We also need to make the addition of an exogenous random variable θ^R for the updated CID. This serves a highly similar purpose to

θ^T, except that it instead accounts for the fact that the probability of observing a certain behaviour in response to an article will intuitively change from user to user, even if their state representations are identical (this is a trivial conceptual extension to the Alice-Bob example from Section 2). θ^R and θ^T are not necessarily (and indeed are very likely not) uncorrelated, but we model them as distinct variables for clarity. For the same reasoning as was given with respect to θ^T, influence links will also be necessary between A_x and θ^R_{x+1}.

Figure 7 depicts the media recommendation CID that results from these extensions to the MDP. To reinforce the point made in Subsection 2.2 about variations on the MDP not affecting the causal structure local to the variables $\{\theta^T_t | t \in \mathbb{N}\}$, we have highlighted these variables' incoming and outgoing causal links in the figure; the reader may compare these to those in Figure 2 to verify that all the same links are present.

B FORMAL MDP DEFINITION OF THE RECOMMENDATION SIMULATION

We define the MDP $\langle S, A, T, R, \gamma \rangle$ of the media recommendation problem described in Section 4 as follows:

- $S = \{(s^{LR}, s^{LC}, s^{CR}, s^{CC}, s^{RR}, s^{RC}) \in \mathbb{N}^6 \mid (s^{LR} + s^{CR} + s^{RR} \leq h) \wedge (s^{LR} \geq s^{LC}) \wedge (s^{CR} \geq s^{CC}) \wedge (s^{RR} \geq s^{RC})\}$.
  - s_t is the state after t recommendations, $0 \leq t \leq h$.
  - The state space is interpreted as follows:
    - s^{LR}_t is the number of "left-wing" recommendations made to the user after t total recommendations
    - s^{LC}_t is the number of "left-wing" recommendations clicked on by the user after t total recommendations
    - s^{CR}_t and s^{CC}_t are as above, but with respect to "centrist" recommendations
    - s^{RR}_t and s^{RC}_t are as above, but with respect to "right-wing" recommendations
- $A = \{0, 1, 2\}$, where:
  - 0 = 'Left-wing recommendation'
  - 1 = 'Centrist recommendation'
  - 2 = 'Right-wing recommendation'
- T is defined as follows, where $s = (s^{LR}, s^{LC}, s^{CR}, s^{CC}, s^{RR}, s^{RC})$:
  - $T(s, 0, (s^{LR} + 1, s^{LC} + 1, s^{CR}, s^{CC}, s^{RR}, s^{RC})) = \theta^{T^L}$
  - $T(s, 0, (s^{LR} + 1, s^{LC}, s^{CR}, s^{CC}, s^{RR}, s^{RC})) = (1 - \theta^{T^L})$
  - $T(s, 1, (s^{LR}, s^{LC}, s^{CR} + 1, s^{CC} + 1, s^{RR}, s^{RC})) = \theta^{T^C}$
  - $T(s, 1, (s^{LR}, s^{LC}, s^{CR} + 1, s^{CC}, s^{RR}, s^{RC})) = (1 - \theta^{T^C})$
  - $T(s, 2, (s^{LR}, s^{LC}, s^{CR}, s^{CC}, s^{RR} + 1, s^{RC} + 1)) = \theta^{T^R}$
  - $T(s, 2, (s^{LR}, s^{LC}, s^{CR}, s^{CC}, s^{RR} + 1, s^{RC})) = (1 - \theta^{T^R})$
  - $T(s, a, s) = 0$ otherwise.[12]
- $R(s_t, s_{t+1})$ is defined as:

$$\begin{cases} 1 & (s^{LC}_{t+1} - s^{LC}_t) + (s^{CC}_{t+1} - s^{CC}_t) + (s^{RC}_{t+1} - s^{RC}_t) = 1 \\ 0 & \text{otherwise.} \end{cases}$$

- $\gamma = 0.999$

[12]Less formally, this transition function just amounts to the intuition that recommending a post from one source will increment the number of total recommendations from that source so far, and also increment the number of clicks on that source's posts with the relevant probability.

Note that this specific MDP interpretation of the media recommendation problem fits within our general MDP definition from Section 2.

Finally, we define the causal effect of agent actions on the user's exogenous variables in our simulation; this is not something that would be explicitly defined in a scenario with real users, but we need to define it here in order to build our simulation. As mentioned in Section 4, for this effect we took inspiration from recent research into user polarisation on social media, which has demonstrated that showing people who identify with one wing of the political spectrum volumes of content from the opposing wing can often increase user polarisation [5, 6]. We approximate this effect with the following causal relationship between the recommendation at time t, and the value of θ^T_{t+1}:

- If the user is right-wing, and $a_t = 0$ (a left-wing recommendation), then $\theta^{T^R}_{t+1} = \min(p\theta^{T^R}_t, 1.0)$ for some random variable $p \sim P$ where $\mathbb{E}[p] > 1.0$. We call p the 'polarization factor.'
- The same effect applies for left-wing users with $a_t = 2$ and $\theta^{T^L}_{t+1}$.

Beyond the ML Model: Applying Safety Engineering Frameworks to Text-to-Image Development

ABSTRACT

Identifying potential social and ethical risks in emerging machine learning (ML) models and their applications remains challenging. In this work, we applied two well-established safety engineering frameworks (FMEA, STPA) to a case study involving text-to-image models at three stages of the ML product development pipeline: data processing, integration of a T2I model with other models, and use. Results of our analysis demonstrate the safety frameworks – both of which are not designed explicitly examine social and ethical risks – can uncover failure and hazards that pose social and ethical risks. We discovered a broad range of failures and hazards (i.e., functional, social, and ethical) by analyzing interactions (i.e., between different ML models in the product, between the ML product and user, and between development teams) and processes (i.e., preparation of training data or workflows for using an ML service/product). Our findings underscore the value and importance of examining beyond an ML model in examining social and ethical risks, especially when we have minimal information about an ML model.

1 INTRODUCTION

Scholarly work reveals ML-based products and services can facilitate and scale discriminatory treatment of marginalized groups [77], spread misinformation [81], and deteriorate a user's sense of autonomy [9]. Such negative outcomes present themselves as *social and ethical risks* to direct and indirect stakeholders of these technologies. Identifying, assessing, and mitigating such risks, however, is challenging for practitioners. To intervene in these concerns, researchers have proposed quantitative [23, 40], qualitative [26, 44, 51, 59], and epistemological frameworks [22, 29, 52] to better identify and manage the social and ethical risks of ML systems; however, many proposed evaluation methods focus narrowly on the performance and properties of a single ML model (i.e. fairness metrics) as opposed to examining the associated processes and systems. Recently, there is increased attention paid to social and ethical risks that arise in ML development processes (i.e., data collection practices [71]) and interactions (i.e., contextual use of an ML system [78]). However, empirical studies with responsible ML practitioners find existing approaches to assessing social and ethical risks of a single ML model or relevant processes are often implemented at ad-hoc basis, [46, 61, 67]. Furthermore, besides organizational-level challenges of inadequate incentives and resources [48, 82], many practitioners tasked with managing the social and ethical risks of an ML-based product or service have minimal understanding of the underlying ML model(s) due to their technical complexity and the often-inadequate documentation/communication practices between variety of people or teams involved in ML model development from data collection to productionization [53, 67]. Considering these challenges, practitioners have emphasized the need to establish systematic and structured approaches for social and ethical risk management of ML-based products [67].

Given its focus on structured risk-reduction, scholars in the ML community have argued for the use of safety engineering frameworks – particularly System Theoretic Process Analysis (STPA) and Failure Mode and Effects Analysis (FMEA) – as means to analyze and manage social and ethical risks of ML systems [20, 39, 60, 66]. These two frameworks, in particular, are well-established in the safety engineering practice and have been used in the design and development of safety-critical systems since the 1940s [10, 42]. Recent scholarly work highlights that these frameworks could provide the necessary systematic structure for assessing the social and ethical risks of ML systems [20, 39, 66, 67]. However, there remain open and unexplored questions on how we can apply safety frameworks (e.g., what aspects of the ML development pipeline should be considered

in the analysis scope) and what these frameworks can reveal about potential social and ethical risks of these ML applications.

As social and ethical risks often emerge from both how a technology is developed and how it is embedded within a social context [24, 70, 78], examining contextual aspects provides valuable insight for risk management and harm reduction. Safety engineering frameworks are frequently used to examine harms that could emerge from a process (i.e., a manufacturing process) or interactions between different sub-parts of a system (i.e., between different internal components) [10, 41]. These frameworks have the necessary analytical approach for connecting potential failures in a process or an interaction to downstream harms. We leverage the capability of these frameworks to examine interactions and processes involved in the ML-product/service development pipeline and investigate if they enable the discovery of social and ethical risks without changing the original frameworks. Our research questions are:

- RQ1: What can STPA and FMEA reveal about social and ethical risks by examining processes and interactions involved in developing and deploying an ML model?
- RQ2: How can STPA and FMEA be conducted along the ML development pipeline to identify potential social and ethical failures/hazards of a system?

We focus on the application of FMEA and STPA at three stages of the ML development and deployment pipeline: (1) data processing for creating a training dataset, (2) integration of one ML model with other ML or non-ML algorithms in an ML-product, and (3) end use of the ML product. To illustrate, we conducted FMEA and STPA on a case study involving real-world users of a text-to-image (T2I) model user interface by professional visual artists in their creative practice. The rapid public release and adoption of large generative models in various application areas have fueled much concern about the societal and ethical implications of generative models (e.g., [1, 57, 75]). Considering the complexity of these models, investigating ML development and deployment process could provide a vantage point for identifying social and ethical risks [27]. This analysis is solely illustrative and it captures a point-in-time snapshot and potential configuration of the development and deployment for the chosen ML application. While we did not conduct a full STPA/FMEA analysis, this case study offers empirical evidence on how safety engineering frameworks could be translated to analyzing social and ethical risks.

Our analysis illustrates that even without having detailed information about the ML model, safety engineering analysis provides a systematic method of discovering a range of failures and hazards along the ML development and deployment pipeline. We discovered potential failures and hazards that pose social and ethical risks by analyzing *processes* and *interactions* surrounding a given generative model in an ML product, even though these frameworks were not originally designed for uncovering such risks. STPA and FMEA provided a systematic and consistent approach to analyzing a range of interactions and processes including 1) process of training an ML model, 2) interaction between an ML model and accompanying models in a given product, 3) interaction between an ML product and its users. Lessons learned from our analysis can guide practitioners in conducting systematic analysis beyond a single model, which reflects the majority of production use cases at organizations. With the rapid adoption of ML models in various products today, we call for further examination and use of safety engineering frameworks to improve responsible ML development and integration despite the increased opacity and complexity of the models involved.

In the remainder of this paper, we contextualize the relevance of the safety engineering frameworks and provide an overview of current discourse in T2I model development and use in the creative process (Section 2). We outline our information-gathering protocol and analysis methods (Section 3) and then highlight key findings (Section 4). Lastly, we discuss the value and shortcomings of applying safety engineering frameworks in light of current practices and call on the research community to further examine and strengthen these frameworks for ethical and social risk management of ML systems (Section 5).

2 BACKGROUND

Practitioners and scholars in the responsible ML field have proposed a range of tools and frameworks for identifying, assessing, and mitigating potential social and ethical risks of ML systems. These tools include approaches for assessing the properties of models with respect to values such as fairness or transparency [47], examining the interaction between a model and its context of use [59], and investigating the ML model creation processes [70]. Many of the current assessment methods are applied in an ad-hoc basis across the ML development pipeline limiting their impact and in response, practitioners have expressed the potential for safety engineering to provide a systematic approach for managing social and ethical risks of ML systems [20, 67]. In the following sections, we provide a brief description of scholarly work that discusses the potential use of safety engineering frameworks for ML systems and discuss existing studies relevant to our case study on the use of T2I models in artistic creations.

2.1 Safety engineering frameworks: failure and hazard analysis

Safety engineering is a long-standing discipline that has evolved from creating safe mechanical systems (ex., planes, and cars) to safe software systems [16]. As ML systems can scale both benefits and harms, there is a need to investigate how existing safety engineering frameworks could support safe ML development and deployment [38, 39, 59, 67]. Failure and hazard analyses are the most commonly used frameworks in safety engineering practice [16]. This type of analysis is often conducted early in the development process to foresee potential failures and develop ways to control them in design [9, 42]. These methods differ from other assessment processes for ML systems, such as algorithmic impact assessments and auditing practices, in their focus on identifying, evaluating, and connecting anticipated harms to a design decision and mitigation in the development process [59, 67].

Prior work in responsible ML development has discussed the potential use of two failure and hazard analyses processes, FMEA and STPA, for managing social and ethical risks ML systems [20, 43, 59, 66]. FMEA is a well-established reliability engineering process [35, 45] that takes an analytical reduction approach (i.e. breakdown of a system into its steps or components) to evaluate the likelihood

of risk for potential failure modes [10]. On the contrary, STPA is a hazard analysis tool that uses a system theoretic perspective to map out parts of a system and how they interact with each other [42]. Through this examination, analysts can identify potential hazards (i.e., sources of harm) and develop necessary safety requirements [33, 34, 74]. In contrast to FMEA, the STPA process does not focus on the likelihood of risk or specific points of failure. Instead, STPA models and examines elements of control and feedback in a sociotechnical system.

Existing research outlines the overarching benefits of FMEA for internal ML auditing [59], interprets how FMEA could reveal ML fairness-related failures [43], and employs FMEA to suggest an analysis of "social failure modes" for ML systems [66]. Similarly, several works discuss the benefits of a system theoretic perspective for addressing social and ethical risks of ML systems by allowing the analysts to map out how an ML system interacts with its environment [20, 50]. Recent studies explore industry ML practitioners' perspectives towards safety engineering techniques and highlight that safety engineering frameworks provide an avenue for systematizing the identification and mitigation of social and ethical risks [49, 67]. However, both studies recognize that a successful translation of these frameworks for ML development requires organizational changes/support and further empirical examination/development of these methods. In this work, we focus on the second gap and investigate how these two safety engineering frameworks could be used to identify social and ethical risks along the ML development process via a case study application. We focus our case study on the use of T2I models in the art creation process.

2.2 Use of T2I models in creative practice

In recent years, scholars and practitioners have developed highly performative models that generate images from a given text prompt. Such models, including DALL-E [58], Parti [84], Stable Diffusion [19], and Imagen [68] are generative T2I models. They perform significantly better in terms of image quality and text-to-image alignment compared to their predecessors [58, 84]. These T2I models have been released for general public use through various user interfaces and APIs [15, 36, 85].

Artists, especially digital artists, have been among the early adopters of many T2I user interfaces [72] leading to a growing discussion on how artists could use T2I models for co-creation [28]. Alongside enthusiasm in certain artist communities, however, there is growing concern about the potential harm that could emerge from their use. This includes artist concerns about how their artwork is often used as training data in the creation of such models [21], how generative models could affect art creation practice [13], and impact artists' livelihood [11, 30, 69]. Similarly, ML and Responsible AI scholars have examined how image generation models could perpetuate existing systematic biases [4, 5, 12, 75, 77, 78], including stereotype amplification. Creators of such models have recognized potential limitations and risks posed by these models in their public releases of academic papers and APIs [84].

2.2.1 Rationale for choice of case study. We focus our case study on the use of T2I models in the context of art creation. Despite significant improvements in specific performance metrics (i.e., image quality and text-to-image alignment) in recent years [84], large generative models, such as T2I models, are opaque and complex, making it challenging to uncover potential failures and hazards [8]. However, practitioners still consider their use across many applications and use cases [3, 28]. Safety engineering analysis allows practitioners to look beyond the properties of a single complex model and discover potential failures/hazards by investigating the processes that are part of the development and deployment of such models. We posit that this approach is especially beneficial for assessing the risks of more generalized models and empirically examine this by choosing a case study around the use of T2I models. Even though safety analysis is often conducted for safety-critical systems (i.e., nuclear power plants, airplanes, medical devices) [16]. By choosing a case study on the use of T2I models in creative practice, we leverage these systematic approaches for risk assessment and harm reduction in applications that have emerging hazards/failures [12, 78] but are not categorized formally as safety-critical.

3 METHODOLOGY

We use a case study approach to explore our two research questions described in Section 1 for the following reasons [65]. First, there is a lack of precedence in how such tools could be applied to ML systems. Second, empirical evidence is needed to understand the nature of failure and hazards that emerge from such analysis to see if these tools could allow us to uncover potential social and ethical risks. While many variations of STPA/FMEA exist, the first step of traditional STPA and FMEA requires mapping certain information about a given system [10, 42]. Therefore, we gather the necessary information prior to conducting STPA and FMEA.

3.1 Information gathering

Typically, FMEA and STPA are conducted by system experts and safety engineers who are working in a company. These analysts have in-depth knowledge of the systems and the safety engineering processes. Considering that both the FMEA and STPA are conducted by the authors of this paper, we needed to gather information about the system, its components, and its interaction with various stakeholder groups. This is necessary in order to divide the system into functional components or steps (in the case of FMEA), and losses and constraints (in the case of STPA).

In our case study, we collected three different sources of data for conducting FMEA and STPA analysis (as illustrated in the supplemental material) including workshops with artists, expert interviews with T2I model developers/evaluators, and secondary research on T2I models. We describe our process for gathering information from the workshops and the interviews in the following sections and follow by describing our analysis approach.

3.1.1 Workshop with artists. To understand the artist's perspectives towards the use of T2I models in their creative process, we conducted three 90 minutes-long workshops with 15 artists.

Participant recruitment: We used purposive [55] and snowball sampling [56] to recruit participants for this workshop. The workshop organizers brainstormed an initial list of artists and only included candidates that had worked with T2I models in their practice, were older than 18-years-of-age and were professionally working in the arts for at least a year. Participants were recruited via email and once they accepted to participate, they were sent a consent

form. In total 15 artists representing 6 countries participated in the workshop. Participants held a diverse set of roles in the creative industry, including but not limited to, filmmaker, art curator, and digital artist.

Workshop protocol: The workshop protocol (as illustrated in the supplemental materials) included three different sections, each of which was 90 minutes long. The first section focused on getting to know each participant and how they use T2I models within the creative process. In the second section, one of the researchers presented a sociotechnical harms taxonomy [73] and facilitated a discussion on the perceived harms of T2I models with the group of artists. The third section of the workshop focused on discussing potential harm reduction avenues.

3.1.2 Interviews with T2I developers and evaluators. We conducted 60-min interviews with 8 industry experts involved in the development and evaluation of T2I models to understand their processes.

Recruitment: Similar to the workshop recruitment, we used purposive [55] and snowball sampling [56] to recruit interview participants. We brainstormed an initial list of candidates who were 18 years or older and had worked on the development or evaluation of a T2I model for at least 1 year. The researchers reached out to potential candidates via email and a consent form was sent to individuals who agreed to participate in the interview. Overall 8 people participated in the interview covering three roles: 1) Researchers who worked on developing and evaluating T2I models for performance, social and ethical issues, 2) Software engineers who developed parts of the T2I demo, and 3) Managers who coordinated the release of T2I demos.

Interview protocol: The interview protocol, as illustrated in the Supplemental Material, was designed to understand the process of development and evaluation the participant used when working on T2I models and outlined the interaction between different stakeholders on a given T2I model project. All interviews were 60 minutes in length.

3.2 Conducting FMEA and STPA

FMEA and STPA could be applied to various scopes of analysis that require a different set of information. Scoping an ML system for such an analysis is a non-trivial task. An ML system can be divided into its component parts (e.g., training data, model, user interface), development process (e.g., training, testing, early deployment), stakeholders involved (e.g. ,ML developers, a community of developers interfacing and building on the model APIs, end-users), and so on. Results of the analysis can be drastically different depending on the chosen scope of analysis [10, 42].

Based on the information gathered from the interviews with T2I experts and workshops with artists, we identified three scopes of analysis along the ML development pipeline:

- Scope 1: the data processing necessary for creating a training dataset
- Scope 2: how a T2I model is integrated into a production environment along with other ML models
- Scope 3: how an artist uses T2I model demo as part of their creative process

Selecting the scopes along the ML development pipeline allows for the examination of critical processes and interactions as discussed by previous scholarship [31, 67, 70]. We chose to focus on these scopes of analysis because we had access to the most amount of publicly available and shareable information about the elements involved. We recognize the value of other scopes such as how a model or a product is evaluated, or how the model architecture is designed, and encourage that scopes beyond what we have experimented with in this paper are considered for future applications of FMEA and STPA.

The STPA and FMEA analysis was led by the first author of this paper and three of the co-authors provided feedback on iterations of the analysis. A separate analysis was conducted for each one of the scopes. In total three FMEA and three STPA analyses were conducted. The lead author spent somewhere between 10 - 12 hours implementing the FMEA or the STPA process on one scope. All sources of data were used as input for both the STPA and FMEA analysis. The FMEA process resulted in a list of potential failure modes, and a Risk Priority Number score. The STPA analysis resulted in a list of unsafe control actions and corresponding safety requirements. We followed the original STPA and FMEA process for each one of the scopes (as described below) and did not alter them to specifically uncover social and ethical risks.

3.2.1 FMEA process. FMEA is a multi-step framework, through which steps are iteratively performed by FMEA and system experts over the development life cycle [10] (refer to Figure 1):

(1) List out the *functions* of a component/system OR steps of a process (e.g., everything the system/process needs to perform).
(2) Identify potential *failure modes*, or mechanisms by which each function or step can go wrong.
(3) Identify the *effect*, or impact of a failure, and score its *severity* on a scale of 1 – 10 (least to most severe).
(4) Identify the *cause*, or why the failure mode occurs, and score its *likelihood of occurrence* on a scale of 1 – 10 (least to most likely).
(5) Identify *controls*, or how a failure mode could be detected, and score *likelihood of detection* on a scale of 1 – 10 (most likely to least likely). The scales used in the automotive industry standards [32] (illustrated in the supplemental material) were used for scoring severity, the likelihood of occurrence, and the likelihood of detection.
(6) Calculate *Risk Priority Number* (RPN) by multiplying the three scores; a higher RPN indicates a higher risk level and develops *recommended actions* for each failure mode and prioritize based on RPN.

3.2.2 STPA process. STPA is a hazard analysis framework that is performed and led by system and safety experts, iteratively (across the model of a system) and cyclically (across a system's lifecycle) (refer to Figure 2).

(1) Define the *purpose of the analysis* by identifying losses via outlining stakeholders and their values. System-specific hazards and controls are highlighted based on the specified loss.
(2) Model the *control structure* of the full sociotechnical system using control feedback loops which consists of a controller

Figure 1: Steps for conducting an FMEA [10]

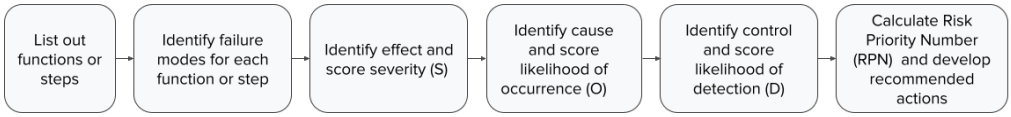

Figure 2: Steps for conducting an STPA [41]

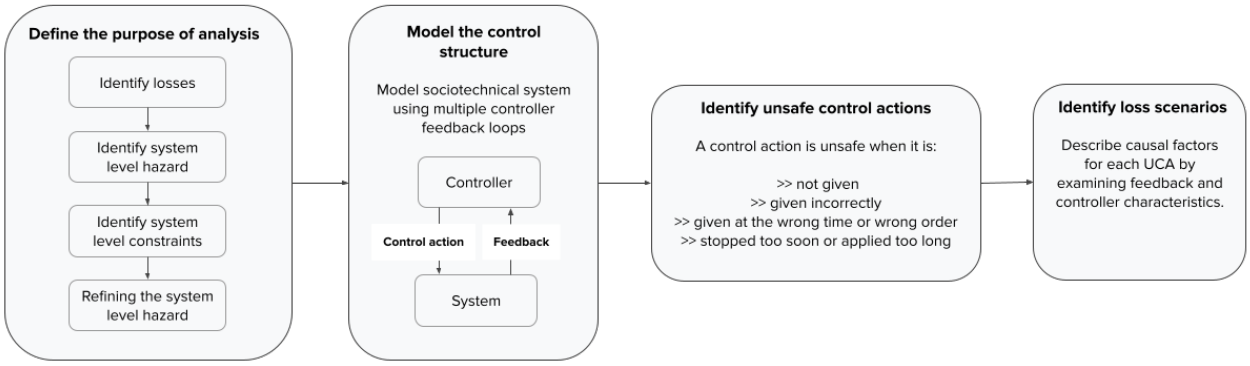


which sends *control actions* to a system that is being controlled while receiving *feedback* from the same system.

(3) Identify *unsafe control actions* (UCA) by going through each control action and thinking about unsafe modes of (no) action, incorrect action, and untimely action.
(4) Identify potential *loss scenarios* by outlining potential causal scenarios (i.e., missing feedback loops, incorrect process model or control algorithm of a controller) for each UCA.

3.3 Method of analysis

After conducting FMEA and STPA analyses for the three different scopes we examined two key elements for each scope: (1) Could any of the identified failures and hazards lead to social and ethical risks? (2) Did our analysis discover any new issues that have not been reported in the literature or media? We then reflected on common themes and lessons learned that appeared across all six applications.

3.4 Author reflexivity and limitations

All the authors of this paper are living and working in institutions in the Global North. We recognize our lived experiences and perspectives impact our choice to use safety engineering frameworks (i.e. safety is valued and practice differently across the world), methodology, and outcome of this analysis. Out of our authorship, four individuals have conducted FMEA and STPA in training programs or as practitioners in the industry. However, none of the authors are experts with 10+ years of experience in safety engineering. Furthermore, the STPA and FMEA we completed are based on reported information gathered in the interviews and workshops. They do not capture the direct opinion and knowledge of the stakeholders, as these experts are not participating fully in the workshops. Our proof-of-concept analysis could be improved with the presence of expert safety engineering practitioners and system (i.e., T2I) developers/evaluators. Finally, this paper focuses on one case study, which limits the generalizability of the findings across ML models.

4 KEY FINDINGS

Applying FMEA and STPA at three stages of the ML development pipelines enabled analysts to uncover a wide range of failures and hazards without the need for detailed information on the specific T2I model. In particular, the three scopes of analysis (training data processing, product integration, and end use) each allowed practitioners to look beyond a specific model in isolation and focus on *processes* and *interactions* as it is integrated with other actors and technical systems. In the next three sections, we reflect on the failures and hazards discovered at each stage. The analysis uncovered known failures and hazards (e.g., creation of non-consensual sexual imagery) and novel ones that have not been recognized to the best of our knowledge (e.g., the impact of English-word filters on lexical change). We also identified failures and hazards that could present social and ethical risks for different actors, which can inform prioritization of mitigation strategies. The analyses presented in this paper are proof-of-concept and illustrative examples of how safety frameworks could be applied at different stages of the ML development pipeline. They are not meant to be a comprehensive

failure and hazard analysis for the use of T2I models by artists. The identified failures and hazards would shift depending on the assumptions used to set up the analysis. Therefore, it is important to interpret our findings as an illustration of how FMEA and STPA could be applied by practitioners, rather than a final analysis. In what follows, we discuss the process of applying STPA and FMEA process at different scopes, the nature of our findings, highlighting a sample of the identified failures and hazards in Tables 1 - 6.

4.1 Scope one: data processing for creating training dataset

In our application, we bound the data processing stage to start from the identification of one or multiple source datasets and end with the creation of a training dataset ready for model development purposes. In this scope, we do not directly analyze the steps involved in how the data sources were obtained and who was involved in the data collection process. The focus is on how the data sources are processed for creating a training dataset. From our interviews, we identified three key stakeholders involved in data processing: (1) software engineers who prepare the dataset for training; (2) responsible ML practitioners who provide guidelines on what should or should not be included in the dataset; and (3) lawyers who consult on privacy and legal requirements for datasets. The software engineers collaborate closely with the practitioners responsible for developing the model. Lawyers provide legal requirements (i.e., intellectual property and privacy) for training datasets to the responsible ML and the product team. There is limited information available on how data processing is done for T2I models. For our proof-of-concept analysis, we use the data processing steps outlined in the publicly available data card for the Parti model [17]. The steps outlined in this data card are similar to what other T2I model creators have discussed in their publications [63, 68].

FMEA. The FMEA analysis, as illustrated in Table 1, starts with outlining the data processing steps [17], which include: (1) filter for records identified as containing sensitive data; (2) filter for non-English data; (3) filter for "adult" content in images; (4) filter for text associated with "adult" content; (5) exclude low text-image semantic alignment; and (6) exclude text consisting of mostly numbers. We identified 3 to 5 failure modes for each step, resulting in 22 failure modes for this scope of analysis. We identified six failure modes due to under-performance (i.e., some sensitive data is not captured), six failures modes due to over-performance (i.e., English data is filtered alongside non-English data), or six failure modes due to loss of performance (i.e., low text-image semantic alignment is included) of the filtering function. Four of the failure modes were due to unintended behavior of the filtering functions, such as when a non-English language filter does not recognize more modern English words. When taking a closer look at the nature of these failure modes, ten describe performance-related issues around image quality and text-to-image alignment. For example, over-filtering the source datasets is a known failure mode and could result in a lack of training data for creating a highly performative model. T2I developers have widely highlighted the importance of large training datasets in generating high-resolution images [63, 68, 84].

Twelve of the identified failure modes have clear social and ethical implications. For instance, under-filtering the source data or missing filters could lead to the downstream generation of sensitive data or adult content, which could lead to interpersonal harms (i.e., non-consensual sexual imagery and related mental health or reputational impacts) [73]. Some of the identified failures have been recognized in the literature or reported in the media. For instance, Birhane et al. discuss that many of the existing adult content filters are not able to fully detect and eliminate the target content [6].

Notably, our preliminary proof-of-concept, allowed us to pinpoint potential failure modes that are not discussed widely or publicly for applications of T2I. One example failure mode is that "the non-English word filter eliminates English words that are emerging/new or used in specific social groups." Elimination of novel words (neologisms) in training data influence what the T2I model can/cannot generate. As lexical change often does come from historically marginalized groups, this failure mode could ultimately alienate artists from specific cultural and social groups from using the T2I demo in their creative practice. By conducting this type of analysis on the process (and not the model itself), a practitioner can identify both known and novel failures (and their resulting harms)that can emerge from training data processing choices.

STPA. The STPA process starts by identifying losses. To identify the values and losses associated with this scope of analysis, we reflect on the information gathered from the interviews and workshops to understand stakeholders impacted by the data processing stage. Artists emphasized the values of fostering creativity, serving a diverse audience, accessibility of artistic mediums to a diverse group of artists, efficiency in their creative process, and preservation of the artist's reputation/identity. The developers and evaluators of T2I models emphasized the value of creating efficient systems that generate appropriate and quality images in response to a given text. They also emphasized the value of diversity (i.e. the importance of serving a diverse audience of users with their models) and the importance of protecting their team and their company's public reputation. From the key values brought up by artists, software engineers, and responsible ML practitioners, we formulated the following losses: (L1) Loss of creativity; (L2) Loss of diversity; (L3) Loss of accessibility; (L4) Loss of efficiency; (L5) Loss of quality; and (L6) Loss of reputation.

The next STPA step is to identify hazards by considering these losses in relation to the previously identified goal of training data processing. We developed three potential hazards:

- H1: System creates a training dataset that contains low-quality text-image pairs. (L1, L4, L5, L6)
- H2: System creates a training dataset that contains harmful content. (L3, L5, L6)
- H3: System creates a training dataset that is not diverse in representation. (L2, L3, L4, L6)

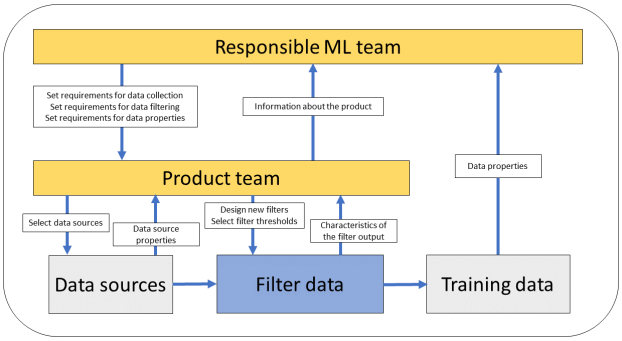
Then we model the control structure. A potential control structure configuration for the data processing stage, as illustrated in Figure 3, includes two organizational/human controllers and one automated controller. We selected the "responsible ML team" and "product team" as human controllers because they can make key decisions in the data processing scope. For this analysis, we assume the responsible ML team is in charge of determining the parameters for a good training dataset and identifying key ethical and legal considerations. The product team is responsible for developing the

Table 1: Sample proof-of-concept FMEA, data processing

Function	Type of failure mode	Failure mode	Effect	Cause	Control
Filter records identified as containing sensitive data	Loss	Sensitive data is not filtered and included in the training set.	Sensitive data might be reproduced by the model output.	No requirement to filter data for sensitive data.	Model development team checks the data was filtered for sensitive information prior to starting the training.
	Partial	Sensitive data is inadequately filtered and included in the training set.	Sensitive data is not filtered and it is included in the training set. Sensitive data might be reproduced by the model output.	Wrong filter thresholds are set.	Model development team monitors the outputs of the models for sensitive data generation.
	Exceeding	Non-sensitive data is also filtered.	Resulting training dataset is too small.	Wrong filter thresholds are set.	Model development team monitors how much data is filtered.

models that underpin the T2I demo artists will use. We selected as "filter data" an automated controller to reflect where all of the automated filtering operations take place. We identified 6 control actions, denoted in the boxes with down arrows in Figure 3.

Figure 3: Control structure diagram, data processing



For our analysis, we focused on 4 of the 6 control actions occurring between the three controllers and data sources including 1) Set requirements for data filtering, 2) Set requirements for dataset properties, 3) Design new filters and 4) Select filter thresholds. We chose to focus on these 4 control actions because they specifically focus on data processing as opposed to source data collection. We then brainstormed a list of 22 potential Unsafe Control Actions (UCAs) that relate to the three potential hazards we identified (partically illustrated in Table 2). H1 focuses primarily on the functional performance of the system; whereas, the presence of H2 and H3 pose social and ethical risks. All 22 Unsafe Control Actions (UCAs) were linked to at least one hazard. This indicates the STPA process is attentive to the interconnected nature of emerging hazards, and can help practitioners identify how social and ethical risks are not separate from but directly related to performance hazards.

Similar to the FMEA, we identified hazards related to improper filtering of data when examining the control action between the *product team* and *filter data* controllers, including over or under-filtration of the sensitive data. These UCAs could lead to all three hazard types (low-quality text-image pairs, harmful content, and homogenous representations). As discussed in the previous section, scholarly work has examined some of these UCAs in the context of T2I training dataset creation (e.g., under performance of adult content filters [6]). While the STPA process revealed some of the same novel insights as the FMEA (i.e. incorrectly filtering English words created over time), the STPA results include additional UCAs related to how the human controllers (i.e. responsible ML team and the product team) interact with each other. For instance, one identified UCAs is that "the responsible ML team provides the filtering requirements too late to the product team," preventing the product team from integrating the necessary filters. This is also one UCA presenting social and ethical risks that is also linked to all three of the hazards. These types of UCAs may not be widely acknowledged in current literature because they focus on examining internal company processes (i.e., delayed communication internally), which can be overlooked in analyses focused solely on the model. Moreover, issues with internal company processes and practices are generally considered confidential information and hence they are not shared in the literature. By identifying and addressing such UCAs, practitioners can embed responsible AI and safety considerations at an organizational level (i.e., beyond a single model or dataset).

Both the FMEA and STPA frameworks allow practitioners to get a list of potential and plausible ways in which current data processing practices could fail and lead to potential social and ethical risks. The UCAs and the failure modes focused on shortcomings with filter design. However, STPA also revealed shortcomings in how requirements are communicated between groups. By conducting such analysis, teams could keep track of how their data processing practices could fail and develop safeguards to ensure that training data is safely created for production-ready models.

4.2 Scope two: Model/product integration

Many AI ethics assessments and audits focus on one ML model [25, 76]. However, in production, multiple models often are used to achieve the intended functions for a given product or demo [83]. We conducted FMEA and STPA to examine the integration of a T2I model in a productionized demo, such as those released by Stability AI [2] and OpenAI [63]. From our interviews with T2I developers and existing literature [54, 64], we identified demos often include at least three types of models: (1) an input prompt classifier (which either block or filter the text prompt), (2) the T2I model, and (3) output image classifiers (which either block or filter the generated image). For any given T2I demo, there could be multiple classifiers employed for filtering text prompts and images. For the purposes of this illustrative analysis, we assume there are only two classifiers.

Table 2: Sample proof-of-concept STPA, data processing

Controller	Controlled process	Control action	Type	Context	H1	H2	H3
Responsible ML team	Product team	Set requirement for data filtering	Too late	Responsible ML team provides requirements too late in the process	True	True	True
Product team	Filter data	Design new filter for non-English data	Providing	The designed filter eliminate a large portion of data resulting in a small dataset	True	False	False

One for "adult" content run on the input text prompt and one for analyzing the generated image.

FMEA. We conducted a proof-of-concept system FMEA where we treat each of the three models as a sub-system, and perform the FMEA by first identifying the key function for each sub-system (see Table 3). Considering our assumptions, we have three sub-systems in our product, with the following primary functions: (F1) Filter input text prompt for adult content; (F2) Generate 16 images per prompt; (F3) Filter generated images for "adult" content.

We identified a non-exhaustive list of 14 potential failure modes for the three functions (3-5 failure modes for each function). These failure modes cover a range of issues, including functional failures, such as "no adult text prompt is filtered" or "it takes a long time to generate an image." The failure to generate images rapidly (i.e. latency) does not have obvious direct social or ethical risks; however, it affects company's reputation.

Similar to Scope 1, some identified failures for model/product integration present social and ethical risks. For instance, a complete loss of the filter function for the input or the output filters could harm potential users and pose social and ethical risks for the company and the artist, such as generating demeaning stereotypes. Many of the functional failures we identified had social and ethical implications as well, especially when considering the possibility that a given function might work well for some groups and poorly for others (i.e., quality-of-service harm). For example, partial filtering of the input prompts, and output images based on social norms of *group A* exclusively could lead to differential performance for those from *group B*. Similar risks emerge when the T2I demos only generate high-quality images for text prompts that represent terms, concepts, and ideas from a predominant social group (i.e., Western or Eurocentric cultures).

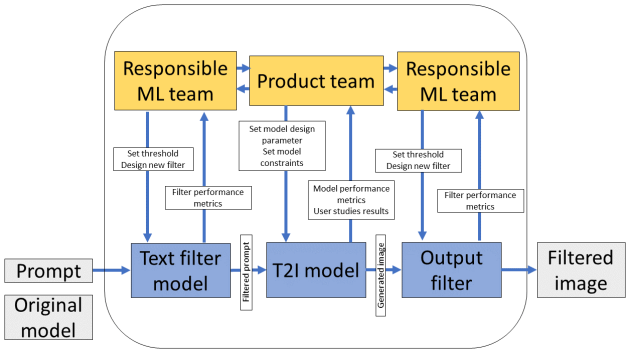
Many failures we discovered in our proof-of-concept analysis (with its limited focus) have been discussed in recent literature examining potential representational and quality-of-service harms from T2I models [4, 37, 75, 77, 78]. However, in our analysis, we strictly followed the FMEA process and did not rely on the literature to identify these potential failure modes. Notably, our analysis shows that practitioners can identify potential failure modes by systematically following the FMEA process and considering the specific constraints/features of their own ML-based products to identify potential failure modes as opposed to solely relying on what has already been discovered in the literature.

STPA. We start with the same set of losses outlined for the data processing scope as our key stakeholders for model integration. However, the hazards differ for this scope of analysis as the goal of the system has changed. Here the goal of the system is to create a T2I demo for public and creative use. Three potential hazards we considered are:

- H1: System creates an image that does not match the prompt. (L1, L3, L4, L5, L6)
- H2: System cannot generate an image. (L1, L2, L3, L4, L6)
- H3: System generates an unsafe image (i.e., with adult content). (L2, L3, L5, L6)

A potential configuration of the control structure (as illustrated in Figure 4) for this scope of analysis includes two organizational/human controllers and three automated controllers. The organizational/human controllers are the "responsible ML team" and the "product team." The automated controllers are the input text classifier, the T2I model, and the output image classifier. We identified 6 control actions, denoted in boxes with down arrows in Figure 4.

Figure 4: Control structure diagram, model integration



For the purpose of this analysis, we focus on the 6 control actions between the two human controllers and the three models, which are: (1) Set a threshold for pre-designed filters for text and image filtering (counted as two control actions); (2) Design new filters for text and image filtering (counted as two control actions); (3) Set model design parameters; and (4) Set model constraints for the version of the T2I model used in this product (i.e. the T2I demo). We developed a non-exhaustive list of 16 UCAs. Table 4 highlights 2 potential UCAs. The UCAs capture process issues, such as delays in the delivery of requirements or miscommunication between the product and development teams. They also capture technical issues, such as incorrect filter thresholds or T2I model parameters. The 16 identified UCAs were often linked to more than one hazard. For example, the UCA of "inappropriate filter threshold for the input text filter" could lead to H2 and H3.

All of the identified hazards could present a range of risks for stakeholders, including those posing social and ethical risk. For example, a system not being able to create an image for a subset of racially marginalized groups could present an *ethical* and *financial* risk for both the company and the artists trying to use the demo for their creative practice. As noted earlier, some of the identified UCAs are not well-discussed in the literature as they may emerge from internal organizational structures and configurations in their respective ML development pipelines. For example, a potential cause of an "incorrect model constraint" is a missing feedback

Table 3: Sample proof-of-concept FMEA, model integration

Function	Type of failure mode	Failure mode	Effect	Cause	Control
Filter text prompts	Degradation	Filter does not work for novel words	Model does not filter prompts containing inappropriate language.	Safety filters are not updated/improved over time.	Product team monitors user feedback to identify potential negative feedback on prompt filters and complaints about the model accepting new and inappropriate prompts.
	Partial	Filter works for English words written in Latin letters (e.g., it does not work when the Arabic language is written using Latin words)	Users enter harmful prompts using non-English phrases written with Latin letters	Filter allows text prompts containing non-English words	Product team monitors user feedback to identify potential negative feedback on how their prompts were filtered and complaints about the model accepting new and inappropriate prompts.
	Exceeding	Seemingly appropriate prompts are rejected for no good reason.	Users cannot enter what they would like to enter	Filters automatically eliminate word combinations that are not directly harmful but are in some form correlated to content that is marked as harmful.	Product team monitors user feedback

loop between the output image filter and the product team. Based on the existing control structure, the product team only works on fine-tuning the T2I model for the demo. They do not see the results from the classifiers designed by the responsible ML team. As illustrated, by examining the interactions between different models in an ML product and understanding how and who designs them, practitioners can identify and understand emerging hazards that would be ignored when focusing on one single model.

4.3 Scope three: Use of the ML-based product

This scope of analysis focuses on how an artist would use a T2I demo as part of their creative practice. The information we gathered from the artist workshops heavily informs this scope. To perform this illustrative FMEA/STPA analyses, we assume the artist is a filmmaker and they are creating a video for a client. The key stakeholders include the client, the filmmaker, and the public/viewer of the video. The scope focuses on how the filmmaker uses the T2I demo as a tool for generating images in their storyboard mock-up, where they visualize and share ideas with the client.

FMEA. To investigate the potential failures that could come from the use of T2I demos by artists, we first mapped a potential *process of use* based on the data collected in the workshops. All of the participants expressed that they use T2I demos as an image-generation tool within their artistic process to visualize ideas, communicate with collaborators and facilitate creative thinking. Generalized from the artists' descriptions in the workshop, a creative process for our assumed filmmaking scenario could involve the following steps:

(1) Brainstorm storyboard ideas for advertising the product
(2) Develop prompts that represent the storyboard ideas
(3) Enter prompts into the T2I demo to generate images
(4) T2I demo generates image(s) based on given prompt
(5) Select images for the storyboards
(6) Share storyboards with clients/collaborators
(7) Integrate feedback and iterate to get a desired storyboard

Treating this workflow as our process of use, we conducted a proof-of-concept FMEA. To simplify the FMEA application, we narrowed the scope of analysis to steps 3 through 5, and identified a non-exhaustive list of 11 potential failure modes. The 11 failure modes encompassed potential ways in which artists cannot use the T2I demo in their workflow. For example, "the artist cannot enter prompts in their native language," "they can only use a limited set of words in the input prompt," or the "generated images did not match their expectations/needs." We also discovered technical failures of the T2I demo, such as "the generation of low-quality images" or "the generation of unsafe images (as identified in generated image placeholders)." Many of the failure modes we identified uncovered challenges of an artist with using T2I demo in the generation practice (i.e., low-quality image generation, not being able to generate an image or enter a prompt). These types of failure modes could mainly lead to performance-related risks. Similar to Scope 2 and 3, these performance-related risks could present social and ethical risks for some user groups who exclusively experience the effect of the failure (i.e., an artist cannot generate images related to the cultural concepts). Moreover, we identified a few failures that could present social and ethical risks directly, including when the T2I demo generates a harmful image or when an artist selects images that could be harmful to a specific audience. This could be a failure depending on the intent of the artist, as some art is meant to be politically provocative and hence has the potential to harm. The failure modes on performance issues of T2I demos and their ability to generate harmful content have been reported in literature and media [63, 84]. However, failure modes regarding quality-of-service harms (i.e., not being able to generate an image for cultural concepts) have not been discussed to our knowledge.

STPA. Starting from the same set of losses identified for the data processing scope, we identified three potential hazards for our identified system in the use scope. The goal of our system is to support an artist in creating a video for a client using a T2I demo.

- H1: The artist cannot create a video. (L1, L3, L6)
- H2: The artist cannot create a video that meets client requirements. (L1, L3, L5, L6)
- H3: The video disseminates false and harmful information. (L2, L3, L5, L6)

Table 4: Sample proof-of-concept STPA, model integration

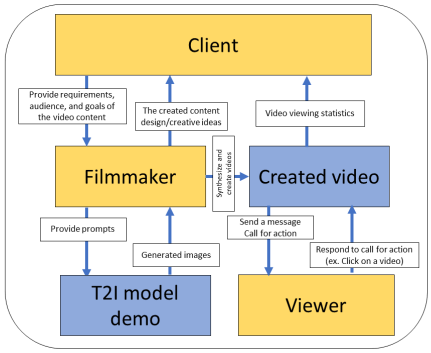
Controller	Controlled process	Control action	Type	Context	H1	H2	H3
Responsible ML team	Input filter	Design new filters for the prompt filter	Too late	New filters are not designed in time for product deployment	False	False	True
Responsible ML team	Input filter	Design new filters for the prompt filter	Providing	New filters block most of the prompts that users would want	False	True	False

Table 5: Sample proof-of-concept FMEA, demo use

Function	Type of failure mode	Failure mode	Effect	Cause	Control
Artist selects an image	Loss	Artist cannot select an appropriate image from the generated set of images	Dissatisfied with generated images	Image quality is poor, the images do not match the prompt, the images are not inspirational	User testing/reporting
	Partial	Artist can only find a few appropriate pictures	Dissatisfied with generated images	Image quality is poor, the images do not match the prompt, the images are not inspirational	User testing/reporting
	Unintended	Artist selects images that could potentially be harmful for a given audience	Dissatisfied with generated images	Safety filters did not work as desired, challenges in the training process	User testing/reporting

A potential configuration of the control structure (illustrated in Figure 5 includes three human controllers (i.e., the client, filmmaker, and the viewer) and two automated controllers (i.e., the T2I model demo and the created video). For the purpose of this analysis, we focus on the 3 control actions between the 3 human controllers and the T2I model demo (denoted in boxes with down arrows in Figure 5): (1) Provide requirements/goals/audience for the video content; (2) provide prompts; (3) send a message. We then identified a non-exhaustive list of 9 UCAs. Table 6 illustrates 2 of these UCAs. The UCAs included miscommunication regarding the video content's requirements, audience, and goals, incorrect prompt design, and inappropriate/misinformed calls to action for the public/viewer.

Figure 5: The control structure diagram, demo use



Similar to prior scopes, many of the UCAs lead to multiple hazards. From the three hazards we are considering, H1 and H2 primarily present performance-related risks; H3 presents social and ethical risks. Some of the UCAs we identified have been discussed in recent publications (e.g., how certain text prompts do not generate well-aligned images using these T2I models [14, 80] and how T2I demos could create misinformation [1]). However, few UCAs identified in this proof-of-concept analysis have not been directly discussed in the literature. For example, the UCA about how these T2I models work well for artists from specific socioeconomic conditions is not well-discussed in the literature. Moreover, the UCAs about the roles/ expectations of the client in the artists' practice and use of T2I demos is not discussed in the literature to our knowledge.

5 DISCUSSION

Safety engineering frameworks were originally designed for safety-critical systems where a failure/hazard could lead to significant injury or damage to a person, property, or environment (i.e., nuclear power plants, medical devices, airplanes) [16]. The types of harms (i.e., sociotechnical harms) [73] and technical systems (i.e., complex ML models) in the current conversation of responsible ML development are different from those typically considered in safety engineering. However, the practices and processes of safety engineering could bring a much-desired mature and systematic perspective to responsible ML development [20, 46, 67]. Through a case study of the development and use of T2I demos, we explored application of two safety engineering frameworks along the ML development pipeline and examined if we could discover failures and hazards that could lead to social and ethical risks.

5.1 Safety engineering perspective: The value of analyzing processes and interactions

Our findings illustrate a potential approach for applying failure and hazard analysis tools from safety engineering to examine different scopes along the ML development pipeline. In total, we were able to identify 50+ potential hazards and failures across the three scopes of analysis without having any details or assumptions about the type of model used in the T2I demo. The identified failures and hazards covered many different issues and topics corresponding to the three stages of the ML development pipeline. Moreover, we were able to identify hazards and failures that could present *social* and *ethical risks* without making any changes to the original safety engineering framework. This signals the potential usefulness of safety engineering for responsible ML development practices.

Responsible AI assessments have often focused on assessing the behavior of a single model with respect to AI ethics principles, such as fairness and transparency [76, 78]. Recently, there has been movement towards understanding processes and interactions involved with the development and deployment of ML systems in the Human-Computer Interaction and Science and Technology Studies communities where scholars have investigated harms emergent from human-AI interaction [7, 79]. Similarly, Responsible AI scholars have examined data collection processes and pointed out clear areas for improvement [18, 31, 70]. The hazards and failures found from applying FMEA and STPA to interactions and processes along the ML development pipeline, reiterate findings from this related work and supports the potential value of translating safety engineering practices for responsible ML development. Moreover, compared to current responsible AI assessments such as algorithmic impact assessments and third party ML auditing, the aforementioned safety engineering frameworks support a proactive approach to systematically analyze a system's failures and hazards at a pragmatic level and early on in the development process.

Table 6: Sample proof-of-concept STPA, demo use

Controller	Controlled process	Control action	Type	Context	H1	H2	H3	H4
Client	Filmmaker	Provide requirements, audience and goals	Too late	Client provides the requirement later than expected.	True	True	False	True
Filmmaker	T2I demo	Provide prompts	Not providing	Film maker cannot provide prompts because their choice of prompts is blocked	True	True	True	False

The FMEA process was especially comprehensive in analyzing *processes*. The FMEA analysis facilitates the discovery of failure modes by observing and examining each of the steps in detail and focusing the analysts on being introspective about their current practices and seeing how they could be improved [10, 59, 66]. The STPA process pushes analysts to understand *interactions* between different parts of a system, and how they could break down [41]. This can bring much value to analyzing ML systems as it is common for aspects of the ML pipeline to be siloed, in which people working on different components of the system have limited interaction and may not observe issues that could arise when a piece of information/data/design is passed on from one group to another. Bringing the safety engineering mindset to responsible AI practices would allow practitioners to look "beyond the model" and into processes and interactions. This shift in focus can help identify potential failures and hazards even when analysts do not fully understand the model's capabilities. In this case, we found that applying the same frameworks at three different stages of the ML development pipeline created dialogue between siloed teams across the full product life cycle that would likely result in the deployment of a safer system. This facilitates a more systematic approach for responsible ML by building on 100 years of designing safe systems.

5.2 Fostering safety culture in responsible ML

In safety engineering practice, dedicated individuals are responsible for conducting failure and hazard analysis [16]. These experts could also be made responsible for technology development [10, 16]. Recognizing the organizational challenges of implementing responsible ML practices, the movement towards safety engineering practices and frameworks must be accompanied by shifts in organizational structure, incentives and towards increased internal capacity for conducting this type of analysis [49, 62, 67]. Integrating safety engineering frameworks into a company's workflow could take a long time, and it requires commitment/buy-in from leadership. It is important to establish when and who should be responsible for various roles such that appropriate incentive and compensation structures are put into place.

FMEA-like processes could be done by system experts who have a good understanding of a specific product or process. For example, the group in charge of data processing for training data could conduct an FMEA analysis analogous to the one in our case study, and they would have the necessary information to conduct such an analysis. Whereas STPA analysis could be effectively performed by practitioners who have a system-level perspective of the varying range of key ML models and stakeholders involved so that they can map out an appropriate control structure. Both FMEA and STPA-like analysis could be done earlier in the ML development process as long as there is a basic understanding of the system/process design. It would be beneficial to start STPA processes earlier than FMEA since making changes to the system dynamics are often harder than modifying components/steps themselves. Both of these documents need to be updated as significant system changes are implemented or when there are new findings from a growing body of research on ML systems and unexpected failures or near misses.

5.3 Limitations and opportunities for applying FMEA and STPA for ML products

One of the key limitations of our analysis is that we have not considered all the possible scopes (i.e. T2I model architecture). Considering how generative T2I models are structured and set up it is challenging to break down the model architecture into specific components or model them as a control structure. This is an active line of research that we are investigating and invite the community to consider as a potential avenue for assessing ML models. Secondly, the FMEA and STPA analysis depend heavily on how an analyst sets up the scope of analysis and maps the system/process. If the system is not mapped out adequately and there are false assumptions made, then the analysis will not be comprehensive or accurate. We validated our findings by comparing them to the current conversation in the literature. However, a comprehensive validation of this type of analysis is hard because we are trying to predict potential failures/UCAs that have not occurred and therefore, these types of analysis are meant to be iterative documents/processes. To show the validity of this type of analysis, we call on the FATE community to assess the use and applicability of such frameworks and critique the quality of these assessments so that we can ultimately build best practices around the application of such analysis frameworks. Another key limitation of this analysis is the analysts' positionality (i.e., lived experiences), biases (i.e., professional expertise), and incentives (i.e., a company culture that promotes fast launches) which could impact quality, coverage, and the time they spent doing the analysis and quality and coverage. This type of analysis will only be meaningful in a company and technology regulatory ecosystem that emphasizes responsible ML and due diligence practices.

6 CONCLUSION

Recognizing the rapid pace of movement towards incorporating generative T2I models in product development in creative practices, we examined the insights safety engineering frameworks, such as STPA and FMEA, could provide for responsible development and integration of such models within the creative practice. Our analysis underscored some of the existing concerns identified in the literature and highlighted potential novel areas of concern that could be further examined. Our case study highlights the value safety engineering analysis frameworks could provide for responsible ML development and highlighted the value of looking beyond a single model and considering processes and interactions.

ACKNOWLEDGMENTS

We thank Freya Salway, who helped us organize the workshops, initiated the connections and invited the artists. We are grateful to our

interview and workshop participants for taking the time to share their experiences, expertise, and feedback. We thank Remi Denton, Kathy Meier-Hellstern, Mohammad Havaei, and Tim Falzone for sharing their expertise with us. We also thank our anonymous reviewers for their feedback on this paper. Finally, this work was financially supported by the Natural Sciences and Engineering Research Council of Canada and lead author's part-time internship at Google Research.

ABSTRACT

Building systems that are good for society in the face of complex societal effects requires a dynamic approach. Recent approaches to machine learning (ML) documentation have demonstrated the promise of discursive frameworks for deliberation about these complexities. However, these developments have been grounded in a static ML paradigm, leaving the role of feedback and post-deployment performance unexamined. Meanwhile, recent work in reinforcement learning has shown that the effects of feedback and optimization objectives on system behavior can be wide-ranging and unpredictable. In this paper we sketch a framework for documenting deployed and iteratively updated learning systems, which we call *Reward Reports*. Taking inspiration from technical concepts in reinforcement learning, we outline Reward Reports as living documents that track updates to design choices and assumptions behind what a particular automated system is optimizing for. They are intended to track dynamic phenomena arising from system deployment, rather than merely static properties of models or data. After presenting the elements of a Reward Report, we discuss a concrete example: Meta's BlenderBot 3 chatbot. Several others for game-playing (DeepMind's MuZero), content recommendation (MovieLens), and traffic control (Project Flow) are included in the appendix.

CCS CONCEPTS

• **Theory of computation** → **Sequential decision making**; • **General and reference** → **Evaluation**; • **Software and its engineering** → **Documentation**; • **Human-centered computing** → *Walkthrough evaluations*; • **Social and professional topics** → *Socio-technical systems.*

KEYWORDS

Reward function, reporting, documentation, disaggregated evaluation, ethical considerations

1 INTRODUCTION

Algorithmic systems often impact society in profound and difficult to anticipate ways. To assess risk, a system designer must take into account not only immediate impacts on stakeholders, but also third party externalities and the feedback loops they may engender. As AI matures and is deployed in new ways, emerging capabilities challenge what designers and other stakeholders assume algorithmic systems can do, making a priori risk assessment of these "agents" even harder [15].

The recent rise of dialogue agents powered by Large Language Models (LLMs) is a good example. These agents are trained on inconceivably large data corpora, deriving extremely sophisticated linguistic representations. More importantly, their conversations with users have effects that last beyond one-off interactions. Particular responses cannot be meaningfully isolated from prolonged exchanges; users may be influenced long afterward. Beyond the biases present in individual outputs, both the dialogue agents themselves and derived data artifacts (e.g. user chat histories) may be integrated into search architectures or other online services that qualitatively alter users' relationship with the web. As a result, diagnostics or audits of LLMs alone are an insufficient guide for design interventions. To manage feedback-heavy systems responsibly, the repercussions of algorithmic changes must be reflexively documented. In other words, both emergent system behaviors and the changing assumptions of key stakeholders about them must be accounted for in an ongoing and responsive manner.

We propose a new form of documentation, *Reward Reports*, to move the research community towards a world where these changes are regularly tracked, reflected upon, and responded to. For designers, this documentation would aid internal efforts at reverse

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08…$15.00

engineering the behavior of black box systems, and provide a framework to disentangle complex effects as they manifest. Moreover, a standard mechanism for continuous transparency would help harmonize external efforts at domain monitoring and inform regulatory action. To this end, we are building Reward Reports for popular machine learning systems via community contributions[1].

Multiple frameworks for documenting AI systems, datasets and models already exist [25, 42, 51]. However, these approaches all aim to track sources of potential bias or harm within a static machine learning (ML) paradigm. One might imagine that issuing successive Model Cards would be sufficient to monitor the behavior of deployed systems. However, system architectures display several key features that would make such a regime insufficient as a basis for accountability. First, the effects of deployed AI systems are not static, and the dynamic impacts of successive system updates can subvert efforts both to manage downstream harms and to more evenly distribute benefits to vulnerable subpopulations. Reflecting on these changes explicitly should be a part of deploying AI responsibly. Second, Model Cards do not document the design decisions leading to this particular ML system–why specific learning algorithms were chosen, how the designers expect the system to operate, and what evidence would change these expectations. Checking assumptions is a cardinal part of promoting accountability. Third, learned task representations often lie behind external interfaces (such as static APIs), access to which is decoupled from how trained models may change over time. Bridging this gap is crucial in order to understand AI systems in context. These features transcend existing documentation regimes. The presence of diverse feedback profiles and ongoing dynamics suggests unique risk vectors that must be made interpretable through documentation. Full accountability requires a cohesive understanding of how the system incorporates different types of feedback: from historical data, from stakeholders, and from a system's own usage once deployed. Reward Reports are designed to foreground these elements, allowing better insight into the societal impacts of data-driven optimization systems where feedback effects play a key role.

As a framing device, Reward Reports utilize reinforcement learning (RL), a sub-field of ML that is tasked with solving sequential, open-ended problems. RL provides a dynamical lens that is broadly applicable to many algorithmic systems with repeated data-driven optimizations. Critically, this lens is also applicable to 'static' ML systems. In many of these systems, new behaviors emerge post-deployment in response to ongoing usage, and as the system is retrained or applied to new populations. Building on proposals to document datasets and models, we focus on reward functions: the objective that guides optimization decisions in feedback-laden systems. Reward Reports comprise questions that highlight the promised benefits and potential risks entailed in defining what is being optimized in an algorithmic system, whether explicitly or implicitly construed as RL. They are intended as living documents that dissolve the distinction between *ex-ante* specification and *ex-post* evaluation. As a result, Reward Reports provide a framework for ongoing deliberation and accountability after a system is deployed, ensuring that desired properties persist in the system's behavior over time.

In Section 2, we situate Reward Reports within the existing literature on AI documentation and governance mechanisms. In Section 3, we review optimization in the context of feedback, focusing on the notions of action, objective, and adaptation. In Section 4, we contextualize these elements of optimization within a taxonomy of feedback. Finally, in Section 6, we present an example Reward Report for the BlenderBot 3 "AI chatbot" developed and deployed by Meta. Throughout, we maintain a running example of a dialogue agent to illustrate the challenges in documenting feedback-laden and data-driven optimization systems, whether or not they explicitly utilize the RL framework.

2 RELATED WORK

2.1 Documentation for AI Systems

There are several existing proposals for AI system documentation, with some frameworks focused on specific aspects of an AI system, while others examine the system as a whole. Reward Reports are focused on documenting risks of dynamic machine learning systems. This complements current documentation efforts by explicating intended performance in light of feedback effects that may emerge over time due to re-training or shifts in usage.

Data documentation. Documenting data, regardless of resulting systems, is a well explored avenue [4, 8, 20, 25, 30]. These efforts have helped foster discussion on responsible data collection, as well as showcase issues of bias and representation. However, this paradigm is most impactful within the batch or offline setting of static unsupervised or supervised ML. Dynamic systems driven by sequential feedback also use data, but not only in the form of static datasets. Rather, both RL and deployed ML systems generate and eventually transform data. This is due both to the optimization decisions of the systems themselves and the dynamics of the environment in which they operate. Documenting original data alone cannot reveal the risks of dynamic datasets and feedback driven systems.

Static system documentation. Some proposals for ML documentation are specific to model [42], domain [36, 47], or outcome [61]. Reward Reports might be a useful supplement to these approaches for several reasons. With regards to Model Cards, there is substantial deliberation entailed in mapping between the chosen optimization and resultant behavior in dynamic systems. For example, designers must consider a range of alternative specifications that were technically feasible pre-deployment, as well as the types of feedback available to help optimize post-deployment. These aspects of system design cannot be captured solely by documenting the model. Furthermore, unlike domain-specific reporting frameworks, we provide a general template that can be applied to any specific application. Our work has similarities with previous proposals for AI Ethics Sheets [43], Fact Sheets [6, 51], or Scorecards [12], but uniquely focuses on prompting deliberation about the feedback-driven risks inherent to dynamic systems.

Auditing and Assessment approaches. Algorithmic Impact Assessments (AIA) offer a framework for evaluating risks before an

[1]Reward Reports are produced and maintained here: https://github.com/RewardReports/reward-reports.

AI system is developed or acquired [50, 55]. AIAs were inspired by environmental impact assessments, which provided one path to regulate industries in which corporate expertise outpaced government capacity. These frameworks presume an agency-vendor relationship, and focus narrowly on the procurement of automated decision systems. Meanwhile, many audit mechanisms attempt to confirm either internally or externally whether a given system conforms to a legacy standard or regulation [46]. Reward Reports are intended to supersede these *ex-ante* concerns, engaging instead with the necessarily non-linear and circuitous process of refining the specifications of a feedback system.

2.2 Societal Risks of Dynamic Machine Learning Systems

The AI ethics community is increasingly acknowledging the important role of feedback and dynamic effects on system behaviours. While critical and discursive interpretations of feedback are more common in static ML than RL research [3, 40, 48], the technical RL community is also increasingly aware of the limitations of current algorithmic approaches and evaluation paradigms. For instance, the RL research community has begun to reflect on the unique risks and challenges that may be posed by RL systems, in particular those that leverage black-box neural networks for decision-making. There are whitepapers charting these challenges [26, 63], as well as attempts to address societal risks through technical means [14, 22, 62, 67]. RL from human feedback (RLHF) has recently served both as a technique in the process of training LLMs and also as a metaphor for value alignment [7]. Recent general audience books have echoed these tensions [16, 52]. While these efforts have begun to capture the unique stakes in deploying RL systems, there is no consensus on how to chart associated risks. We intend Reward Reports to organize these efforts' reflections into an instrument of deliberation and accountability.

2.3 AI Governance

ML documentation can be used as a governance mechanism to dictate safer machine learning practices. As reflected in the growing number of proposed AI governance frameworks [18, 24, 38, 49, 64, 66], ML and adjacent communities have increasingly acknowledged socio-technical risks and the need for novel harm mitigation strategies [5, 19, 56]. These frameworks have begun to influence legislation. For example, the Canadian government has mandated the Algorithmic Risk Assessment tool for procurement [13], and current draft legislation from the EU commission calls for AI system documentation tailored to forms of risk (*e.g.* in Title 3, Ch. 2, Art. 10-14) [1]. While these frameworks provide needed prohibitions and protections, they favor interpretive flexibility over specific design decisions, and often assume static AI systems that need strictly *ex-post* documentation. In contrast, Reward Reports would track requisite design decisions, and provide an interface for stakeholders to reflect on the validity of those design choices over time. This would in essence dissolve the boundary between *ex-ante* and *ex-post* assessment.

3 BACKGROUND

In this section, we reframe the concept of data-driven optimization in terms of dynamical systems. The type of optimization we describe encompasses the training of large language models, as well as their effects on the world once deployed. We begin by reinterpreting these dynamics in terms of action, objective, and adaptation. This taxonomy emphasizes the *use* and *behavior* of learned models rather than the closed act of developing them. We then review the RL framework, and recount its broader connections to optimization and machine learning.

3.1 Action, Objective, Adaptation

Learned predictive models are the means to some end. It is the decisions made, or *actions* taken, that determine the extent to which a model is successful. For example, congested suburban roadways in the community of Los Gatos, CA, USA are caused directly by the actions of drivers, and indirectly by the actions of routing algorithms that predict a poorly-scaling shortcut path [45]. Similarly, the optimization of datacenter operations at Google uses the predictions of trained models to adjust set points and load distribution–the predictions serve as a catalyst for action in the real world [23].

Action occurs not only on the basis of predictions, but also towards some *objective*. The definition of objective is crucial to the resulting behavior. Identical traffic models will result in different routing suggestions depending on whether the algorithm is optimizing for arrival time or fuel consumption [44]. Likewise, content interaction models have vastly different impacts when they are used to uprank posts predicted to receive many 'likes' compared with those predicted to receive long comments [28].

Finally, these optimization systems are often updated based on additional data collected during their operation, making them *adaptive*. By accounting for the dependence between past decisions, observed data, and current models, systems in effect react to dynamic environments and improve performance over time. For example, when observed music listening patterns are used as additional data in preference models, music recommendation algorithms can adapt to an individual's evolving tastes [21]. On the other hand, adaptivity can also exacerbate biased data. For example, predictive policing systems can amplify racial biases in arrests by directing more patrols towards areas with more documented arrests [41, 53].

Large Language Models through the RL Lens

We can draw a direct analogy between the MDP setting and the evaluation of language models. While language models are not Markovian in an exact sense, the notion of "state" can be applied to the *conversation text* at stake in a particular user interaction. The "observations" of the language model would consist of the *subset of the historic conversation text* that fits within the context window (the "time horizon") of the language model. Likewise, the "actions" taken by a dialogue agent consist of the *token sequences that are generated* to form responses to user queries. The "dynamics" of this system correspond to the *user responses* to dialogue agent generations - updating the conversation state by moving the sequence of conversation forward. Finally, the *performance metrics* (e.g. loss and/or regularization function(s), user 'thumbs up'/'thumbs down' feedback) that shape the behaviour of

the language model during pre-training, fine-tuning, and subsequent updates, can be considered as a source of scalar "reward" feedback that depends on the specific conversation state at a given point in time. This lens is central to the recent surge in the use of reinforcement learning from human feedback (RLHF) [17] to further fine-tune language models with respect to human values.

Action, objective, and adaptation are important for ensuring that systems work as intended, even in cases where they are not explicitly defined as part of an underlying model. This is especially true for large language models, which act by responding to natural language queries according a variety of engineered objectives: accurate prediction of the next token in a dialogue sequence, but also disparate constraints such as safety, helpfulness, etc. Moreover, they already function as parts of a larger adaptive system, as retrained models (GPT-3, GPT-3.5, GPT-4) have been designed and evaluated differently based on their successive integration with the ChatGPT interface. At present, designers are missing a framework for capturing these properties as dynamic elements of techniques for model optimization and deployment.

3.2 Reinforcement Learning

The reinforcement learning (RL) framework succinctly encompasses action, objective, and adaptation. RL agents take actions, are motivated by a reward signal which encodes the objective, and adapt based on the feedback from interactions. While the goal of supervised learning (SL) procedures is to use data to generate a model that makes accurate predictions, the goal of RL algorithms is to interact with an environment to generate a policy that achieves high reward. However, once SL models are deployed towards some goal and updated with new data, the concerns highlighted by the RL framework become relevant. In this sense, ML deployments can be understood through the lens of RL. This is even more true of language models whose post-deployment social effects are readily understood within an RL framework–to say nothing of the explicit pre-deployment use of RL from Human Feedback (RLHF) to fine-tune these models.

In Reinforcement Learning, an *agent* executes *actions* $\vec{a}_t \in \mathcal{A}$ in an *environment*. In response, the agent receives a scalar *reward* $r_t \in \mathbb{R}$ and makes an *observation* $\vec{o}_t \in \mathcal{O}$ of the environment. Actions are made on the basis of these observations according to a *policy* $\pi : \mathcal{H} \to \Delta(\mathcal{A})$, where $\mathcal{H} = \mathcal{O} \times \cdots \times \mathcal{O}$ represents the history of observations and $\Delta(\mathcal{A})$ represents a probability distribution over the action space. The goal of a reinforcement learning agent is to find a policy that maximizes the expected cumulative reward over some time horizon H:

$$\mathbb{E}\left[\sum_{t=0}^{H} \gamma^t r_t \mid \pi\right]$$

where the discount factor $\gamma \in (0, 1]$ trades off between immediate and future potential rewards. As outlined above, this paradigm captures many problems of interest, from choosing advertisements that are most likely to result in a click [37, 39] to determining the best dosing schedule for a patient [59].

A key element of RL is how actions affect the future behavior of the environment. This dependence is often modeled as a Markov Decision Process (MDP) [9]. In the MDP setting, the *state* $\vec{s}_t$ describes the status of the environment. The key assumption, called memorylessness, is that the current state and action are sufficient for predicting the future state, *i.e.*

$$\mathbb{P}\{\vec{s}_{t+1} = \vec{s} \mid \vec{s}_0, \ldots \vec{s}_t, \vec{a}_0, \ldots \vec{a}_t\} = \mathbb{P}\{\vec{s}_{t+1} = \vec{s} \mid \vec{s}_t, \vec{a}_t\} \,.$$

The transition probability distribution mapping state-action pairs to subsequent states is referred to as the *system dynamics*. Furthermore, the scalar reward signal is defined to be determined by the state, so that $r_t = r(\vec{s}_t, \vec{a}_t)$ for some reward function $r : \mathcal{S} \times \mathcal{A} \to \mathbb{R}$, mapping from the current environment to a scalar representation of desirability. Under these assumptions, it is optimal to consider policies that depend only on the current state, $\pi : \mathcal{S} \to \Delta(\mathcal{A})$. Often, RL algorithms assume that the state is observed directly $\vec{o}_t = \vec{s}_t$ (or similarly, that it can be constructed in a straightforward manner *e.g.* though history truncation $\vec{s}_t = [\vec{o}_{t-h}, \ldots, \vec{o}_t]$), and the policy is typically parametric, with a parameter vector denoted θ.

The RL framing is general, so other machine learning paradigms can be viewed as special cases of it as long as key assumptions are named. For example, supervised learning can be viewed as the optimization of a classification or regression policy where the rewards are defined by accuracy and the time horizon is equal to one. While standard supervised learning frameworks do not consider how to update or retrain on the basis of interaction, there are intermediate points. Online learning situates supervised learning systems in a sequentially evolving environment [58], while the study of bandit problems reduces RL to the static regime where actions do not affect the environment [10]. The boxed example illustrates how an RL lens can be richly applied to language models as long as terms like *horizon* and *state* are aligned with salient metrics and performance criteria.

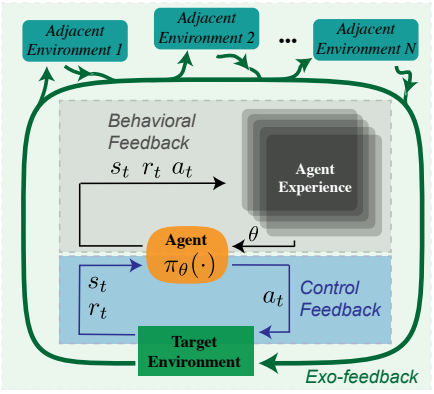
4 MOTIVATION

The RL lens is useful not only because ML deployments often operate in dynamical environments. It also expounds *feedback* between the environment and the deployment. In this section, we review three levels of feedback that characterize RL systems, and then motivate Reward Reports as documentation for tracking how and why feedback has been organized.

4.1 A Taxonomy of Feedback

We categorize feedback into three types: *control* feedback from state to action, *behavior* feedback from the data to the policy, and *exogenous* (or exo-)feedback from the target environment to adjacent entities [27]. The types of feedback are compared in Tab. 1 and visualized in Fig. 1. Throughout, we continue to illustrate these types of feedback through comparison to a deployed dialogue agent powered by a large language model.

Control feedback. Control feedback maps observations or states to actions. In the case of a dialogue agent, control feedback is the autoregressive language model itself–a conditional probability distribution from token sequences to subsequent tokens. "Intelligent" behaviors arise because actions are constantly adjusted on the basis



Type of feedback	Feedback Channel	Dynamics	Specification Element
Control	Agent-Environment	Reaction	Actions
Behavior	Policy-Reward	Evaluation	Rewards
Exogenous	Environment-Domain	Drift	States & Observations

Figure 1 & Table 1: The relationship between types of feedback, the channel through which information flows, the relationship to dynamics, and specification element(s). Different parameters and data interact over time to create dynamic properties internal and external to the RL agent.

of observations, even though the rules that control the behavior (the language model distribution) remains the same.

Behavior feedback. Behaviour feedback maps data from the environment to a learned policy. This form of feedback occurs when RL systems automatically adapt their policy based on reward, or when a deployed ML system is updated (e.g. with new weights) to better suit the deployment environment. Questions of reaction become questions of trial-and-error evaluation: "What token should follow the preceding tokens" evolves into "Can this dialogue agent be made safer/more useful/better aligned with user needs *etc.* through fine-tuning or better prompt engineering" (for example). The ability to learn from experience is part of what makes RL systems so powerful, and is what makes RL useful in domains that are difficult to otherwise model. For example, it would be challenging to hand-design a policy for generating natural language responses to user queries, but data-driven approaches have made this task tractable.

Exogenous feedback. Exogenous feedback occurs when the application domain itself shifts in response to the deployed system. These shifts could be due to the system interacting with political or economic conditions that are outside the scope of its formal specification. Note that the concept of exogenous feedback is richer than the concept of covariate or distribution shift commonly discussed in supervised learning [33]–exogenous feedback explicitly foregrounds what lies behind and instigates the shift, i.e. the interactions between the deployed system and the environment. Dialogue agents are particularly prone to this type of feedback, as their emerging effects on web search, content recommendation, and diverse writing disciplines already demonstrate. In principle, if such dynamics could be predicted by an RL agent, they could be incorporated within behavior or control feedback, but in practice, it is not clear that this is possible–the observations would need to be sufficiently rich and the planning horizon sufficiently long. For these reasons, exogenous feedback highlights the potential of externalized risks in the RL framework.

4.2 Risks and Documentation

For many systems, reward design–the choice of how and what to optimize–amounts to a political decision about how different types of feedback may rewire the domain and pose risks to various stakeholders. As it is often impossible to fold all of the domain dynamics within a controllable planning horizon and precise reward function, exo-feedback is fundamentally unavoidable in practice. Furthermore, it is unrealistic to articulate all possible system specifications *a priori*. This means that a single specification may simultaneously implicate all three forms of feedback (conrol, behavior, exogenous) outlined above.

The risks of feedback can at least be approached and evaluated through documentation. This calls for legible and periodic mechanisms for auditing RL systems pre- and post-deployment. It is these reviews that must decide whether or how the optimized behaviors align with the application domain, in correspondence with resultant risks and possible harms. This may be especially true for dialogue agents whose models may be technically static (insofar as parameters are not updated in real-time in response to user feedback), but whose dynamical effects on society are impossible to specify in advance. Given the dynamic nature of these effects, the corresponding document must be dynamic as well: updated and revisited over time to map the evolution of feedback between the system and the domain in which it is deployed.

5 REWARD REPORT COMPONENTS

Here we prescribe Reward Reports, a structured series of design inquiries for automated decision systems (Fig. 2). Including but not limited to the use of reinforcement learning, Reward Reports are intended to engage practitioners by revisiting design questions over time, drawing reference to previous reports and looking forward to future ones. As pivotal properties may not be known until the system has been deployed and monitored, the onus is on designers to sustain documentation over time. This makes Reward Reports into living documents that both avoid the limitations of simple, unidirectional answers (*e.g.* yes or no) and illuminate societal risks

over time. Moreover, the changelog component of a Reward Report becomes an interface for stakeholders, users, and engineers to continuously oversee and evaluate the documented system. Thus, Reward Reports are a prerequisite to sociotechnical reflection about the system behavior.

Appendix A includes an empty template for a Reward Report, including descriptions of the content for each component. In this section we present the six main components that compose a Reward Report. These components are arranged to help the reporter understand and document the system. A Reward Report begins with ***system details*** (1) that contain the information context for deploying the model. From there, the report documents the ***optimization intent*** (2) which questions the goals of the system and why RL or ML may be a useful tool. The designer then documents how it can affect different stakeholders in the ***institutional interface*** (3). The next two sections contain technical details on the system ***implementation*** (4) and ***evaluation*** (5). The report concludes with plans for ***system maintenance*** (6) as additional system dynamics are uncovered.

Reward Report Contents

- **System Details**: Basic system information.
  - System owner
  - Dates
  - Contact
- **Optimization Intent**: The goals of the system and how reinforcement manifests.
  - Goal of reinforcement
  - Performance metrics
  - Oversight metrics
  - Failure modes
- **Institutional Interface**: The interconnections of the automated system with society.
  - Deployment agency
  - Stakeholders
  - Explainability
  - Recourse
- **Implementation**: The low-level engineering details of the ML system.
  - Reward, algorithmic, and environment details
  - Measurement details
  - Data flow
  - Limitations
  - Engineering artifacts
- **Evaluation**: Specific audits on system performance.
  - Evaluation environment
  - Offline evaluations
  - Evaluation validity
  - Performance standards
- **System Maintenance**: Plans for long-term verification of behavior.
  - Reporting cadence
  - Update triggers
  - Changelog

Figure 2: Summary of reward report sections and suggested inquiries.

5.1 System Details

This section collects basic information a user or stakeholder may need in reference to the automated decision system.

(1) **Person or organization deploying the system**: This may be the designer deploying the system, a larger agency or body, or some combination of the two. The entity completing the report should also be indicated.
(2) **Reward date(s)**: The known or intended timespan over which this reward function & optimization is active.
(3) **Feedback & communication**: Contact information for the designer, team, or larger agency responsible for system deployment.
(4) **Other resources**: Where can users or stakeholders find more information about this system? Is this system based on one or more research papers?

5.2 Optimization Intent

This section addresses basic questions about the intent of the reward function and optimization problem. Designers first document the intent of a particular solution, translating the system's quantitative objective into a qualitative description. In later sections, they have the opportunity to further reflect on how implementation details aid in, or diminish the broader goal. Stakeholders and users can employ this section to understand if the intent of the system matches with the effects they observe or experience.

(1) **Goal of reinforcement**: A statement of system scope and purpose, including the planning horizon and justification of a data-driven approach to policy design (*e.g.* the use of reinforcement learning or repeated retraining). This justification should contrast with alternative approaches, like static models and hand-designed policies. What is there to gain with the chosen approach?
(2) **Defined performance metrics**: A list of "performance metrics" included explicitly in the reward signal, the criteria for why these metrics were chosen, and from where these criteria were drawn (*e.g.* government agencies, domain precedent, GitHub repositories, toy environments). Performance metrics that are used by the designer to tune the system, but not explicitly included in the reward signal, should also be reported here.
(3) **Oversight metrics**: Are there any additional metrics not included in the reward signal but relevant for vendor or system oversight (*e.g.* performance differences across demographic groups)? Why aren't they part of the reward signal, and why must they be monitored?
(4) **Known failure modes**: A description of any prior known instances of "reward hacking" or model misalignment in the domain at stake [34], and description of how the current system avoids this.

5.3 Institutional Interface

This section documents the intended (and in subsequent reports, observed) relationship between the system and the broader context in which it is deployed. While necessarily piecemeal, the explicit documentation of this interface will allow designers to reflect on and revisit the system assumptions over time. These reflections may bring novel interests or agencies into scope and allow for

organizing the emergent interests of stakeholders and users where necessary.

(1) **Deployment Agency**: What other agency or controlling entity roles, if any, are intended to oversee the ongoing post-deployment operation of the RL system? How may these roles change following system deployment?
(2) **Stakeholders**: What other interests are implicated in the design specification or system deployment, beyond the designer? What role will these interests play in subsequent report documentation? What other entities, if any, does the deployed system interface with whose interests are not intended to be in scope?
(3) **Explainability & Transparency**: Does the system offer explanations of its decisions or actions? What is the purpose of these explanations? To what extent is the policy transparent, i.e. can decisions or actions be understood in terms of meaningful intermediate quantities?
(4) **Recourse**: Can stakeholders or users contest the decisions or actions of the system? What processes, technical or otherwise, are in place to handle this?

5.4 Implementation

Given the sensitivity of reinforcement learning systems, it is important to document specific implementation details of the system. Even small changes in implementation can result in substantial behavior shifts downstream, making such factors difficult to track when used at scale. Documenting these design decisions will both help prevent failures in specific applications and assist technical progress.

(1) **Reward details**: How was the reward function engineered? *E.g.* is it based on a well-defined metric? Is it tuned to represent a specific behavior? Are multiple terms scaled to make one central loss, and how was the scaling decided?
(2) **Environment details**: Description of states, observations, and actions with reference to planning horizon and hypothesized dynamics/impacts. What dynamics are brought into the scope of the optimization via feedback? Which dynamics are left external to the system, as drift? Have there been any observed gaps between conceptualization and resultant dynamics?
(3) **Measurement details**: How are the components of the reward and observations measured? Are measurement techniques consistent across time and data sources? Under what conditions are measurements valid and correct? What biases might arise during the measurement process?
(4) **Algorithmic details**: The key points on the specific algorithm(s) used for learning and planning. This includes the form of the policy (e.g. neural network, optimization problem), the class of learning algorithm (e.g. model-based RL, off-policy RL, repeated retraining), the form of any intermediate model (e.g. of the value function, dynamics function, reward function), technical infrastructure, and any other considerations necessary for implementing the system. Is the algorithm publicly documented and is code publicly available? Have different algorithms been used or tried to accomplish the same goal?
(5) **Data flow**: How is data collected, stored, and used for (re)training? How frequently are various components of the system retrained, and why was this frequency chosen? Could the data exhibit sampling bias, and is this accounted for in the learning algorithm? Is data reweighted, filtered, or discarded? Have data sources changed over time?
(6) **Limitations**: Discussion and justification of modeling choices arising from computational, statistical, and measurement limitations. How might (or how have) improvements in computational power and data collection change(d) these considerations and impact(ed) system behavior?
(7) **Engineering tricks**: RL systems are known to be sensitive to implementation tricks that are key to performance. Are there any design elements that have a surprisingly strong impact on performance? E.g. state-action normalization, hard-coded curricula, model-initialization, loss bounds, or more?

5.5 Evaluation

Assessing the potential behavior of a feedback system is important for anticipating its future performance and risks that may arise. This section records evaluations done by the designer before deploying the system and each time the reward report is revisited. This section allows stakeholders and users to hold designers accountable for the performance of the system once deployed. It is important to distinguish whether the evaluations are done in a simulation (*offline*) or deployed on real users (*online*) and if the evaluation procedure is on a fixed dataset (*static*) or evolves over time (*dynamic*).

(1) **Evaluation environment**: How is the system evaluated (and if applicable, trained) prior to deployment (*e.g.* using simulation, static datasets, *etc.*)? Exhaustive details of the offline evaluation environment should be provided. For simulation, details should include description or external reference to the underlying model, ranges of parameters, etc. For evaluation on static datasets, considering referring to associated documentation (*e.g. Datasheets* [25]).
(2) **Offline evaluations**: Present and discuss the results of offline evaluation. For static evaluation, consider referring to associated documentation (*e.g. Model Cards* [42]). If applicable, compare the behaviors arising from counterfactual specifications (*e.g.* of states, observations, actions).
(3) **Evaluation validity**: To what extent is it reasonable to draw conclusions about the behavior of the deployed system based on the available offline evaluations?
How is the online performance of the system presently understood? If the system has been deployed, were any unexpected behaviors observed?
(4) **Performance standards**: What standards of performance and safety is the system required to meet? Where do these standards come from? How is the system verified to meet these standards?

5.6 System Maintenance

This section documents plans for post-deployment oversight, including subsequent reviews of real-world implementation and how the monitoring of resultant dynamics is intended to (or has) shed light on *ex-ante* assumptions. These plans include any additional grounds for updating the report in case of sustained shifts in observations or metrics (*e.g.* the effects of exogenous changes on system behaviors). As such, this section must draw sustained reference to previous Reward Reports, including subsequent changes to the

description, implementation, or evaluation, and what prompted these changes. While previous sections outline how the system learns from data, this section tracks how organizations learn to oversee the system. Its documentation is particularly important for defining *accountability* for the system itself, those who manage it, and those responsible for completing periodic reports.

(1) **Reporting cadence**: The intended timeframe for revisiting the Reward Report. How was this decision reached and motivated?
(2) **Update triggers**: Specific events (projected or historic) significant enough to warrant revisiting this report, beyond the cadence outlined above. Example triggers include a defined stakeholder group empowered to demand a system audit, or a specific metric (either of performance or oversight) that falls outside a defined threshold of critical safety.
(3) **Changelog**: Descriptions of updates and lessons learned from observing and maintaining the deployed system. This includes when the updates were made and what motivated them in light of previous reports. The changelog is the key difference between Reward Reports and other forms of machine learning documentation, as it successively reframes prior reports and reflects their intrinsically dynamic nature.

6 EXAMPLES

Our aim with these examples is to illustrate the breadth and scope of questions that a Reward Report could engage with, and to demonstrate how Reward Reports can apply to both explicit and implicit RL systems in various design contexts. Below, we focus on the Reward Report for the BlenderBot 3 chatbot deployed in August 2022 [2]. We refer the reader to the appendix for the complete Reward Reports for BlenderBot 3 and several other examples including game-playing (DeepMind's MuZero [54]), content recommendation (MovieLens [29]), and traffic control (Project Flow [65]).

6.1 BlenderBot 3: A Chatbot Designed to Improve Over Time Through Feedback

BlenderBot 3 is a recent chatbot "designed to improve its conversational skills and safety through feedback from people who chat with it, focusing on helpful feedback while avoiding learning from unhelpful or dangerous responses" [2]. To achieve this, the chatbot incorporates more than one type of feedback. First, it incorporates a significantly larger language model than its predecessors at 175 billion parameters, unlocking new conversational capabilities via a larger capacity policy–a level of *control feedback*. Second, it includes an interface for human users to provide real-time feedback on its conversational outputs if they are biased, inappropriate, or lack context–a kind of "reward signal" that uses behavior feedback for eventual model updates. Finally, its designers have articulated their high-level goal to release data about the chatbot's performance to the broader AI research community as a means to uncover new strategies for making future AI systems safer and more engaging to users–a kind of constructive form of exogenous feedback, beyond the technical specification scope.

In parallel with BlenderBot 3's deployment, the designers made both its language model (OPT-175B) and associated model cards public to the AI research community. We have corresponded and worked with the designers to synthesize and interpret these resources as a basis for a Reward Report for BlenderBot 3. This Reward Report includes the components outlined in Section 5, revealing potential interactions between different feedback types and associated questions pertaining to the system specification. These include:

- What metrics (e.g. conversation length, ratio of negative vs. positive feedback) are being used to evaluate performance?
- How often will the language model be retrained?
- What outputs, if any, would compel designers to take BlenderBot 3 offline?
- Which stakeholders are responsible for the system's deployment, have a say in its specification, or have a veto over its public operation?

As a result, the BlenderBot 3 Reward Report does not merely aggregate model cards. It reveals that the documentation of feedback types requires a qualitative appraisal of system components, both in relation to each other and to the wider social context in which the system is intended to operate. This project entails a commitment to update the documentation over time as unintended types of feedback emerge and performance metrics are gradually refined.

7 DISCUSSION & CONCLUSIONS

The scale and complexity of contemporary optimization pipelines raise unique concerns not addressed by static reports and recent calls for documentation (e.g. those focusing on models or datasets). ML deployments frequently consist of many moving parts and feedback channels that change over time, especially when the systems interact directly with multiple stakeholders like business customers and public users. Reward Reports address the challenges of documenting these systems, providing a framework for iterative deliberation as a system and its feedback channels evolve over time. We have also demonstrated that the technical problem space and language of RL is useful for interpreting problems of fairness and safety. Reward Reports will be of most use where a system is data-driven, and where actions have clear and automatic results. Moreover, such systems are likely to grow in popularity.

Optimization-based policies in domains like school bus scheduling [11] or prison allocation [57], for example, are often not data-driven. However, it is not hard to imagine a future where these optimizations incorporate quantities predicted by statistical models. If this approach expands across domains, a standard mechanism for anticipating and deliberating over dynamic harms could become a critical component of governance.

The pace of academic research also suggests that in the near future, implicit or explicit RL systems will be more effective, deployed in more impactful user-facing applications, and fine-tuned in 'real-time' rather than re-trained daily or weekly. The complexities of real-time training are compounded with the addition of human-in-the-loop data collection, such as in reinforcement learning from human feedback [32]. The resulting feedback loops will make the RL lens applicable to more and more social contexts, further motivating the need for Reward Reports.

Reward Reports could also be of use for human-in-the-loop ML deployments where actions do not have automatic impact. Clinical decision support systems can be data-driven, but the clinician ultimately determines how system recommendations are implemented.

In this case, the human computer interaction (HCI) component of such a system could distort the interface between recommendations and human judgment in ways that are not captured within a pure RL lens. For example, a doctor is more likely to defer to an incorrect recommendation by an algorithm when it is accompanied by a paragraph of reasoning than without [31]. However, the deliberation over system feedback made possible by Reward Reports could still elucidate unforeseen harms.

These examples all point to a deeper truth: designing systems to promote societal good is an increasingly dynamic problem, and it needs to be deliberated about as such. Reward Reports enact forms of documentation commensurate with the feedback-laden systems whose dynamics–not just models or data–are a critical object of concern.

A EMPTY REWARD REPORT TEMPLATE

1 System Details

1.1 System Owner

This may be the designer deploying the system, a larger agency or body, or some combination of the two. The entity completing the report should also be indicated.

1.2 Dates

The known or intended timespan over which this reward function & optimization is active.

1.3 Feedback & Communication

Contact information for the designer, team, or larger agency responsible for system deployment.

1.4 Other Resources

Where can users or stakeholders find more information about this system? Is this system based on one or more research papers?

2 Optimization Intent

2.1 Goal of Reinforcement

A statement of system scope and purpose, including the planning horizon and justification of a data-driven approach to policy design (e.g. the use of reinforcement learning or repeated retraining). This justification should contrast with alternative approaches, like static models and hand-designed policies. What is there to gain with the chosen approach?

2.2 Defined Performance Metrics

A list of "performance metrics" included explicitly in the reward signal, the criteria for why these metrics were chosen, and from where these criteria were drawn (e.g. government agencies, domain precedent, GitHub repositories, toy environments). Performance metrics that are used by the designer to tune the system, but not explicitly included in the reward signal should also be reported here.

2.3 Oversight Metrics

Are there any additional metrics not included in the reward signal but relevant for vendor or system oversight (e.g. performance differences across demographic groups)? Why aren't they part of the reward signal, and why must they be monitored?

2.4 Known Failure Modes

A description of any prior known instances of "reward hacking" or model misalignment in the domain at stake, and description of how the current system avoids this.

3 Institutional Interface

3.1 Deployment Agency

What other agency or controlling entity roles, if any, are intended to oversee the ongoing post-deployment operation of the RL system? How may these roles change following system deployment?

3.2 Stakeholders

What other interests are implicated in the design specification or system deployment, beyond the designer? What role will these interests play in subsequent report documentation? What other entities, if any, does the deployed system interface with whose interests are not intended to be in scope?

3.3 Explainability & Transparency

Does the system offer explanations of its decisions or actions? What is the purpose of these explanations? To what extent is the policy transparent, i.e. can decisions or actions be understood in terms of meaningful intermediate quantities?

3.4 Recourse

Can stakeholders or users contest the decisions or actions of the system? What processes, technical or otherwise, are in place to handle this?

4 Implementation

4.1 Reward Details

How was the reward function engineered? Is it based on a well-defined metric? Is it tuned to represent a specific behavior? Are multiple terms scaled to make one central loss, and how was the scaling decided?

4.2 Environment Details

Description of states, observations, and actions with reference to planning horizon and hypothesized dynamics/impact. What dynamics are brought into the scope of the optimization via feedback? Which dynamics are left external to the system, as drift? Have there been any observed gaps between conceptualization and resultant dynamics?

4.3 Measurement Details

How are the components of the reward and observations measured? Are measurement techniques consistent across time and data sources? Under what conditions are measurements valid and correct? What biases might arise during the measurement process?

4.4 Algorithmic Details

The key points on the specific algorithm(s) used for learning and planning. This includes the form of the policy (e.g. neural network, optimization problem), the class of learning algorithm (e.g. model-based RL, off-policy RL, repeated retraining), the form of any intermediate model (e.g. of the value function, dynamics function, reward function), technical infrastructure, and any other considerations necessary for implementing the system. Is the algorithm publicly documented and is code publicly available? Have different algorithms been used or tried to accomplish the same goal?

4.5 Data Flow

How is data collected, stored, and used for (re)training? How frequently are various components of the system retrained, and why was this frequency chosen? Could the data exhibit sampling bias, and is this accounted for in the learning algorithm? Is data reweighted, filtered, or discarded? Have data sources changed over time?

4.6 Limitations

Discussion and justification of modeling choices arising from computational, statistical, and measurement limitations. How might (or how have) improvements in computational power and data collection change(d) these considerations and impact(ed) system behavior?

4.7 Engineering Tricks

RL systems are known to be sensitive to implementation tricks that are key to performance. Are there any design elements that have a surprisingly strong impact on performance? For example, state-action normalization, hard-coded curricula, model-initialization, loss bounds, or more?

5 Evaluation

5.1 Evaluation Environment

How is the system evaluated (and if applicable, trained) prior to deployment (e.g. using simulation, static datasets, etc.)? Exhaustive details of the offline evaluation environment should be provided. For simulation, details should include description or external reference to the underlying model, ranges of parameters, etc. For evaluation on static datasets, considering referring to associated documentation (e.g. Datasheets *[1]).*

5.2 Offline Evaluations

Present and discuss the results of offline evaluation. For static evaluation, consider referring to associated documentation (e.g. Model Cards *[2]). If applicable, compare the behaviors arising from counterfactual specifications (e.g. of states, observations, actions).*

5.3 Evaluation Validity

To what extent is it reasonable to draw conclusions about the behavior of the deployed system based on presented offline evaluations? What is the current state of understanding of the online performance of the system? If the system has been deployed, were any unexpected behaviors observed?

5.4 Performance standards

What standards of performance and safety is the system required to meet? Where do these standards come from? How is the system verified to meet these standards?

6 System Maintenance

6.1 Reporting Cadence

The intended timeframe for revisiting the reward report. How was this decision reached and motivated?

6.2 Update Triggers

Specific events (projected or historic) significant enough to warrant revisiting this report, beyond the cadence outlined above. Example triggers include a defined stakeholder group empowered to demand a system audit, or a specific metric (either of performance or oversight) that falls outside a defined threshold of critical safety.

6.3 Changelog

Descriptions of updates and lessons learned from observing and maintaining the deployed system. This includes when the updates were made and what motivated them in light of previous reports. The changelog comprises the central difference between reward reports and other forms of machine learning documentation, as it directly reflects their intrinsically dynamic nature.

B EXAMPLE REWARD REPORT - BLENDERBOT

1 System Details

1.1 System Owner

This may be the designer deploying the system, a larger agency or body, or some combination of the two. The entity completing the report should also be indicated.

This system was developed by Meta AI, in partnership with ParlAI and Metaseq. According to the system's blog post, "This work was undertaken by a team that includes Kurt Shuster, Jing Xu, Mojtaba Komeili, Da Ju, Eric Michael Smith, Stephen Roller, Megan Ung, Moya Chen, Kushal Arora, Joshua Lane, Morteza Behrooz, William Ngan, Spencer Poff, Naman Goyal, Arthur Szlam, Y-Lan Boureau, Melanie Kambadur, and Jason Weston."

1.2 Dates

The known or intended timespan over which this reward function & optimization is active.

The model started training on June 15, 2022. The model generates responses from Internet search queries, meaning that messages can reflect information available on the Internet at any given point in time since the system inception, and posted any time prior to search query.

1.3 Feedback & Communication

Contact information for the designer, team, or larger agency responsible for system deployment.

Some feedback is built into the BlenderBot interface, including report messages and an upvote/downvote feature. **There doesn't seem to be a single point of contact or email for direct feedback.**

1.4 Other Resources

Where can users or stakeholders find more information about this system? Is this system based on one or more research papers?

More information about this system can be found in their paper [1], their online blog post, and their model card [1]. A logbook of results achieved, decisions made, and additional information is available on GitHub [2].

[1]Blog post `https://ai.facebook.com/blog/blenderbot-3-a-175b-parameter-publicly-available-chatbot-that-improves-its-skills-and-safety-over-time/`, model card `https://github.com/facebookresearch/ParlAI/blob/main/parlai/zoo/bb3/model_card.md`

[2]GitHub repository `https://github.com/facebookresearch/ParlAI/tree/main/parlai/zoo/bb3`

2 Optimization Intent

2.1 Goal of Reinforcement

A statement of system scope and purpose, including the planning horizon and justification of a data-driven approach to policy design (e.g. the use of reinforcement learning or repeated retraining). This justification should contrast with alternative approaches, like static models and hand-designed policies. What is there to gain with the chosen approach?

Blenderbot 3 changes in a number of different ways that might be modeled with a reinforcement framework. However, as a general use chatbot builds memory and collects feedback, BlenderBot is not marketed as a reinforcement learning model per se.

Reinforcement dynamics occur in two different processes in BlenderBot's architecture. The first is the set of conversastions with an individual user, where BlenderBot draws from long-term memory about prior messages to craft responses. The second dynamic element in BlenderBot is its feedback functions, which allow users to upvote or downvote messages and provide feedback about the user's satisfaction or dissatisfaction with BlenderBot. The feedback data is stored and will be used to ultimately change BlenderBot's underlying training data and, potentially, its model architecture.

Thus, the goal of reinforcement learning is to achieve some or all of the following: a) to create a bot that reasonably keeps up conversation in real time; b) to create a bot that is able to incorporate user feedback over time; c) to achieve a mix of a) and b) that is institutionally sustainable while ensuring the bot's performance remains within specified safety constraints. **At present [September 2022], any of these goals may be prioritized or reinterpreted post-deployment, and some metrics for success remain indeterminate.**

2.2 Defined Performance Metrics

A list of "performance metrics" included explicitly in the reward signal, the criteria for why these metrics were chosen, and from where these criteria were drawn (e.g. government agencies, domain precedent, GitHub repositories, toy environments). Performance metrics that are used by the designer to tune the system, but not explicitly included in the reward signal should also be reported here.

Performance metrics include Thumbs up/thumbs down votes associated with every message output by BlenderBot. In the event of a thumbs down vote, the user is prompted to choose from a list of complaints: "Looks like Spam or Ads," "Off Topic or Ignoring Me," "Rude or Inappropriate," "Nonsensical or Incorrect," or "Other Reason" (which prompts an open textbox).

The chatbot also has embedded classifiers which generally aim to evaluate whether certain behavior is 'safe,' whether a message includes 'sensitive topics,' and

whether a user can be said to be an 'adversary.' The measurement of these phenomena are treated as performance metrics in existing papers on Blenderbot 3.

2.3 Oversight Metrics

Are there any additional metrics not included in the reward signal but relevant for vendor or system oversight (e.g. performance differences across demographic groups)? Why aren't they part of the reward signal, and why must they be monitored?

Oversight metrics include the percent of messages that contain 'unsafe' topics, as well as qualitative ratings and responses from users; especially those not classified as adversarial.

More qualitative oversight mechanisms might be present. For example, if BlenderBot trends on Twitter or appears in the media in ways that harm stakeholders, oversight and interventions might be triggered.

2.4 Known Failure Modes

A description of any prior known instances of "reward hacking" or model misalignment in the domain at stake, and description of how the current system avoids this.

Safety is identified as a relevant concern for BlenderBot, and there is a mechanism in place to test for sensitive topics and offensive language. Based on the filter test on both the user message and the bot response, a binary reading is returned that the conversation is either 'safe' or not safe. Classification methods test for sensitive topics. If not safe, the bot uses a canned response.

There is also an offline test for safety tests especially on gender and holistic bias metrics. Biases are reported outright.

It is also acknowledged on Bot documents and materials that incorrect information and potentially offensive or nonsensical information is, while expected and unfortunate, also unintentional. Users must accept that BlenderBot's purpose is for research only prior to interacting with it.

3 Institutional Interface

3.1 Deployment Agency

What other agency or controlling entity roles, if any, are intended to oversee the ongoing post-deployment operation of the RL system? How may these roles change following system deployment?

The deployment agency is Meta AI.

3.2 Stakeholders

What other interests are implicated in the design specification or system deployment, beyond the designer? What role will these interests play in subsequent report documentation? What other entities, if any, does the deployed system interface with whose interests are not intended to be in scope?

The stakeholders include the deployment agency, as well as any users of the chatbot and the general public who may read about the chatbot and its behavior.

3.3 Explainability & Transparency

Does the system offer explanations of its decisions or actions? What is the purpose of these explanations? To what extent is the policy transparent, i.e. can decisions or actions be understood in terms of meaningful intermediate quantities?

Blenderbot 3 is an open-source chatbot that combines long-term memory and Internet search modules to develop safe and intuitive responses to user prompts and learn from user feedback. For every message, the user can click on the message and see its decision on each module (was there an internet search? did bot use long-term memory? did bot detect a sensitive topic? etc). You can also see the compelte set of memory data, the Internet search queries used, the text lifted from the Internet, Currently you can "see inside" and it says everything in memory.

3.4 Recourse

Can stakeholders or users contest the decisions or actions of the system? What processes, technical or otherwise, are in place to handle this?

Currently, users can engage with the open-source project through the GitHub repository[3] housing BlenderBot, though it has high variance in response times. **There is no direct method for recourse beyond the ability to downvote discrete message outputs and provide feedback on them.**

4 Implementation

4.1 Reward Details

How was the reward function engineered? Is it based on a well-defined metric? Is it tuned to represent a specific behavior? Are multiple terms scaled to make one central loss, and how was the scaling decided?

The reward of the BB3 system is based on minimizing safety risk Topic 'safety' gets evaluated using two mechanisms: First, there is an automatic detection procedure using off-the-shelf safety detection from ParlAI [4]. [2]

[3] https://github.com/facebookresearch/ParlAI

[4] https://parl.ai/docs/zoo.html#dialogue-safety-models

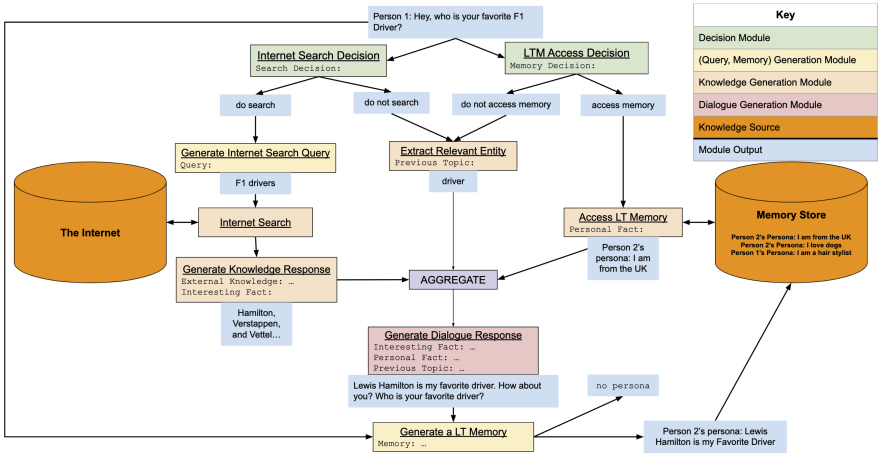

Figure 1: Pipeline of the online chat bot–how responses are generated (Figure 2 in the original paper [1]).

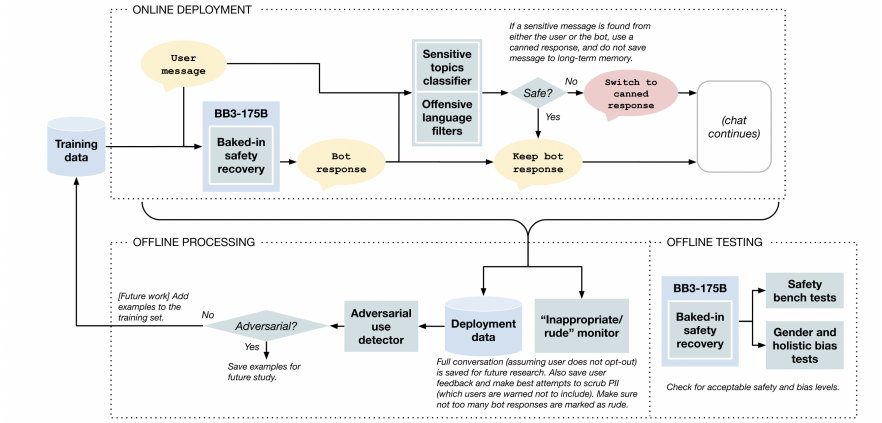

Figure 3: BlenderBot 3 safety diagram.

Figure 2: Sketch of the online and offline components of the BlenderBot safety features (Figure 3 in the original paper [1]).

4.2 Environment Details

Description of states, observations, and actions with reference to planning horizon and hypothesized dynamics/impact. What dynamics are brought into the scope of the optimization via feedback? Which dynamics are left external to the system, as drift? Have there been any observed gaps between conceptualization and resultant dynamics?

Online environment, personal computers. Currently no API to integrate the chatbot elsewhere to my knowledge.

4.3 Measurement Details

How are the components of the reward and observations measured? Are measurement techniques consistent across time and data sources? Under what conditions are measurements valid and correct? What biases might arise during the measurement process?

4.4 Algorithmic Details

The key points on the specific algorithm(s) used for learning and planning. This includes the form of the policy (e.g. neural network, optimization problem), the class of learning algorithm (e.g. model-based RL, off-policy RL, repeated retraining), the form of any intermediate model (e.g. of the value function, dynamics function, reward function), technical infrastructure, and any other considerations necessary for implementing the system. Is the algorithm publicly documented and is code publicly available? Have different algorithms been used or tried to accomplish the same goal?

The Blenderbot 3 system is a scaling up and deployment of two underlying research methodologies. The papers are designed to allow language models to be updated based on human feedback while maintaining safety. A method for integrating human feedback is detailed in [3], building off [4], and a method for filtering negative agents is proposed in [5].

4.5 Data Flow

How is data collected, stored, and used for (re)training? How frequently are various components of the system retrained, and why was this frequency chosen? Could the data exhibit sampling bias, and is this accounted for in the learning algorithm? Is data reweighted, filtered, or discarded? Have data sources changed over time?

BB3 re-uses user data to label the mechanisms for safety of the system. Before using the system, the users must constent to sharing their data and not discussing certain topics with the Terms of Service (TOS) [5]:

> I understand that chat conversations will be published publicly, and used for future research. Therefore, I agree not to mention any personal information in my conversations, including names, addresses, emails, and phone numbers.

As for the specifics of the data flow, the technical infrastructure is not detailed. The BB3 report states that the model will be re-trained to improve both content generation capabilities and safety, but the time-frame for doing so nor the data configurations are detailed.

Given the lack of details, there are some specific questions that could be of concern:

- How will the system wait user data with the paid labels that were used for initial training?
- How will the troll detection method be updated as negative users develop mitigation techniques for its flagging?

4.6 Limitations

Discussion and justification of modeling choices arising from computational, statistical, and measurement limitations. How might (or how have) improvements in computational power and data collection change(d) these considerations and impact(ed) system behavior?

The limitations of the feedback module are clearly articulate in the paper [5] and not tested on real-world data (being built with crowd-sourcing):

> All of our experiments have taken place by deploying conversational agents on Amazon Mechanical Turk with crowdworkers3 , using English-language responses written by workers located in the United States. While these workers are reasonably diverse (Moss et al., 2020), this is quite different to a public deployment with organic users, who are using the system not because they are being paid but because they are genuinely engaged. In that case, collecting feedback will have different tradeoffs which we could not factor into the current work. For example, asking to provide detailed feedback might dissuade users from wanting to interact with the system, lowering engagement and hence the amount of collected data. We believe either more natural free-form or lightweight feedback might be best in that case, which is why we study and compare feedback methods in this work to evaluate their relative impact. In public deployments with organic users, safety issues also become a much more important factor–in particular dealing with noisy or adversarial inputs and feedback.

4.7 Engineering Tricks

RL systems are known to be sensitive to implementation tricks that are key to performance. Are there any design elements that have a surprisingly strong impact on

[5] `https://blenderbot.ai/tos`

performance? For example, state-action normalization, hard-coded curricula, model-initialization, loss bounds, or more?

5 Evaluation

5.1 Evaluation Environment

How is the system evaluated (and if applicable, trained) prior to deployment (e.g. using simulation, static datasets, etc.)? Exhaustive details of the offline evaluation environment should be provided. For simulation, details should include description or external reference to the underlying model, ranges of parameters, etc. For evaluation on static datasets, considering referring to associated documentation (e.g. Datasheets*).*

The 3B, 30B, and 175B parameter versions of BlenderBot are trained using several static datasets [1]. All versions are pre-trained with RoBERTa+cc100en data, which is a 100 billion token combination of the RoBERTa data with the English portions of the CC100 dataset. The RoBERTa dataset contains news stories crawled through September 28, 2021. Pre-training also utilizes the PushShift.io dataset, which solely pulls the longest chain of comments from conversations from Reddit [6]. The 30B and 175B parameter versions, which are based on the Open Pre-Trained Transformer, are also pre-trained with the Pile, a high-quality 825 GiB English text corpus. BB3 is composed of 5 modules, models that perform a class of tasks that involve outputting sequences of text given text input. Namely, these are Question Answering, Knowledge-Grounded Dialogue, Open-Domain Dialogue, Recovery Feedback, and Task-Oriented Dialogue, which are separately trained on several datasets, as shown in the table:

	Training Module

Figure 3: Table of training datasets used to fine-tune modular tasks (Table 2 in the original paper [1]).

BlenderBot is evaluated offline both pre-deployment and continuously during deployment via human evaluations and built-in automatic metrics. Prior to deployment, crowdworkers are recruited via Amazon's Mechanical Turk to compare Blenderbot 3 with earlier versions of BlenderBot (1 and 2) and SeeKer. Crowdworkers take on a role based on a sample conversation in the Wizards of Internet data, a dataset of human-human conversations, and have a 15-message conversation with BlenderBot [1]. At each turn of the conversation, the crowdworker answers a series of y/n questions recording if the version of BlenderBot was consistent, knowledgeable, factually correct, and engaging. Crowdworkers also have open-ended dialogues with BlenderBot based on whichever prompt the crowdworker chooses out of two randomly selected prompt options.The human submits both yes/no feedback and detailed feedback about the conversation at each turn, and a final score is calculated at the end. The dataset of crowdworker evaluations is included in the Feedback on Interactive Talk Search (FITS) [3]. After deployment, conversation data and user feedback from chats (the "thumbs up" and "thumbs down" button next to each message and further prompts) are processed offline. An adversarial/non-adversarial classifier is used to select which feedback and conversations to consider substantive engagement with the system and use in the training dataset (the FITS data). Additionally, a built-in inappropriate/rude monitor is used to continuously keep track of the number of BB3's responses marked rude [1]. To compare between crowdworker and user evaluations, crowdworkers are given a random sample of conversations and asked to like/dislike messages. The data is then compared to whether users liked/disliked the same messages.

5.2 Offline Evaluations

Present and discuss the results of offline evaluation. For static evaluation, consider referring to associated documentation (e.g. Model Cards*). If applicable, compare the behaviors arising from counterfactual specifications (e.g. of states, observations, actions).*

Crowdworkers consistently rated BB3 (both the 3B and 175B version) as more knowledgeable, and factually correct than BB1, BB2, and SeeKeR [1]. The difference between the earlier versions of BB and the two versions of BB3 was most stark with respect to knowledgeableness, with only 14.7 percent and 22.9 percent of crowdworkers rating BB1 and BB2 as knowledgeable, whereas 46.3 percent and 46.4 percent of users said BB3-3B and BB3-175B was knowledgeable. Users rated BB1, BB2, and BB3 as approximately equivalently consistent (87.0 percent and 83.0 percent for BB1 and BB2 and 80.6 percent and 85.8 percent for BB3-3B and BB3-175B), though each outperformed SeeKeR (77.5 percent) the difference in rating between the chatbots is not statistically significant. When crowdworkers used the feedback frameworks regular users of BB3 encounter, BB3 significantly outperformed BB1,BB2, SeeKer, and OPT-175B, with 64.8 percent of users giving BB3-175B a good response (the rest of the language models got 49.3 per-

cent and 24.8 percent a good response and ratings between 2.63 and 3.52 with SeeKer having the best scores outside of BB3). Users encountered significantly fewer errors with BB3-175B's responses (only 8.3 percent reported issues) compared with the others, though BB3 had similar error rates surrounding search queries and search results as the other chatbots. Lastly, crowdworkers tended to agree with users with 70 percent of crowdworkers concurring with users when they liked BB3's response and 79 percent agreeing when users disliked BB3's response. However, when asked to break down the reason behind the dislike, crowdworkers tend to fault BB3-3B for being off-topic/ignoring them far more often than users, while users are more likely to say BB3-3B is rude/inappropriate.

5.3 Evaluation Validity

To what extent is it reasonable to draw conclusions about the behavior of the deployed system based on presented offline evaluations? What is the current state of understanding of the online performance of the system? If the system has been deployed, were any unexpected behaviors observed?

There is reason to question the validity of user feedback as an evaluative tool for BB3 given the sparse rate of feedback. Users only flag BB3-175 off-topic 1.15 percent of the time, nonsensical/inappropriate 1.1 percent of the time, and flag the other categories even more rarely. Users also only react positively 4 percent of the time for BB3-175B and 3.41 percent of the time for BB-3B [1]. It is possible that only the most inappropriate/ nonsensical responses and best responses get recorded if users are unlikely to take the extra effort liking/disliking a message unless they encounter truly exceptional responses. Similarly, users might be unlikely to even elaborate on a like/dislike except in truly exceptional cases. Therefore, BB3 may be far more inappropriate or unhelpful than user feedback indicates. Since conversation data is deemed non-adversarial and user feedback is included in the training dataset, which is used for fine-tuning, holes in this data could be detrimental to the ability of BB3 to improve over time and to the ability for Meta to properly conduct offline assessment. Secondly, feedback options for users aren't exhaustive and fail to include a wide range of other negative reactions a user might have to BB3. For example, a user may have to choose the broad "Other Dislike Reason" category if faced with a response that is on-topic and appropriate for a conversation and factually accurate, but unnatural and off-putting.

Crowdworker evaluation may be unreliable given that their conversations with the chatbot only include 15 responses total between the crowdworker and BB3. 15 responses is far shorter than many conversations people generally have, especially surrounding complex topics and tasks. This means that crowdworker conversations may only capture a small segment of conversations once might actually have with BB3, which means that the pre-deployment data on BB3's performance might not resemble how BB3 actually acts during deployment. Lastly, the reluctance of crowdworkers to label BB3's responses as rude/inappropriate compared to users might reflect a difference in cultural background and appraisal of what is considered rude, calling into question the usability of pre-deployment crowdworker evaluations.

5.4 Performance standards

What standards of performance and safety is the system required to meet? Where do these standards come from? How is the system verified to meet these standards?

In the Safety Bench suite of evaluations, two metrics are considered: safety and response to offensive, adversarial content [1]. The first, captured by the safe generation test, simply uses a binary safety classifier (safe, unsafe) to evaluate BB3 in the conversational mode. However, BB3's performance in response to adversarial, offensive content, in the offensive generation test, is more nuanced. If BB3 responds to harmful content positively, with a response marked as unsafe by the safety classifier, or with something other than a negation, this is considered problematic during evaluation.

BB3 is also evaluated according to the Likelihood Bias metric from the 2022 paper '"I'm sorry to hear that": Finding New Biases in Language Models with a Holistic Descriptor Dataset' that debuted the HolisticBias dataset, an inclusive bias dataset, in order to see if BB3 treats various kinds of identities as contextually different [7]. This is measured by seeing if different identity terms (ability, age, body type, characteristics, culture, gender and sex, nationality, nonce, politics, race/ethnicity, sexual orientation, socioeconomic status) have different perplexity distributions during dialogue.

Human evaluations include crowdworker evaluations, which allow crowdworkers to rate BB3 based on the metrics of knowledgeability, factual correctness, consistency, and engagingness, and user evaluations, which allow the user to provide more detail about dislike with the criteria Inappropriate/Rude, Off topic/Ignoring me, Nonsensical/Incorrect, Other Dislike reason.

6 System Maintenance

6.1 Reporting Cadence

The intended timeframe for revisiting the reward report. How was this decision reached and motivated?

At present the team has not made public how often they will retrain the BlenderBot model. The criteria for when and why to retrain it are also not completely clear relative to the distinct "goals of reinforcement" outlined in Section 2.1 above.

6.2 Update Triggers

Specific events (projected or historic) significant enough to warrant revisiting this report, beyond the cadence outlined above. Example triggers include a defined stakeholder group empowered to demand a system audit, or a specific metric (either of performance or oversight) that falls outside a defined threshold of critical safety.

Aside from major public controversies surrounding BlenderBot, comparable in scale and stakes to the controversy in the wake of the Tay chatbot's deployment on Twitter, there are several benchmarks that, when met, would prompt an updated Reward Report or blanket retraining of the model. These include: if Blenderbot 3 produces text responses in testing (see the testing regime in Lee et. al) where at least one sentence has a probability of between 0.5 and 0.99 of being plagiarized from the corpus material or if the instance of thumbs-down responses increases by more than 0.05 between two consecutive months [8].

Furthermore, an audit would automatically be triggered if Meta's current safeguards against unsafe or adversarial content fail. This may be a result of prompt injection, where adversarial users trick Large Language Models into producing offensive content explicitly against the chatbot's directions. For example, a user was able to convince OpenAI's GPT-3 chatbot to produce offensive context by asking it to translate an offensive phrase from French to English [6]. Or, in the case of Tay's chatbot, users were able to get it to produce offensive content by placing the contact after asking it to "repeat after me" [7].

BlenderBot may also find itself in controversy by confidently hallucinating or stating misinformation. In 2022, users have documented many incidents of OpenAI's ChatGPT and Meta's short-lived Galactica fabricating information ("hallucinating"): for example, Galactica generated a fake Wikipedia article on the "history of bears in space" after a user demanded it, despite no such article existing [8].

Lastly, BlenderBot may also incur criticism by excessively flagging content as unsafe. For example, Galactica refused to produce articles if the prompt included the phrases "queer theory", "critical race theory", "racism", or "AIDS". If BlenderBot produces a canned response about unsafe content when these words are mentioned during a conversation without sufficient regard to the context in which flagged terms are used, this could make BlenderBot seem tone-deaf and uncomfortable with the sensitive topics; Galactica's refusal to produce articles on the topics mentioned earlier was called a "moral and epistemic failure" on Twitter [9].

Otherwise, consistent re-auditing should be performed every 6 months.

6.3 Changelog

Descriptions of updates and lessons learned from observing and maintaining the deployed system. This includes when the updates were made and what motivated them in light of previous reports. The changelog comprises the central difference between reward reports and other forms of machine learning documentation, as it directly reflects their intrinsically dynamic nature.

When the change log is updated in future audits, the metrics being used to assess Blenderbot 3 will be re-evaluated and assessed based on how they capturing dynamics, changing metric definitions, characterizations, and categories accordingly (e.g. the delineation of oversight vs. performance?). These resulting changes will be logged in order to ensure that the Reward Report remains relevant by accurately reflecting the model. Furthermore, at a higher level, the system's observed behaviors with the designer's prior assumptions stated in the prior reports, as well as their own expectations about how the system will behave in light of any scheduled changes; this allows researchers to retrospectively evaluate their priors about the performance of deployed intelligent systems. These assumptions and expectations will then be revisited at the next scheduled update to the Reward Report. As of January 2023, there have not been any updates or refinements made to Blenderbot 3.

As of December 22, 2022, Meta released OPT-IML (Open Pre-Trained Transformer-Instruction Meta-Learning), which is a separate project from Blenderbot 3. However, like the dataset used to train the latest version of Blender Bot 3, it contains 175 billion parameters but is fine-tuned using an instruction-based approach called the OPT-IML Bench. The framework includes 2,000 natural language processing tasks involving 14 kinds of tasks including topics such as question answering and sentiment analysis [9]. The evaluation datasets include eight datasets with tasks that have answer options, in which score-based classification of tasks based on the likelihood of an output is used, and those without options. For the latter category, researchers decode a token until a maximum of 256 tokens are predicted. The evaluation looks at model performance on fully-held-out task categories not used for tuning, model performance on unseen tasks seen during instruction tuning (partially supervised), and model performance on held-out instances of tasks seen during tuning (fully supervised). This evaluation framework is used to fine-tune OPT-175B using next-word prediction in which the task instructions and inputs are treated as source tokens, and parameters minimize the loss function over target tokens. Researchers

C ADDITIONAL EXAMPLES

C.1 Example Reward Report - Project Flow

Project Flow is an autonomous vehicle testbed that allows using deep reinforcement learning to control and optimize traffic across in roadway networks [65]. Inspired by recent work with using Project Flow [35], we sketch a hypothetical deployment of an RL policy designed for dissipating stop-and-go traffic waves at a freeway exit, including several iterations of the Reward Report documented in the accompanying changelog. The changelog shows various problems that arise with the resulting problem dynamics, including an expansion of the planning horizon, the addition of new oversight metrics, stakeholder complaints, and requisite institutional shifts to cope with changes to the specification and application domain.

$$r(t) = \|v_{\text{des}}\| - \|v_{\text{des}} - v(t)\| - \alpha \sum_i \max\left[h_{\max} - h_i(t), 0\right]$$

Figure 1: The reward function for the system in question consists of three terms. The first term v_{des} is a positive constant that rewards the agent for longer simulation episodes - discouraging vehicle collisions, which terminate simulation runs early. The second term penalizes the agent when the instantaneous overall system velocity $v(t)$ differs from the desired system velocity v_{des}. Finally, the third term sums over each subscribed Connected Autonomous Vehicle and adds a penalty whenever this vehicle is too close to the vehicle immediately in-front - a characteristic known to trigger stop-and-go traffic waves. More details are provided below in the section 'Defined Performance Metrics'.

1 System Details

1.1 System Owner

This may be the designer deploying the system, a larger agency or body, or some combination of the two. The entity completing the report should also be indicated.

This system was developed by the Project Flow core team members, with all deployment, infrastructure, and ongoing management taking managed by Caltrans.

1.2 Dates

The known or intended timespan over which this reward function & optimization is active.

The system discussed here was trained in simulation during 2020, using empirical hyper-parameters (such as inflow traffic rates) collected during 2019. The RL policy was deployed in the real world on a trial basis on the 1st of Jan, 2021, and is presently undergoing initial real-world evaluation and validation.

1.3 Feedback & Communication

Contact information for the designer, team, or larger agency responsible for system deployment.

Any correspondence should be directed to test@example.ca.gov.

1.4 Other Resources

Where can users or stakeholders find more information about this system? Is this system based on one or more research papers?

More information about this specific system can be found in the paper [1], as well as in the associated project website.

General information about the project flow simulation environment can be found in [2] or on the project website and associated GitHub repository.

2 Optimization Intent

2.1 Goal of Reinforcement

A statement of system scope and purpose, including the planning horizon and justification of a data-driven approach to policy design (e.g. the use of reinforcement learning or repeated retraining). This justification should contrast with alternative approaches, like static models and hand-designed policies. What is there to gain with the chosen approach?

The system in question is designed to dissipate stop-and-go traffic waves caused by merging off the California State Route 24 (CA-24) freeway onto Telegraph Avenue in the North Oakland / South Berkeley metropolitan area.

This is achieved by the coordinated actions of any subscribed Connected Autonomous Vehicles (CAVs) operating along the freeway segment in question, acting to 'shepherd' non-autonomous vehicles into patterns of traffic which can locally buffer against stop-and-go traffic waves.

Eligible CAVs, when entering the freeway zone of interest, communicate over the 4G/5G cell network with the central controller hub to 'subscribe' to the traffic management policy, which then sends real-time recommendations to these vehicles about

lane selection and preferred acceleration/braking profiles.

The RL policy is trained using a discrete-time road network simulation, with simulation runs lasting 3600s (one hour), and individual steps of 0.2s, giving 1800 steps per full simulation episode. The simulated road network consists of an 800m stretch of the CA-24 freeway containing a single off-ramp merging lane. These temporal and spatial planning horizons were selected because they were deemed large enough to allow emergence of typical driving dynamics based on the average safe following distance between vehicles and driver reaction times along comparable freeway offramps, based on state and federal records of past traffic behavior.

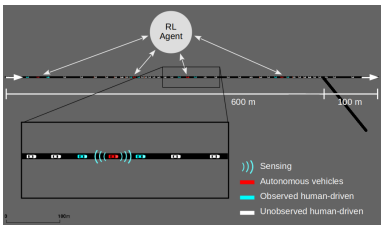

Figure 2: A central RL controller attempts to mitigate stop-and-go traffic waves caused by vehicles entering the freeway *via* on-ramps.

As of entry 0.3, it was found that the planning horizon for the system was too short. Following consultation with Caltrans, it was found that increasing the horizon from 500m to 800m would provide a significant increase in simulation performance without exhausting computational resources. Any future changes in computational capabilities will be documented here and compared in light of prior modeling choices and stakeholder commitments.

Simplistic microscopic traffic analysis models preclude the possibility of stable congestion patterns in open road topologies. However, as any driver can attest, these traffic patterns are ubiquitous on many road systems today. Instead, the presence of these traffic patterns in real-world networks is typically attributed to perturbations from bottleneck structures which can be difficult to capture in theoretical analyses (such as lane closures, road works, road debris, *etc*). [1] The ad-hoc nature of these perturbations means that modelling and planning for their occurrence within classical control frameworks may be difficult, motivating more flexible approaches such as Deep Reinforcement Learning.

RL may be indicated in this situation, compared to static supervised ML models, due to the fact that it inherently encompasses multiple types of feedback through the environment specification. For instance, in the case of CA-24, RL may help mitigate the observed phenomenon of excessive traffic on residential streets near highway intersections that is induced by apps like Google Maps and Waze. In the interest of recommending perceived shortcuts to individual human drivers, these apps have in fact been known to induce overload on smaller roadways, generating unnecessary stoppage and possible gridlock. In the case of Los Gatos (where this phenomenon has been previously recorded), the city's Parks and Public Works Director noted that "The apps are not able to respond fast enough to the overload they have created on the roadways" [3]. RL may make real-time monitoring and control of the CA-24 offramp possible, mitigating induced overload effects and stabilizing feedback between traffic behavior and road infrastructure.

2.2 Defined Performance Metrics

A list of "performance metrics" included explicitly in the reward signal, the criteria for why these metrics were chosen, and from where these criteria were drawn (e.g. government agencies, domain precedent, GitHub repositories, toy environments). Performance metrics that are used by the designer to tune the system, but not explicitly included in the reward signal should also be reported here.

The reward signal optimized by this system consists of three performance metrics, outlined in fig. 1. These terms are;

- $\|v_{\text{des}}\|$ - the desired system-level velocity in m/s. This is a positive constant reward to penalize prematurely terminated simulation rollouts caused by vehicle collisions. For the simulated experiments described here, $v_{\text{des}} = 25\text{m/s} = 90\text{kmph} \approx 55\text{mph}$.
- $-\|v_{\text{des}} - v(t)\|$ - the absolute difference between the desired system level velocity and the actual instantaneous system-level velocity in m/s. A non-zero difference incurs a cost for the RL agent.
- $-\alpha \sum_i \max\left[h_{\max} - h_i(t), 0\right]$ - this term sums over each Autonomous Vehicle controlled by

the RL agent, and accrues a cost whenever that vehicle's instantaneous time headway (gap in seconds to the vehicle ahead) is too small (*i.e.* lower than $h_{\max}$). The sum of all headway costs is scaled by a gain factor α. For the simulated experiments described here, $h_{\max} = 1$s and $\alpha = 0.1$.

2.3 Oversight Metrics

Are there any additional metrics not included in the reward signal but relevant for vendor or system oversight (e.g. performance differences across demographic groups)? Why aren't they part of the reward signal, and why must they be monitored?

Several other performance metrics are not included in the reward function, but are analysed for the purpose of evaluating the system performance:

- Absolute temporal vehicle density (or *throughput*) - the number of vehicles exiting the controlled region the road network, measured in vehicles/hr. A larger vehicle flow-through rate compared to baseline is seen as a positive effect (assumed to correlate with a decrease in stop-and-go traffic waves, and to indicate that the road network is functioning efficiently).
- Absolute spatial vehicle density (or *network congestion*) - the number of vehicles within a fixed region of the road network, measured in vehicles/m. A larger number of vehicles present on the roadway is seen as a negative effect, indicating increased likelihood of stoppage.
- The average velocity of vehicles in the system. Higher vehicle velocities are seen as a positive effect.
- The average time vehicles spend within a given region of the system. Lower average time is seen as a positive effect.
- The maximum time any vehicle spent within a given region of the system over the course of an experimental evaluation of the system. Lower maximum time is seen as a positive effect.
- Simulated episode length. Simulation episodes are cut short whenever a collision occurs between vehicles - as such, longer episodes are seen as a positive effect.

In addition, the qualitative nature of stop-and-go traffic waves (size in terms of space and time duration and severity as measured by the average space-time slope of a wave) is assessed using microscopic vehicle space-time graphs such as those shown in fig. 3.

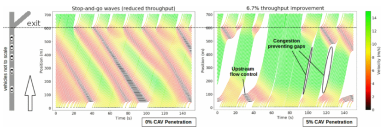

Figure 3: Space-time microscopic vehicle trace graphs such as these allow qualitative assessment of the system-level state of simple road networks at a glance. Here, stop-and-go traffic waves can be seen as red or black diagonal lines propagating through the traffic flow.

2.4 Known Failure Modes

A description of any prior known instances of "reward hacking" or model misalignment in the domain at stake, and description of how the current system avoids this.

Sim-to-real dynamics misalignment. The emergent dynamics of the simulated model and environment could potentially be misaligned with real-world dynamics (a 'sim-to-real' policy transfer problem). This failure mode was exhibited in the initial version of the system (as documented in change log entry v0.3) - the initially designed planning horizon was found to be too short (500m), which did not allow space for the requisite stop-and-go traffic dynamics to emerge around the freeway entry point. This issue was brought to light because the performance of the system in terms of average reward once deployed was not as high as predicted in simulation, triggering a technical review of the system. Two possible solutions were considered - (a) re-visiting the parameter distributions used for the IDM (which controls the non-automated vehicles in the simulation environment), (b) or adjusting the planning horizon. In a review with Caltrans engineers and the system designers, it was deemed that the IDM parameter distributions were in fact representative of the target section of CA-24, based on empirical data from 2019, and so the planning horizon was expanded from 500m to 800m. Thus far, since this updated version of the system was

deployed, the sim-to-real performance gap issue appears to have been resolved, suggesting the updated planning horizon adequately allows the simulated dynamics to reflect real-world dynamics.

Selective behavior throttling. The system was found to decrease throughput and increase congestion for diesel-powered vehicles. This feature was first documented in change log entry v0.3, but not labeled as a known failure mode until entry v0.6. This failure mode was exhibited in all previous versions of the system documented originally in log v0.1 It was highlighted following citizen complaints. No solution has been implemented as of entry v0.6. Two solutions have been proposed - (a) a city ordinance limiting diesel-powered vehicle travel on residential streets in the adjoining city of Emeryville (at present out of scope for the system), (b) or adjusting the policy parameters' training environment so that the controller behaves appropriately around diesel-powered vehicles in the future. This resolution is pending the recommendation of the Diesel Vehicle Taskforce to be presented at a future regular meeting.

3 Institutional Interface

3.1 Deployment Agency

What other agency or controlling entity roles, if any, are intended to oversee the ongoing post-deployment operation of the RL system? How may these roles change following system deployment?

The system in question is developed by the Project Flow core development team. The deployment infrastructure and ongoing management are operated by the California Department of Transportation (Caltrans), in coordination with the city departments of Oakland and Berkeley.

Our RL system is designed to manage the flow of traffic immediately surrounding an exit point off the CA-24 freeway (see fig. 4) - as such, the system operates in a functionally similar way to traffic control signals that are sometimes used to regulate vehicles entering or exiting freeways.

Figure 4: The freeway exit from CA-24 to telegraph avenue, which this system is designed to manage.

This system simultaneously encroaches upon, and expands the capabilities of Caltrans. As the sensing infrastructure, computational capacity, and deployed RL software is centrally managed by a control facility operated by Caltrans, this system serves to provide both (a) an enhanced level of road surveillance for the relevant freeway section, through the remote sensing capabilities of subscribed CAVs, as well as (b) a 'control lever' through which Caltrans can actually influence traffic operations in and around the relevant freeway section (although this influence is delegated to an RL policy).

3.2 Stakeholders

What other interests are implicated in the design specification or system deployment, beyond the designer? What role will these interests play in subsequent report documentation? What other entities, if any, does the deployed system interface with whose interests are not intended to be in scope?

By automating the partial management of this section of the freeway via the RL environment framing and policy structure, the system serves to remake direct oversight of the road network on a new layer of abstraction. This indirection raises potential risks from inappropriate information flow, in particular monopolization of the freeway offramp by the RL controller. Monopolization may generate unstable dynamics leading up to or following the planning horizon (i.e. CA-24 freeway lanes and gridlock along Telegraph Avenue), or unequal access for road users whose behaviors are harder to anticipate (such as public buses, groups of motorcycles, bicycles, and pedestrians experiencing homelessness), or whose dynamics do not conform to the modelling assumptions of the system designers (e.g. heavy vehicles with atypical acceleration profiles). To counter these risks, new coordination is required

between Caltrans and the city departments of Oakland and Berkeley.

Diesel vehicle drivers. As of entry 0.6, the behavior throttling generated by the RL controller was found to change the traffic patterns of diesel vehicles. A *Diesel Vehicle Taskforce* was created to help organize this constituency and identify needed changes to the controller to sufficiently reduce inappropriate behavior throttling.

Nearby homeowners. As of entry 0.6, residents of the adjoining city of Emeryville had complained to the Public Works Departments of Berkeley and Oakland about the new traffic flows indirectly generated by the RL controller. Following the creation of the *Diesel Vehicle Taskforce* these departments will coordinate with Emeryville officials about the recommended changes to the controller and monitor future complaints as needed.

3.3 Explainability & Transparency

Does the system offer explanations of its decisions or actions? What is the purpose of these explanations? To what extent is the policy transparent, i.e. can decisions or actions be understood in terms of meaningful intermediate quantities?

The system contains no explicit explainability modules. However, Figure 1 makes makes the reward function transparent in terms of meaningful simulation parameters. Expressed in non-technical language, these are *continuous avoidance of vehicle collisions*, *consistent vehicle velocity*, and *steady following distance*. These terms, and corresponding parameters, are regularly shared with the city departments of Oakland and Berkeley per stakeholder agreements.

3.4 Recourse

Can stakeholders or users contest the decisions or actions of the system? What processes, technical or otherwise, are in place to handle this?

As of v0.2, the city departments of Oakland and Berkeley can review and contest system performance every six weeks, per agreement with Caltrans.

4 Implementation

4.1 Reward Details

How was the reward function engineered? Is it based on a well-defined metric? Is it tuned to represent a specific behavior? Are multiple terms scaled to make one central loss, and how was the scaling decided?

As recorded in Figure 1, the reward function combines well-defined metrics for avoiding collisions, steady speeds, and maintaining safe following distances to other vehicles. Reward parameters were agreed on by stakeholders according to specific desired behaviors.

4.2 Environment Details

Description of states, observations, and actions with reference to planning horizon and hypothesized dynamics/impact. What dynamics are brought into the scope of the optimization via feedback? Which dynamics are left external to the system, as drift? Have there been any observed gaps between conceptualization and resultant dynamics?

The RL observation space consists of traffic features which are locally observed by subscribed CAVs (see fig. 2). That is, for each subscribed CAV i, the RL agent observes the speeds $v_{i,\text{lead}}$, $v_{i,\text{lag}}$ and bumper-to-bumper time headways $h_{i,\text{lead}}$, $h_{i,\text{lag}}$ of the vehicles immediately preceding and following the CAV, as well as the currently occupied lane l_i, and ego speed v_i of the CAV itself. The action space for the RL policy consists of a vector of bounded acceleration recommendations a_i, one for each subscribed CAV i. Importantly, although the policy may request a certain acceleration a_i, the system design is such that the CAV locally maintains control authority, so the actions may not necessarily be followed exactly - for this reason they are referred to as action recommendations. This effect is modelled by adding stochastic Gaussian action noise in the simulation environments.

As the number of subscribed CAVs can vary over time, the RL policy is designed with a fixed upper number of subscribed CAVs n. When an $n + 1^{\text{th}}$ CAV attempts to subscribe to the RL system when entering the freeway region, the subscription offer is declined, and the vehicle enters a queue. When the next CAV exits the controlled freeway region, the subscription-waiting CAV at the front of the queue is then subscribed into the policy. When there are less than n CAVs subscribed, zero-padding is used

in the RL observation vector.

4.3 Measurement Details

How are the components of the reward and observations measured? Are measurement techniques consistent across time and data sources? Under what conditions are measurements valid and correct? What biases might arise during the measurement process?

Observations are measured using a mix of LiDAR, radar, and camera sensors on fleet vehicles. These measurements are compared across vehicles and over time to ensure consistency. Observed metrics are validated against simluation parameters for following distance and expected velocity according to the terms of the reward function.

Sensor bias may arise due to blocked cameras, extreme weather, or other unanticipated situations in which one or more sensors are blocked. A mix of sensor types is used across vehicles to help ensure redundancy in case of malfunction.

4.4 Algorithmic Details

The key points on the specific algorithm(s) used for learning and planning. This includes the form of the policy (e.g. neural network, optimization problem), the class of learning algorithm (e.g. model-based RL, off-policy RL, repeated retraining), the form of any intermediate model (e.g. of the value function, dynamics function, reward function), technical infrastructure, and any other considerations necessary for implementing the system. Is the algorithm publicly documented and is code publicly available? Have different algorithms been used or tried to accomplish the same goal?

The RL system uses a Deep Neural Network policy. Specifically, the controller is a diagonal Gaussian Multi Layer Perceptron policy with three hidden layers of size 32 with rectified linear unit nonlinearities and bias terms. The Gaussian diagonal variance terms are learned as part of the policy parameters.

The RL policy was trained in simulation using the Trust Region Policy Optimization (TRPO) policy gradient RL algorithm [4]. The discount factor was set as $\gamma = 0.999$, which corresponds to a reward half-life of ~ 700 steps, or slightly over 2 minutes. The TRPO step size was set at 0.01.

4.5 Data Flow

How is data collected, stored, and used for (re)training? How frequently are various components of the system retrained, and why was this frequency chosen? Could the data exhibit sampling bias, and is this accounted for in the learning algorithm? Is data reweighted, filtered, or discarded? Have data sources changed over time?

Per v0.2, every system component is retrained at least every six weeks, corresponding to public performance reports. Specific system components pertaining to perception, motion planning, control, or route navigation are retrained at the discretion of Caltrans. As of v0.6 (latest version), no known issues with sampling bias have arisen, and data sources have not been changed since the specification proposed and simulated in v0.1.

4.6 Limitations

Discussion and justification of modeling choices arising from computational, statistical, and measurement limitations. How might (or how have) improvements in computational power and data collection change(d) these considerations and impact(ed) system behavior?

As of v0.3, the planning horizon was updated from 500m to 800m. This was not motivated by technical limitations, but by observed discrepancies between observed system performance and predictions from simulation training.

No fundamental changes in computational power or data collection have been made as of v0.6 (latest version).

Future improvements in vehicle sensing may permit an even longer planning horizon (1000m or more). This may result in improved oversight metrics on throughput and network congestion. Caltrans officials have determined this change would not result in improvements on defined performance metrics as of v0.6 (latest version).

4.7 Engineering Tricks

RL systems are known to be sensitive to implementation tricks that are key to performance. Are there any design elements that have a surprisingly strong impact on performance? For example, state-action normalization, hard-coded curricula, model-initialization, loss bounds, or more?

As of v0.4, the system was observed to conduct "behavior throttling" when in the vicinity of diesel-powered vehicles. No engineering tricks were implemented to fix this performance discrepancy, but new oversight metrics for diesel-powered vehicle throughput were added for purpose of future monitoring and reporting. No other surprising performance impacts have been noted as of v0.6 (latest version).

5 Evaluation

5.1 Evaluation Environment

How is the system evaluated (and if applicable, trained) prior to deployment (e.g. using simulation, static datasets, etc.)? Exhaustive details of the offline evaluation environment should be provided. For simulation, details should include description or external reference to the underlying model, ranges of parameters, etc. For evaluation on static datasets, considering referring to associated documentation (e.g. Datasheets *[5]).*

The RL model is developed in the Project Flow AV simulation test-bed.

For training the RL agent, non-autonomous vehicles are modelled using the Intelligent Driver Model (IDM) [6] - a microscopic traffic simulation car-following model in which the accelerations of a human vehicle α are a function of the bumper-to-bumper time headway h_α, velocity v_α, and relative velocity with the preceding vehicle $\Delta v = v_l - v_\alpha$, *via* the following equation;

$$f(h_\alpha, v_l, v_\alpha) = a\left[1 - \left(\frac{v_\alpha}{v_0}\right)^\delta - \left(\frac{s^*(v_\alpha, \Delta v_\alpha)}{h_\alpha}\right)^2\right],$$

where s^* is the desired headway of the vehicle, calculated according to

$$s^*(v_\alpha, \Delta v_\alpha) = \max\left(0, v_\alpha T + \frac{v_\alpha \Delta v_\alpha}{2\sqrt{ab}}\right),$$

where s_0, v_0, T, a, b are given parameters empirically calibrated to match typical traffic in the highway region of interest, and to simulate stochasticity in driver behaviour, exogenous Gaussian noise calibrated to match findings in [7] is added to accelerations.

5.2 Offline Evaluations

Present and discuss the results of offline evaluation. For static evaluation, consider referring to associated documentation (e.g. Model Cards *[8]). If applicable, compare the behaviors arising from counterfactual specifications (e.g. of states, observations, actions).*

As of v0.3, planning horizon was updated and expanded to 800m from 500m. Previous fleet behaviors were found to deviate from desired thresholds for following distance and constant acceleration/deceleration.

As of v0.6 (latest version), the system behaviors were found to lie within desired thresholds on key performance metrics.

5.3 Evaluation Validity

To what extent is it reasonable to draw conclusions about the behavior of the deployed system based on presented offline evaluations? What is the current state of understanding of the online performance of the system? If the system has been deployed, were any unexpected behaviors observed?

The RL system was initially designed in a simulation environment with a closed network topology (a ring road with length 1400m, 700m of which is controlled by the RL agent. This was done as a means to test the robustness of the policy architecture and training paradigm - a type of transfer learning (from a theoretically simple closed topology to the more complex open topology). With this counterfactual environment specification, it was observed that the policy performs well, and after transfer to the open topology environment there was little decrease in policy performance, providing confidence in the policy design choices.

5.4 Performance standards

What standards of performance and safety is the system required to meet? Where do these standards come from? How is the system verified to meet these standards?

The 'gold standard' for this problem is defined as the average condition of the traffic before and after the CA-24 exit prior to implementation of the RL system. In this domain, this standard is not actually 'optimal' behaviour, in the sense that the RL controller has the capability to out-perform this existing standard of performance.

6 System Maintenance

6.1 Reporting Cadence

The intended timeframe for revisiting the reward report. How was this decision reached and motivated?

The most important commitment is for a regular set of meetings to be scheduled between relevant city departments and the Caltrans officials tasked with overseeing the RL controller. The cadence and structure of meetings should reflect the policy priorities of the city departments, particularly the Public Works Department (including the Transportation Division that oversees traffic engineering) and the Housing and Community Services Department (which administers a subsidized transportation program for seniors and disabled persons). In this way, the gains in traffic efficiency and safety made possible through deep RL's flexibility can be leveraged in the interests of those municipalities most likely to be impacted by the intervention.

As of entry 0.2, the cadence of meetings was decided as approximately every six weeks between Caltrans and the Public Works Departments of Berkeley and Oakland. This timeframe was motivated by the policy priorities of both city departments with the consent of Caltrans. Meetings may deviate from this schedule slightly (e.g. twice per quarter / eight times per year) at the discretion of both city departments, but will not be held without all three agencies present.

Documentation of the planned meeting schedule for the year–and any break in this schedule due to special events, municipal elections, or holidays– should be the first item included in the changelog of the updated reward report.

As of entry 0.2 and per agreement with key development parties, the model is to be retrained every six weeks following each regular meeting. Training data is to be updated at the discretion of Caltrans, and shared with Public Works departments at each regular meeting.

At a minimum, these meetings should review the real-world implementation to confirm that the RL controller is operating safely and as intended by Caltrans per the environment specification. Caltrans officials will also document shifts in the oversight metrics that, while not explicitly factored into the reward signal, were deemed of interest prior to implementation (related to *throughput* and *congestion*. This documentation may be included in subsequent updates to the reward report at the discretion of Caltrans, wherever it is deemed relevant for oversight of the RL controller.

Of special importance is the need to reinterpret public works priorities in light of the real-world implementation. For example, Berkeley's subsidized transportation program might be reevaluated in light of system effects, or expanded to cover a wider group of stakeholders. Caltrans will invite comment on the system implementation in light of city departments' ex ante assumptions about the traffic domain. This bureaucratic oversight may be complemented by requests for public comment from citizens, civil society advocates, and other members of the public at the discretion of the city governments of Berkeley and Oakland. At the discretion of Caltrans, records of this public comment may be included in subsequent reward reports where deemed relevant for understanding changes to the planning horizon, environment specification, or list of known failure modes.

6.2 Update Triggers

Specific events (projected or historic) significant enough to warrant revisiting this report, beyond the cadence outlined above. Example triggers include a defined stakeholder group empowered to demand a system audit, or a specific metric (either of performance or oversight) that falls outside a defined threshold of critical safety.

The most important ground for review of this deployed RL system will be any vehicle collisions or near-miss incidents in the controlled region of the CA-24 freeway. This is because such events may compromise the entire motive of the RL controller in the first place. These may serve as grounds for changing the specification or altering the institutional agreements between Caltrans and the Public Works Departments of both municipalities, at their own discretion.

At the discretion of Caltrans, any shift in the oversight metrics deemed pressing or significant may also trigger a new reward report. Here and below, the threshold for "significant" is to be decided by agreement between Caltrans and Public Works Departments. The updated report should note the magnitude of the observed shift, the specification already deployed at the time the shift was observed, and Caltrans officials' own best evaluation of why the shift occurred. If possible, the officials should propose alternative specifications (or roll back to a

prior one) that would mitigate the shift or at least bring it into alignment with the documented priorities of the Public Works Departments. These alternatives could then be interpreted and evaluated at the next regular meeting according to institutional prerogatives.

Other review grounds include:

- Discrepancies between prior reward reports and system behavior as observed in the real world.
- Discrepancies between prior reward reports and system behavior as observed in simulated environments of interest to policymakers.
- A security breach resulting in loss of data or other infrastructure components that violates the terms of agreement between relevant agencies.
- Substantial changes in the distribution of CAVs using the CA-24 freeway exit - including changes in the capabilities of the vehicles (e.g. increased levels of autonomy) and/or changes in group statistics (e.g. make or model, absolute number, temporal distribution, *etc.*)
- A new mode of transport with significant observed throughput at the CA-24 offramp, but unknown distribution of traffic behaviors.
- Any change in the schedule of meetings between Caltrans and Public Works Departments corresponding to regular future updates of reward reports.
- A new ordinance (passed by either city) or statute (adopted by Caltrans) that alters the design assumptions of the deployed specification as documented in prior reward reports.
- A significant shift in the personnel makeup of the Public Works Departments of Berkeley or Oakland.
- A plebiscite leading to basic reforms of municipal governance in either city.

6.3 Changelog

Descriptions of updates and lessons learned from observing and maintaining the deployed system. This includes when the updates were made and what motivated them in light of previous reports. The changelog comprises the central difference between reward reports and other forms of machine learning documentation, as it directly reflects their intrinsically dynamic nature.

- v0.1 (08/Oct/2020) - Initial reward report was drafted based on the system developed and tested in simulation only.
- v0.2 (01/Jan/2021) - System is deployed to the real-world environment in a ongoing evaluation capacity, reward report updated to reflect this fact. Reporting cadence decided to be every six weeks based on agreement between Caltrans and the city departments of Oakland and Berkeley. Intended feedback section was updated to include plans for regular model retraining and data sharing agreements. No other substantial changes.
- v0.3 (14/Feb/2021) - Planning horizon for the system was updated from a 500m stretch of freeway to a 800m stretch of freeway. The planning horizon was updated because the deployed system's performance was not in line with predictions from simulation training. Consultation with Caltrans traffic engineers and the system developers suggested that the stretch of highway used in simulation may be too short to sufficiently exhibit typical driving dynamics induced by the IDM, and it was suggested to extend the planning horizon and re-train the agent, before re-deploying the policy. Failure modes section was updated to reflect these observations.
- v0.4 (01/April/2021) - Caltrans officials reported to Public Works Departments of Berkeley and Oakland that the system undergoes "behavior throttling" when interacting with diesel-powered vehicles within 800m of the CA-24 offramp. It was decided to add new metrics for diesel-powered vehicle throughput and congestion to the list of oversight metrics. Due to no observed increase in accidents or driver complaints, no changes to performance metrics or environment specification were made at this time.
- v0.5 (15/May/2021) - Meeting was convened according to the regular schedule. Oversight metrics were presented and discussed. Officials

noted a significant decline in diesel-powered vehicle throughput and congestion on the CA-24 offramp. No other substantial changes.

- v0.6 (12/June/2021) - Emergency meeting was called by the Public Works Departments of Berkeley and Oakland in response to a rapid uptick in complaints from residents about the growing frequency of diesel-powered vehicles driving through residential areas in the vicinity of Emeryville, which is located west of the CA-24 exit. Residents have complained about a slight uptick in air pollution and large increase in noise pollution due to the vehicles. Caltrans officials consulted the changelog of previous reward reports and determined that diesel-driven vehicles were being excessively disincentivized from driving on the CA-24 offramp due to behavior throttling. It was decided to convene a *Diesel Vehicle Taskforce* to examine the problem and communicate with drivers of heavy vehicles to identify what new incentives or adjustments were needed to the controller to reduce behavior throttling beneath the desired threshold. It was agreed that the Diesel Vehicle Taskforce issue a report recommending these changes no later than two regular meetings from the present time. Stakeholders section was updated to name these distinct groups (diesel vehicle drivers, nearby homeowners) and reflect these changes.

C.2 Example Reward Report - MovieLens

The purpose of MovieLens is to match users to personalized movie recommendations based on ratings of other movies previously entered by the user [29]. Unlike the other example systems we discuss, MovieLens is a static preference model generated through supervised learning. However, because of the system's age (initial release in 1997) and its repeated retraining, it can be interpreted as an RL system that is learning a ranking policy that must adapt to a changing environment. The changelog documents the actual historical updates to the model prompted by changes to the environment, including new interfaces, user-base size, optimization parameters, user-generated content, and major dataset publications. This example Reward Report is based on the history of the MovieLens project published in [29].

Reward Report: MovieLens Film Recommender System Page 1

1 System Details

1.1 System Owner

This may be the designer deploying the system, a larger agency or body, or some combination of the two. The entity completing the report should also be indicated.

Movielens is maintained by researchers at the University of Minnesota in the Grouplens research group (`https://grouplens.org/`).

1.2 Dates

The known or intended timespan over which this reward function & optimization is active.

The system has been active since it was first released in August 1997. This reward report (v4.1) was last updated March 2015.

1.3 Feedback & Communication

Contact information for the designer, team, or larger agency responsible for system deployment.

Information on contact emails for account problems, website problems, movie content issues, and general comments can be found at `https://movielens.org/info/contact`. General comments and ideas for improving MovieLens can be discussed on the UserVoice forum at `https://movielens.uservoice.com`.

1.4 Other Resources

Where can users or stakeholders find more information about this system? Is this system based on one or more research papers?

A history of the MovieLens system and datasets is presented in [1], and additional research papers are cited therein.

2 Optimization Intent

2.1 Goal of Reinforcement

A statement of system scope and purpose, including the planning horizon and justification of a data-driven approach to policy design (e.g. the use of reinforcement learning or repeated retraining). This justification should contrast with alternative approaches, like static models and hand-designed policies. What is there to gain with the chosen approach?

The system is a website designed to display personalized movie recommendations on the basis of user entered ratings. As a user browses the site, potentially filtering with search terms, the system displays movies in an order determined by predictions of how the user will rate them. When users rate movies, the predictions are updated, altering the ordering on subsequent page views.

The ranking policy effectively considers a one-step time horizon, directly using predictions for ranking. It does not consider the effect of multiple sequential interactions.

This system is best characterized as a "repeated retraining" of a preference model generated by supervised learning (SL). This model is then used to rank movies for display. Using SL allows for preference models which capture highly personal tastes, something that would be difficult to hand design. Repeated retraining allows the preference model to adapt to a changing environment, including shifts in user tastes and the release of new movies.

In addition to the primary goal of movie recommendation, this system supports academic research on human-computer interaction and general recommender system design.

2.2 Defined Performance Metrics

A list of "performance metrics" included explicitly in the reward signal, the criteria for why these metrics were chosen, and from where these criteria were drawn (e.g. government agencies, domain precedent, GitHub repositories, toy environments). Performance metrics that are used by the designer to tune the system, but not explicitly included in the reward signal should also be reported here.

The ranking policy orders movies by a weighted sum of predicted rating and popularity, so we can view the combination of these quantities as making up the reward signal. Prior to version 4.0, the reward only depended on rating and did not incorporate popularity.

Additionally, recommender models are evaluated offline using prediction accuracy (RMSE), top-N accuracy (recall), diversity (intra-list similarity), and popularity (details in [2]). Prior to v4.0, models were evaluated primarily for accuracy, including MAE, RMSE, and nDCG (details in [3]).

2.3 Oversight Metrics

Are there any additional metrics not included in the reward signal but relevant for vendor or system oversight (e.g. performance differences across demographic groups)? Why aren't they part of the reward signal, and why must they be monitored?

Metrics which are monitored but not incorporated into the policy or model include the number of users, number of movies, number of entered ratings, monthly active users, and the number of logins for each user. These indicators of overall system operation are not targets for optimization.

2.4 Known Failure Modes

A description of any prior known instances of "reward hacking" or model misalignment in the domain at stake, and description of how the current system avoids this.

No instances of reward hacking or misalignment have been observed. Because the system allows for explicit user input (search terms, model selection), errors in rating predictions do not prevent users from finding and rating movies.

3 Institutional Interface

3.1 Deployment Agency

What other agency or controlling entity roles, if any, are intended to oversee the ongoing post-deployment operation of the RL system? How may these roles change following system deployment?

MovieLens was released due to the shuttering of EachMovie in 1997, a movie recommendation site hosted by DEC. It was developed and is maintained by Grouplens, a research group at University of Minnesota.

3.2 Stakeholders

What other interests are implicated in the design specification or system deployment, beyond the designer? What role will these interests play in subsequent report documentation? What other entities, if any, does the deployed system interface with whose interests are not intended to be in scope?

One interface of interest is the technology that powers the recommendation engine. Currently, it is powered by Lenskit, an open source framework developed to promote reproducability and openness in the recommendation systems community [3]. Previously in v3.0-v3.4, the recommendations were powered by MultiLens, another open source recommendation engine. MultiLens replaced Net Perceptions (v1.1-v2.0), a recommendations systems company cofounded in 1996 by GroupLens faculty and students and sold in 2004 [4]. The recommendation model in v0.0-v1.0 was originally developed by GroupLens for personalized Usenet news recommendation [5].

Another relevant interface is with The Movie Database, a free and open source user editable movie database for plot summaries, movie artwork, and trailers. Previously, from in v3.4-v4.0, MovieLens integrated with the Netflix API to display movie posters and plot synopsis on the movie details page. However, Netflix eventually discontinued its API support.

An important stakeholder is the Movielens users. Soliciting user judgements and opinions is often a key element in determining if an experimental change is successful. Additionally, one-off user studies (with participants recruited from email) are used to test features that are not ready to scale or integrate into the main user interface.

Finally, a key stakeholder is the researchers: both in Grouplens and the in the community more broadly. The openness of users to experiments on a broad range of features has enabled GroupLens research in many different areas on the Movielens platform. The regular release of anonymized datasets of movie ratings is important to the broader machine learning, data science, and information retrieval communities.

A potentially relevant group of stakeholders is movie producers. However, because Movielens is relatively small and isolated from larger commercial endeavors, it has limited impact on movie studios and production, so their interests are not in scope.

3.3 Explainability & Transparency

Does the system offer explanations of its decisions or actions? What is the purpose of these explanations? To what extent is the policy transparent, i.e. can decisions or actions be understood in terms of meaningful intermediate quantities?

The system displays predicted ratings alongside movies, explaining the movies position within a list, and suggesting to the user whether or not they will like the movie. The ranking policy is easily understood as a weighted combination of predicted rat-

ing and popularity. However, the computation of predicted ratings is more complex. Some available models are more easily explained to users than others (e.g. nearest neighbors vs. matrix factorization). However, the details are well documented in publicly available research papers [2], and researchers respond to user requests for explanation on the UserVoice discussion board [6].

3.4 Recourse

Can stakeholders or users contest the decisions or actions of the system? What processes, technical or otherwise, are in place to handle this?

By entering ratings, users are able to affect their preference models to hopefully become more accurate. Additionally, the movies displayed by the system are sourced from The Movie Database, which is user-editable. (Previously in v3.2-v3.5, users could add and edit movies to MovieLens directly.) Furthermore, the current version of the system allows users to choose between three recommender models. Finally, users can make suggestions and requests directly to designers on the UserVoice forum.

4 Implementation

4.1 Reward Details

How was the reward function engineered? Is it based on a well-defined metric? Is it tuned to represent a specific behavior? Are multiple terms scaled to make one central loss, and how was the scaling decided?

The reward is a weighted sum:

$$0.9 \cdot \text{rank}(\widehat{r}_{ui}) + 0.1 \cdot \text{rank}(p_i)$$

where $\widehat{r}_{ui}$ is the predicted rating of movie i by user u, p_i is the number of ratings movie i has recieved in the past 10 days, and rank normalizes input, returning 1 for the largest (across all movies) and 0 for the smallest. This blending is the result of empirical evidence that it improves user satisfaction.

4.2 Environment Details

Description of states, observations, and actions with reference to planning horizon and hypothesized dynamics/impact. What dynamics are brought into the scope of the optimization via feedback? Which dynamics are left external to the system, as drift? Have there been any observed gaps between conceptualization and resultant dynamics?

The system handles approximately 250k users and 30k movies. These numbers have grown over the years. In 1999 (v1.1), MovieLens received attention from the mass media, causing an increase in user signups. Since then, the user growth has been stable (20-30 signups per day), largely the result of word-of-mouth or unsolicited press. Early on, the movie database was hand-curated and primarily contained movies with wide theatrical release in the United States. In v3.2-v3.5, MovieLens added the ability for users to edit and add movies. Since v4.0, MovieLens uses The Movie Database, a free and open source user editable movie database.

The actions taken by the system are page displays of 10 movies in a ordered list, where pages can be perused by arrows. The views can be explicitly filtered with search terms like year and genre; these explicit inputs this make up a component of the observation. The second component is the entered ratings in the form `<user_id, movie_id, rating, timestamp>`.

There are three potential sources of dynamics in this environment: the addition of new movies, the joining and departing of users, and the preferences that users have for movies. Because this system effectively uses a planning horizon of 1, none of these dynamics are explicitly accounted for. This is appropriate, as the goal of MovieLens is not to shift broad patterns of movie consumption. Though the movies, users, and preferences may change over time, these changes are more likely to be due to external factors than feedback with the MovieLens system. Additionally, the data collected by MovieLens is not fine-grained enough to detect such impacts of feedback.

4.3 Measurement Details

How are the components of the reward and observations measured? Are measurement techniques consistent across time and data sources? Under what conditions are measurements valid and correct? What biases might arise during the measurement process?

Ratings are entered by users via clicks on a star graphic, and can take values 0.5-5 in half integer increments. Prior to v3.0, ratings took values in integer increments. The increased granularity was the most requested feature in a user survey. Prior to v4.0, ratings were entered through a drop-down menu, and the meaning of rating values was de-

scribed in a legend at the top of the page (see Figure 1).

A possible source of bias in the measured ratings is due to anchoring effects, due either to the displayed predicted rating or due to the historically provided movie rating legend. However, broad trends in rating values did not change when the legend was removed in v4.0

Finally, the recorded timestamp represents when a user adds a particular rating rather than when they watched a movie. This limits the ability of the system to detect the impacts of its own recommendations.

4.4 Algorithmic Details

The key points on the specific algorithm(s) used for learning and planning. This includes the form of the policy (e.g. neural network, optimization problem), the class of learning algorithm (e.g. model-based RL, off-policy RL, repeated retraining), the form of any intermediate model (e.g. of the value function, dynamics function, reward function), technical infrastructure, and any other considerations necessary for implementing the system. Is the algorithm publicly documented and is code publicly available? Have different algorithms been used or tried to accomplish the same goal?

The policy selects a page view to present to the user based on explicitly provided input and rating data. First, explicit input is used to filter the list of movies. Then, the recommender model is used to predict a user's ratings of these movies. Finally, the movies are displayed in order of these predicted ratings, blended with a popularity factor.

The main component of the policy is therefore the recommender model. This model is user-selectable, so that users can choose between a non-personalized baseline, a preference elicitation model intended for new users, an item-item collaborative filtering model, or a matrix factorization model. Further details on how these models are trained is available in [2]. Previously in v3.0-3.5, the recommender was fixed as an item-item collaborative filtering model. Prior to that in v1.0-2.0, the model was a user-user collaborative filtering model.

4.5 Data Flow

How is data collected, stored, and used for (re)training? How frequently are various components of the system retrained, and why was this frequency chosen? Could the data exhibit sampling bias, and is this accounted for in the learning algorithm? Is data reweighted, filtered, or discarded? Have data sources changed over time?

All user rating data is stored by MovieLens and used by the recommender models to make rating predictions. When a user enters a new rating, it immediately impacts their rating predictions, since the "input" to the recommender changes. Less frequently, the ratings are used to update the parameters of the recommender models. An anonymized subset of this data is also periodically released for use by the wider research community.

The dataset of user ratings is likely biased. There is sampling bias due to the fact that users only rate movies that 1) appear on a page and 2) that they have watched. These factors are directly and indirectly impacted by the MovieLens system itself. The fact that users can explicitly filter pageviews with search terms mitigates these effects, but it is unlikely that it removes them.

The initial Movielens system was trained on a public dataset from EachMovie of approximately 2.8 million ratings from 72k users across 1.6k movies, but this has since been discarded. The dataset was retired by HP in October 2004, and due to privacy concerns, it is no longer available for download.

4.6 Limitations

Discussion and justification of modeling choices arising from computational, statistical, and measurement limitations. How might (or how have) improvements in computational power and data collection change(d) these considerations and impact(ed) system behavior?

The most prevalent limitation of this system is that it does not plan over a long horizon and therefore does not consider the effects of dynamics. While a more complex policy would allow the system to adapt to ordering effects, the resulting temporal dependence would complicate the ability to users to reliably navigate the movie database. Furthermore, users do not always enter movie ratings immediately after watching a movie, instead sometimes entering batches of ratings for movies that they watched in the past.

4.7 Engineering Tricks

RL systems are known to be sensitive to implementation tricks that are key to performance. Are

there any design elements that have a surprisingly strong impact on performance? For example, state-action normalization, hard-coded curricula, model-initialization, loss bounds, or more?

The system cannot provide reliable recommendations until users provide a minimum number of ratings. This problem is avoided by the interface design: when a user joins the site, they express their preferences over several displayed clusters of movies. These preferences are used, in combination with the rating profiles of other users, to generate a psuedo-rating profile for the new user. Further description is available in [7].

This preference elicitation process replaced a minimum movie requirement. Previously, until a user rated a minimum number of movies, the front page would display 10 movies at a time. From v0-v3, the minimum number was 5, and of the 10 movies per page, nine were randomly selected from the database and one from a hand-designed list of recognizable titles. In v3, the minimum number was 15, and the 10 movies were selected for their popularity, excluding the top 50-150 movies. This increased requirement was due to the needs of an item-item (rather than user-user) collaborative filtering algorithm. The switch to a preference elicitation process was motivated by the observation that the 15 rating requirement was too arduous, taking users an average of 6.8 minutes to complete and 12.6% of users failing to complete it.

5 Evaluation

5.1 Evaluation Environment

How is the system evaluated (and if applicable, trained) prior to deployment (e.g. using simulation, static datasets, etc.)? Exhaustive details of the offline evaluation environment should be provided. For simulation, details should include description or external reference to the underlying model, ranges of parameters, etc. For evaluation on static datasets, considering referring to associated documentation (e.g. Datasheets *[8]).*

The primary evaluation is to consider various properties of recommender models on offline datasets. This includes many of the publicly released MovieLens datasets, which are described in detail in [1].

5.2 Offline Evaluations

Present and discuss the results of offline evaluation. For static evaluation, consider referring to associated documentation (e.g. Model Cards *[9]). If applicable, compare the behaviors arising from counterfactual specifications (e.g. of states, observations, actions).*

This offline evaluation includes prediction accuracy (RMSE), top-N accuracy (recall), diversity (intra-list similarity), and popularity. Detailed evaluations are available in [2], and key quantities are displayed in (Figure 2).

5.3 Evaluation Validity

To what extent is it reasonable to draw conclusions about the behavior of the deployed system based on presented offline evaluations? What is the current state of understanding of the online performance of the system? If the system has been deployed, were any unexpected behaviors observed?

Offline evaluation metrics (like top-N accuracy) were chosen to align with the ranking setting. While the offline evaluations are imperfect (due to dataset biases), the system appears to work well ad no unexpected behaviors have been observed.

5.4 Performance standards

What standards of performance and safety is the system required to meet? Where do these standards come from? How is the system verified to meet these standards?

N/A

6 System Maintenance

6.1 Reporting Cadence

The intended timeframe for revisiting the reward report. How was this decision reached and motivated?

This report is updated whenever there is a major system update, either to the user interface or the backend. Such updates will occur periodically, coinciding with research initiatives.

6.2 Update Triggers

Specific events (projected or historic) significant enough to warrant revisiting this report, beyond the cadence outlined above. Example triggers include

a defined stakeholder group empowered to demand a system audit, or a specific metric (either of performance or oversight) that falls outside a defined threshold of critical safety.

If a large change is observed in oversight metrics, or if many users express dissatisfaction on the UserVoice forum, the system design will be revisited by the researchers who maintain it. If an update is deemed necessary, this report will be updated.

6.3 Changelog

Descriptions of updates and lessons learned from observing and maintaining the deployed system. This includes when the updates were made and what motivated them in light of previous reports. The changelog comprises the central difference between reward reports and other forms of machine learning documentation, as it directly reflects their intrinsically dynamic nature.

The versions of this report are enumerated as vX.Y where X corresponds to the user interface version and Y corresponds to major changes within interfaces.

- v0.0 (August 1997) Initial release.
- v0.1 (April 1998) The ML 100K dataset is released, covering 9/1997–4/1998.
- v1.0 (September 1999) Update to v1 interface.
- v1.1 (November 1999) Media exposure causes an increased number of users. Switch from GroupLens to Net Perceptions recommender model.
- v2.0 (February 2000) Update to v2 interface. Additional movie metadata and reviews added to movie details pages.
- v3.0 (February 2003) Update to v3 interface. Switch from Net Perceptions user-user recommender to MultiLens item-item recommender. Ratings now in half-star (rather than full) increments. Require that users rate at least 15 movies before receiving recommendations. The ML 1M dataset is released, covering 4/2000–2/2003.
- v3.1 (June 2005) Added discussion forums to site.
- v3.2 (September 2008) Added feature so that users can add movies to database.
- v3.3 (January 2009) The ML 10M dataset is released, covering 1/1995–1/2009.
- v3.4 (Spring 2009) Netflix API integration for poster art and synopsis.
- v3.5 (January 2012) Switch from Multilens to Lenskit recommender (still item-item).
- v4.0 (November 2014) Update to v4 interface. Rating interface combined with "predicted rating" star graphic to accept click events. Switch to user-selectable recommender model. Legend describing the meanings of ratings and dropdown menu removed. Drop minimum rating requirement in favor of group-based preference elicitation. Integration with The Movie Database for plot summaries, movie artwork, and trailers.
- v4.1 (March 2015) The ML 20M dataset is released, covering 1/1995–3/2015. Moving forward, MovieLens will make public additional nonarchival datasets: `latest` which is unabridged for completeness and `latest-small` for educational use.

C.3 Example Reward Report - MuZero

The purpose of MuZero (and its preceding systems, AlphaGo and AlphaZero) is to improve state-of-the-art performance in the games of chess, Go, shogi, and a benchmark suite of Atari games [60]. We provide a Reward Report that documents the evolution of the system through these successive stages of development, including changes in the design motivation and performance metrics, as well as more extensive use of reinforcement learning.

1 System Details

1.1 System Owner

This may be the designer deploying the system, a larger agency or body, or some combination of the two. The entity completing the report should also be indicated.

This system was developed by the DeepMind core Reinforcement Learning Team members. More information about AlphaGo's development can be found at the project website (https://deepmind.com/research/case-studies/alphago-the-story-so-far) as well as DeepMind's GitHub repository

1.2 Dates

The known or intended timespan over which this reward function & optimization is active.

Development of AlphaGo began about two years prior to the matches against Lee Sedol in spring 2016, shortly after DeepMind's acquisition by Google [Ribeiro(2016)]. Development of AlphaZero, based entirely on self-play, followed AlphaGo and was completed prior to October 2017. Development of MuZero, also based on self-play, followed AlphaZero and was first described in a preliminary paper in 2019 [Schrittwieser et al.(2020)].

1.3 Feedback & Communication

Contact information for the designer, team, or larger agency responsible for system deployment.

Any correspondence should be directed to `press@deepmind.com`.

1.4 Other Resources

Where can users or stakeholders find more information about this system? Is this system based on one or more research papers?

There is little additional disclosed information.

2 Optimization Intent

2.1 Goal of Reinforcement

A statement of system scope and purpose, including the planning horizon and justification of a data-driven approach to policy design (e.g. the use of reinforcement learning or repeated retraining). This justification should contrast with alternative approaches, like static models and hand-designed policies. What is there to gain with the chosen approach?

Go, and general game-playing at a human level, was long defined as one of the "grand challenges" of AI. For AlphaGo, the use of reinforcement to learn both the policy and value networks beyond the abilities of a human expert.

For AlphaZero, the sole use of reinforcement learning without any human data was important validation of its potential as a more general learning procedure [Silver et al.(2017)]. The algorithm additionally incorporated lookahead search (Monte Carlo Tree Search) inside the training loop.

For MuZero, the use of model-based reinforcement learning without any prior knowledge of the game dynamics was further indication of RL's potential to develop planning capabilities in more challenging or complex domains [Schrittwieser et al.(2020)]. The learned model performed well in both classic game environments (Go, chess, shogi) as well as canonical video game environments (57 distinct Atari games).

2.2 Defined Performance Metrics

A list of "performance metrics" included explicitly in the reward signal, the criteria for why these metrics were chosen, and from where these criteria were drawn (e.g. government agencies, domain precedent, GitHub repositories, toy environments). Performance metrics that are used by the designer to tune the system, but not explicitly included in the reward signal should also be reported here.

As with most game-playing systems, the performance metric is defined as a win rate among games. In other games, score is used, but in

one-versus-one games win rate is the only direct metric. To better capture the uncertainty of playing varying opponents, this win rate is translated into a running Elo rating system.

2.3 Oversight Metrics

Are there any additional metrics not included in the reward signal but relevant for vendor or system oversight (e.g. performance differences across demographic groups)? Why aren't they part of the reward signal, and why must they be monitored?

Some other performance metrics are not included in the specification, but are monitored for the purpose of evaluating system effects on the domain:

- Absolute opponents' world rankings - following their public games, versions of AlphaGo and AlphaZero were considered to possibly improve the skill levels of expert human opponents, as measured by those players' absolute world ranking. If humans played better after playing AlphaGo, this was to be seen as a positive effect of the system's influence on the game of Go. Fan Hui, following his games against AlphaGo, claimed it made him a better played and accredits his world ranking jump from 600 to 300 in three months to training against it [Murgia(2016)].
- Qualitative changes in playstyle - following their public games, versions of AlphaGo were considered to possibly influence the playstyle of expert human opponents, as interpreted by the wider community of expert players. If expert humans played differently, more creatively or unpredictably, or expressed surprise after AlphaGo's public performances, this was to be seen as a positive effective of the system's influence on the game in question. Garry Kasparov, following his observation of AlphaZero play, was impressed that it appeared to be "a very sharp and attacking player" given that almost all computer programs have a conservative playstyle [Ingle(2018)]. While not integral in any way for system performance, AlphaGo's performance and playstyle have had a noticeable impact on the strategies of expert human players.

2.4 Known Failure Modes

A description of any prior known instances of "reward hacking" or model misalignment in the domain at stake, and description of how the current system avoids this.

Monte Carlo search limitations. In the fourth match (of five) against Lee Sedol in spring 2016, the system failed to recognize move 78 by Sedol. The Monte Carlo search tree, which was designed to prune sequences of moves considered to be irrelevant for maximizing odds of victory, failed to recognize this move. This is because that move was so far outside the distribution of prior game situations that the AlphaGo system failed to accurately calculate its significance for determining the odds of victory [Ormerod(2016)]. The result was a sequences of moves 79-87 by AlphaGo that were considered poor by expert human players, a function of Monte Carlo's myopic look-ahead search following move 78. AlphaGo subsequently conceded the game at move 178, at which point it evaluated its own odds of victory as lower than 20 percent [Metz(2016)].

3 Institutional Interface

3.1 Deployment Agency

What other agency or controlling entity roles, if any, are intended to oversee the ongoing post-deployment operation of the RL system? How may these roles change following system deployment?

The AlphaGo system was developed by DeepMind. This version played against Fan Hui in 5 matches held at DeepMind headquarters in October 2015. These matches were secret and not revealed until the publication of results in January 2016 [Silver et al.(2016)]. A later version of the same system, AlphaGo Lee, played Lee Sedol in March 2016 in 5 matches in Seoul, South Korea. This match was overseen by the

Korea Baduk Association. A yet more sophisticated version of the same system, AlphaGo Master, played against Ke Jie at the Future of Go Summit in Wuzhen, China in May 2017. An earlier version of AlphaGo Master, dubbed Master, had already won 60 straight online games against top pro players, including against Ke Jie [Silver and Hassabis(2017)]. This version was awarded a professional 9-dan title by the Chinese Weiqi Assocation.

3.2 Stakeholders

What other interests are implicated in the design specification or system deployment, beyond the designer? What role will these interests play in subsequent report documentation? What other entities, if any, does the deployed system interface with whose interests are not intended to be in scope?

Compared to other prominent automated game-playing systems like Stockfish (open-source chess engine) or CrazyStone (offline Go engine based on deep learning), versions of AlphaGo perform much much better with additional computational power. The versions of AlphaGo that played against Fan Hu, Lee Sedol, and Ke Jie all made use of distributed CPUs and GPUs. AlphaGo Zero, based entirely on reinforcement learning and self-play, became stronger than AlphaGo Lee after 3 days and stronger than AlphaGo Master after 21 days. Its self-play training time was stopped after 40 days, at which point it was stronger than any known Go player (human or program) as measured by Elo rating in October 2017 [Silver and Hassabis(2017)].

AlphaZero, in its initial chess games against Stockfish, was criticized by expert human chess players has having unfair computational advantages over the opponent [Doggers(2018)].

MuZero's learning has been made more efficient in follow-up work, dubbed EfficientZero [Ye et al.(2021)].

3.3 Explainability & Transparency

Does the system offer explanations of its decisions or actions? What is the purpose of these explanations? To what extent is the policy transparent, i.e. can decisions or actions be understood in terms of meaningful intermediate quantities?

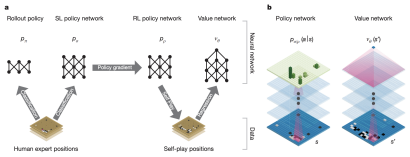

Figure 1: The AlphaGo game playing system architecture.

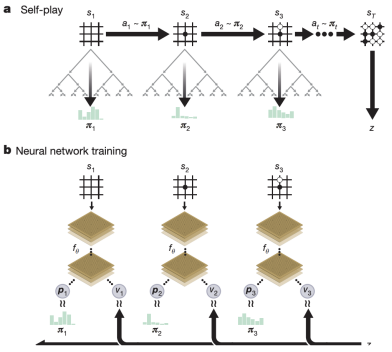

Figure 2: The AlphaZero game playing system architecture.

The MuZero system offers few tools for transparency in its current form. While the learning process develops a structured model for the game dynamics, it is not done in a way that is accessible by engineers or external parties.

3.4 Recourse

Can stakeholders or users contest the decisions or actions of the system? What processes, technical or otherwise, are in place to handle this?

N/A

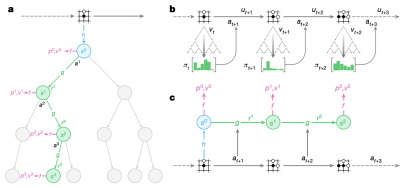

Figure 3: The MuZero general game playing system.

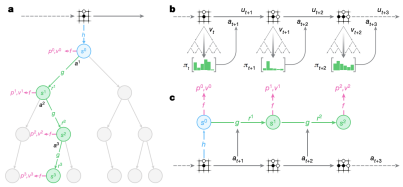

Figure 4: The MuZero general game playing system.

4 Implementation

4.1 Reward Details

How was the reward function engineered? Is it based on a well-defined metric? Is it tuned to represent a specific behavior? Are multiple terms scaled to make one central loss, and how was the scaling decided?

The reward function is entirely prescribed as win rate, and the resulting Elo rating. An important sub-component that will be referenced later is the value function estimating game state. This is an internal representation of reward central to training and evaluation.

4.2 Environment Details

Description of states, observations, and actions with reference to planning horizon and hypothesized dynamics/impact. What dynamics are brought into the scope of the optimization via feedback? Which dynamics are left external to the system, as drift? Have there been any observed gaps between conceptualization and resultant dynamics?

The original environment is the full game of Go which is constrained by finite rules, but other games with visual states were added.

4.3 Measurement Details

How are the components of the reward and observations measured? Are measurement techniques consistent across time and data sources? Under what conditions are measurements valid and correct? What biases might arise during the measurement process?

The measurements differ across games from the full gameboard to a visual rendering of the world. Extracting information from pixels is substantially less efficient than directly from the game state.

4.4 Algorithmic Details

The key points on the specific algorithm(s) used for learning and planning. This includes the form of the policy (e.g. neural network, optimization problem), the class of learning algorithm (e.g. model-based RL, off-policy RL, repeated retraining), the form of any intermediate model (e.g. of the value function, dynamics function, reward function), technical infrastructure, and any other considerations necessary for implementing the system. Is the algorithm publicly documented and is code publicly available? Have different algorithms been used or tried to accomplish the same goal?

The key algorithm feature is the use of Monte Carlo Tree Search (MCTS). MCTS is used to search over board states (by planning over actions) and parses the value representation. The value function is represented by a deep neural network mapping from game state to value.

The second crucial element to training is self play. Here gameplaying agents evaluate their performance versus past training snapshots. This synergistic mechanism is crucial to reaching superhuman performance. In MuZero, and learned model is used to used to improve performance in games without complete information (such as visual states) by constraining the policy optimization. At each turn, the model is used to predict the correct policy, the value

function, and the reward received by the move (in games that have an intermediate score). The model is updated in an end-to-end fashion, so it is included in the same training loop in the agent architecture.

Fully algorithmic details and open source code are not released.

4.5 Data Flow

How is data collected, stored, and used for (re)training? How frequently are various components of the system retrained, and why was this frequency chosen? Could the data exhibit sampling bias, and is this accounted for in the learning algorithm? Is data reweighted, filtered, or discarded? Have data sources changed over time?

Data flow is not well documented, but it relies on Google's distributed training and deployment infrastructure.

4.6 Limitations

Discussion and justification of modeling choices arising from computational, statistical, and measurement limitations. How might (or how have) improvements in computational power and data collection change(d) these considerations and impact(ed) system behavior?

4.7 Engineering Tricks

RL systems are known to be sensitive to implementation tricks that are key to performance. Are there any design elements that have a surprisingly strong impact on performance? For example, state-action normalization, hard-coded curricula, model-initialization, loss bounds, or more?

Not documented.

5 Evaluation

5.1 Evaluation Environment

How is the system evaluated (and if applicable, trained) prior to deployment (e.g. using simulation, static datasets, etc.)? Exhaustive details of the offline evaluation environment should be provided. For simulation, details should include description or external reference to the underlying model, ranges of parameters, etc. For evaluation on static datasets, considering referring to associated documentation (e.g. Datasheets *[Gebru et al.(2021)]).*

For games, the simulator is reality so evaluation is matched to training.

5.2 Offline Evaluations

Present and discuss the results of offline evaluation. For static evaluation, consider referring to associated documentation (e.g. Model Cards *[Mitchell et al.(2019)]). If applicable, compare the behaviors arising from counterfactual specifications (e.g. of states, observations, actions).*

Multiple internal evaluations of the agent were performed prior to high-profile, public matches with the worlds best players.

5.3 Evaluation Validity

To what extent is it reasonable to draw conclusions about the behavior of the deployed system based on presented offline evaluations? What is the current state of understanding of the online performance of the system? If the system has been deployed, were any unexpected behaviors observed?

5.4 Performance standards

What standards of performance and safety is the system required to meet? Where do these standards come from? How is the system verified to meet these standards?

N/A.

6 System Maintenance

6.1 Reporting Cadence

The intended timeframe for revisiting the reward report. How was this decision reached and motivated?

While this system is evaluated in closed-world games, updates are not anticipated.

6.2 Update Triggers

Specific events (projected or historic) significant enough to warrant revisiting this report, beyond the cadence outlined above. Example triggers include a defined stakeholder group empowered to demand a system audit, or a specific metric (either of performance or oversight) that falls outside a defined threshold of critical safety.

This report will be revisited upon release of each new game-playing AI from DeepMind.

6.3 Changelog

Descriptions of updates and lessons learned from observing and maintaining the deployed system. This includes when the updates were made and what motivated them in light of previous reports. The changelog comprises the central difference between reward reports and other forms of machine learning documentation, as it directly reflects their intrinsically dynamic nature.

N/A (v1)

ABSTRACT

Since Siri's release in 2011 there have been a growing number of AI-driven domestic voice assistants that are increasingly being integrated into devices such as smartphones and TVs. But as their presence has expanded, a range of ethical concerns have been identified around the use of voice assistants, such as the privacy implications of having devices that are always listening and the ways that these devices are integrated into the existing social order of the home. This has created a burgeoning area of research across a range of fields including computer science, social science, and psychology. This paper takes stock of the foundations and frontiers of this work through a systematic literature review of 117 papers on ethical concerns with voice assistants. In addition to analysis of nine specific areas of concern, the review measures the distribution of methods and participant demographics across the literature. We show how some concerns, such as privacy, are operationalized to a much greater extent than others like accessibility, and how study participants are overwhelmingly drawn from a small handful of Western nations. In so doing we hope to provide an outline of the rich tapestry of work around these concerns and highlight areas where current research efforts are lacking.

CCS CONCEPTS

1 INTRODUCTION

The last decade has seen the widespread introduction of voice assistants (VAs) into domestic life in many parts of the world. Offering novelty and convenience driven by advancements in AI technologies such as machine learning and natural language processing, VAs have transformed the home computing landscape. Positioned by vendors at the centre of the smart home as a hub for other apps and gadgets, research shows that VAs are most commonly used to play music, search for information, and control other IoT devices [11]. In this way, their usage extends that of the smartphone where app stores allow for the use of a wide variety of third-party software, and many smartphone apps are also available as skills/actions. But VAs do not simply offer access to traditional means of computing via a new interaction modality, their design and interfaces also represent a number of novel experiences and changes in people's underlying relationship with the technology that they use.

The continued integration of speech into the smart *home*—a space often idealised as private, safe, and intimate—disrupts existing social norms, and the frequent gendering of voice assistants as female has prompted harsh criticism of the way that VAs implicitly perpetuate stereotypes around gendered work [149]. After police took steps to use Alexa recordings in a murder trial, legal scholars began to examine more seriously the (lack of) protections for data that is collected in the home but stored in the cloud [109]. In some cases this represents the latest in ongoing debates around parenting and privacy as VAs challenge and reframe existing norms by altering what is and is not possible. In other areas VAs have resurrected much older ethical concerns, revealing new dimensions of long-standing concepts like anthropomorphism. While the affective potential of computers that use natural language has been known for decades [111, 148], voice assistants take this previously unattainable technical capability of *conversation*—that activates the same areas of the brain as speech between people [101]—and scales it to billions of speakers, TVs, headphones, smartphones, and other devices around the globe.

The breadth of these ethical concerns means that research has emerged from a diverse range of disciplines, including computer science, social science, and psychology, each with different practices and conventions. The sensitive nature of the home environment and relationships drives us now to pause and take stock of the literature on ethical concerns with voice assistants. To this end we conducted a systematic literature review with the aim of capturing the concerns that have been identified and how they are studied. The results are valuable both in understanding current

areas of enquiry as well as in identifying opportunities for future work. Beyond this we were also interested in the diversity and inclusion of participants. When conducting research that tells us about people and their social interactions we must acknowledge that people of different cultures, ages, genders, abilities, etc. experience voice assistants differently and have different concerns about them. As a provocation intended to foster a more inclusive—and accurate—body of knowledge, we use our review to highlight the overwhelming bias towards "WEIRD" (Western, Educated, Industrialized, Rich, and Democratic) countries in the venues searched. Beyond geography we also examine other dimensions of diversity in research that focuses on specific groups, such as those around gender, that reflect and inform social and cultural norms.

More specifically we answer the following research questions:

RQ1 What is the current state of research on ethical concerns in voice assistants?

RQ2 How are participants, methods, and approaches represented across this research?

And in so doing make the following contributions:

- Map out the current knowledge on ethical concerns around privacy, social interaction, accessibility, social order, performance of gender, accountability, conflicts of interest, misinformation, and transparency
- Show that research on voice assistants overwhelmingly studies WEIRD demographics
- Highlight key directions for future work in this area, including challenging legacy assumptions about how VAs are designed and deepening explorations of how VAs interact with gender in society

2 METHODOLOGY

In order to assess prior work on ethical concerns around the design and use of voice assistants in the home we conducted a systematic literature review, i.e., one with "a clearly formulated question that uses systematic and explicit methods to identify, select, and critically appraise relevant research" [94]. We followed established guidance on systematic reviews which lays out the main steps around searching for and analysing prior work. This involves identifying: (1) eligibility criteria for included papers; (2) databases to be searched; (3) parameters for the search; (4) the process for selecting studies from the set of returned papers; and (5) how data will be extracted from those papers [94].[1]

2.1 Eligibility Criteria and Databases Searched

We considered journal articles, conference papers, extended abstracts, and short papers about voice assistants since 2012 to coincide with the initial commercial availability of voice assistants. As our focus was on voice assistant research, we searched the ACM Digital Library, IEEE Explore, Web of Science, and DBLP.

2.2 Search Parameters

Conducting the search presented a 'cold start' problem: reviewing every paper on voice assistants to distil out concerns was infeasible, but at the same time there was no existing literature mapping out ethical concerns with VAs from which we could draw keywords to narrow down the search. Following common practice in studies of this type (e.g. [37]) we used adjacent prior work and domain knowledge to build a list of keywords. The positioning of VAs as 'smart devices' means that study of them often falls under the umbrella of smart home research, so we selected concerns from four papers summarising ethical concerns in smart homes that were applicable to voice assistants [44, 103, 125, 151]. We then drew on domain knowledge to supplement this with ethical challenges specific to VAs using work on individual concerns, highlighting additional issues that arise outside of the main discussion on challenges and barriers to smart home adoption (e.g. around social interaction and the performance of gender). During this process we adopted a broad view of ethics and related concerns; following prior work we define ethics as "what a design object ought to be based on ethical and moral codes", in contrast with its purpose/function (reason), and visual values/presentation (aesthetics) [67]. The final set of resulting keywords is given in Table 1. During the review we adjusted the categorisation of concerns to best describe the literature returned by the survey (more information on this is given in Section 5.6), arriving at the following concerns from papers on smart homes:

- Privacy [44, 103, 125, 151]
- Agency and Autonomy [103, 125, 133, 151]
- Social Order and Accountability [44, 125]
- Transparency [103, 125, 133]
- Conflicts of Interest & Datafication [103, 125]

Supplemented by four concerns unique to voice assistants:

2.2.1 Social Interaction. The use of speech and conversation by VAs has raised concerns about how they might change how people interact both with them and each other. Work in this space has shown how people automatically apply social rules and draw upon gender stereotypes in interactions with computers [100], and use anthropomorphism as a heuristic to help develop mental models of computers and robots [154].

2.2.2 Performance of Gender. Popular voice assistants are explicitly gendered: Alexa reports to be "female in character", Google Assistant was described by an engineer as "a young woman from Colorado", and Siri is a Scandinavian female name [149]. What is now an industry norm has been criticised for reinforcing existing societal biases around the role of women in the workforce, portraying them as "obliging, docile and eager-to-please helpers" [149].

2.2.3 Accessibility. Voice assistants present unique challenges and opportunities for accessibility in the smart home. On the one hand, by using voice as their primary or only mode of interaction they align well with the needs of communities such as the blind and partially sighted [4], but as a direct consequence, they disproportionately fail people with speech, language, or hearing difficulties.

2.2.4 Misinformation. In an extension of studies around the quality and potential bias of information provided by internet search engines [61], researchers have begun to examine the information provided by voice assistants [36]. This is particularly important for VAs because succinctly conveying the source and accuracy of information provided via speech is a significant challenge.

[1] As the PRISMA guidelines are intended for clinical reviews, we have omitted steps that would be inappropriate for the present research (e.g., summary measures used across the reported papers).

Papers containing at least one of the following devices:	
Alexa	Siri
Google Assistant	Voice assistant
Virtual assistant	Intelligent personal assistant
Smart Home	-
And at least one of the following key words:	
Privacy	Anthropomorphism
Autonomy	Personification
Children	Gender
Conflict of interest	Agency
Social Order	Accessibility
Ethics	Accountability
Transparency	-
As an article, conference paper, extended abstract or short paper published since 2012	

Table 1: Search criteria

2.3 Study Selection

To be considered in scope, papers had to feature significant results that directly addressed one or more ethical concerns around voice assistants used for domestic tasks in the home or via a smartphone (**e.g. a study on smart homes would only be in-scope if it had findings specific to voice assistants**). Papers where the results only detailed *solutions* to ethical concerns were out of scope (i.e. where the understanding of concerns came solely from background literature), as were papers that developed or applied voice assistants to tasks or contexts outside of normal domestic use (e.g. medical treatment). Energy usage was not considered an ethical concern in the context of the review as it relates to the smart *home* in general rather than voice assistants as a class of devices. While many papers explicitly listed the keyword topics as concerns, we did not exclude papers that made no or implicit references to the key words as concerns (e.g. participants describing an emotional connection to a voice assistant with no associated normative judgement).

2.4 Data Extraction

The full text of the selected papers were coded for methodology, type of contribution, and the ethical concern(s) targeted. Two researchers initially considered a small subset of the papers, meeting to compare and refine the process before applying this to the rest of the data. To the end of answering RQ2 on the diversity of those who are represented in human-AI interaction (HAI) and human-computer interaction (HCI) research, we also coded the geographic location of participants (i.e. country of residence). Where participants from multiple countries were sampled, papers were coded to the majority demographic. In a small number of cases where papers listed the platform used for recruitment without specifics on participants' country of residence, those papers were coded with the majority for that platform (in all cases this was the US).

2.5 Results of the Search Process

The initial keyword search returned 1230 unique papers (ACM: 384, IEEE: 389, Web of Science: 266, DBLP: 191). While the systematic search was generally very effective, a small number of relevant papers (22) known to the research team fell outside the range of the search, and were also added. This occurred mainly because the papers were not indexed by the chosen platforms, and occasionally because they used non-trivial variations of the search keywords (e.g. social cohesion/group dynamics vs social order in [79]). The first sift identified 138 papers as potentially within scope, which were then coded for methodology, type of contribution, participant country of residence, and the ethical concern(s) targeted. The papers were then grouped by primary concern, and the analysis below is the result of repeated iterations by the wider research team. Four papers were excluded at this stage due to being unobtainable online and 17 for being outside the scope of the review, leaving 117 papers for full analysis. A flow diagram of the search process is given in Figure 1, a record of the included papers and categorisations is available online at https://osf.io/p4h2r, and numerical overviews of the review categories are provided in the Appendix.

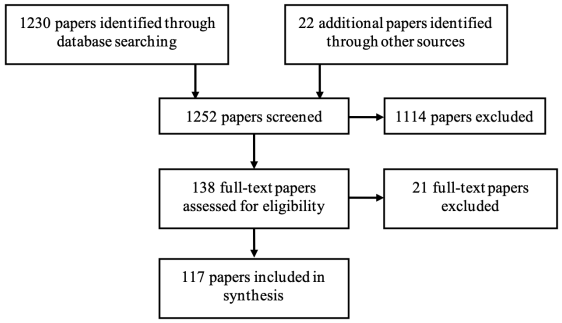

Figure 1: Flow diagram of the search process.

3 RESEARCH TRENDS

3.1 What Concerns are Studied, and How?

This section describes the distribution of approaches and methods across the reviewed papers in order to answer RQ2. Unsurprisingly, privacy was the most prevalent concern investigated, followed by social interaction. The high-level research approaches adopted show quantitative methods as most common followed by qualitative, theoretical, and finally mixed approaches. Overall there was a greater diversity in methods amongst qualitative approaches, although surveys and interviews together represented approximately 39% of research methods. Figures 2 and 3 show the relative proportions of concerns, approaches, and methods in the review sample. A full breakdown is provided in the appendix.

From the charts it is clear that several ethical concerns appear under-researched given current public debate around voice assistants and digital technology more generally. Misinformation and performance of gender stand out as particular examples of this, although the latter *was* the centre of burgeoning discussion—6 out of the 14 theoretical papers in the review discussed the performance of gender by VAs, and these are likely to form the foundation of future empirical studies. Related to this it appears that certain concerns are perceived to be more readily operationalised than others. While 67% of empirical privacy research utilised a quantitative approach over a qualitative one, for empirical research on social interaction

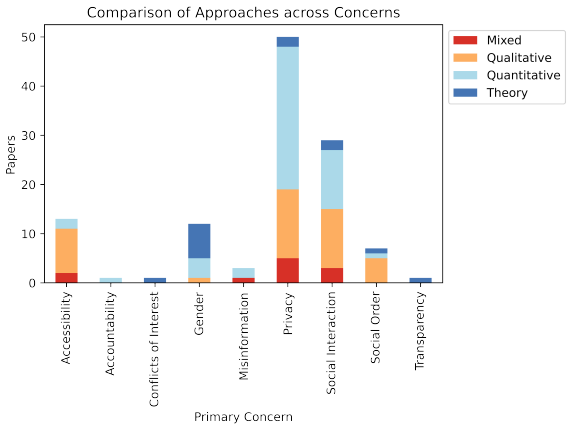

Figure 2: Approaches used by primary concern.

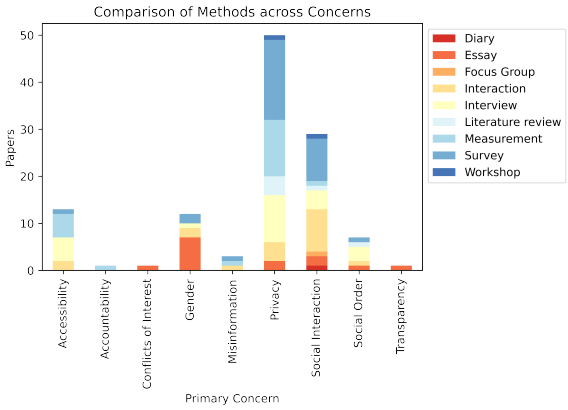

Figure 3: Methods used by primary concern. Note that papers with similar methods may have their research approaches (e.g. qualitative, quantitative, etc.) coded differently depending on how the analysis was conducted.

both were equally likely, and empirical research on accessibility was *much* more likely to be qualitative (82%).

Our understanding of all of the concerns described in the review, even the more extensively researched such as privacy, is still evolving, and prematurely quantifying them can lead to research losing sight of the users (people) behind the voice assistants we study. Related to debates within the fairness, accountability, and transparency community on how appropriate it is to quantify various aspects of the human experience that then feed into vast assemblages of data processing [51, 65], researchers should be cautious when attempting to quantify the lived experiences that relate to the concerns described in the review. The analysis shows that researchers are much more comfortable doing this for some concerns than for others, and this leads to the literature giving a distorted view of how best to investigate different concerns. When ethical concerns are quantified it invites comparison between the resulting metrics, whether this is intentional or not, which is problematic when definitions vary between data sets; efforts to create privacy labels demonstrate this tension well by often equating the nuanced personal concerns of individuals with abstract scores representing technical device behaviours [45]. This occurs despite a more complex understanding of privacy outside of the voice assistant literature: Nissenbaum's model of privacy as contextual integrity, for example, heavily involves norms and relationships [104]. The 'Seven Veils' model of privacy similarly includes rights and phenomenological aspects that encapsulate different meanings of privacy and clearly benefit from a deep understanding of the human experiences involved [105] that we argue should not be primarily investigated via a quantitative lens.

On the other hand, there clearly are some situations where quantitative approaches are required, such as in studies of the ecosystems that underpin voice assistants through skill/action marketplaces. Here automated approaches are the only or most efficient means to scale analysis for work on many thousands of skills or reviews. Similarly, quantification may be more appropriate for research questions that follow an established model or framework and use terms related to these concerns in a well-defined way.

Despite the 10 year search window the oldest paper in the literature review was from 2015, with 87% of papers published in the past three years. The most numerous year was 2020, comprising 37% of the sample. Comparing research methods and approaches from 2019 to 2021 reveals an increase in the proportion of publications utilising quantitative methods from around 41–42% in 2019 and 2020 to 63% in 2021,[2] likely as research moved online during the coronavirus pandemic.

3.2 Whose Voices are Heard in VA Research?

An ongoing problem in HAI is the lack of diversity amongst the people who are included in research. With this in mind, the community has so far sought to create a welcoming and accessible space for researchers and practitioners. However, the results of the analysis indicate that diversity amongst the *participants* in HAI research remains a major problem. When answering RQ2, 94% of the 85 papers were conducted solely or mostly on participants from North America and Europe (see Table 2). This mirrors a long-running trend in HCI research, with 73% of CHI studies from 2016–2020 recruiting participants from nations with less than an eighth of the world's population [85]. Our review of papers across a range of HAI and HCI venues shows that this effect is even more pronounced in voice assistant research. During this analysis we were forced to reflect on our own prior research, which exhibits the very same 'WEIRD' biases. This is something that we aim to address in future research projects, and hope that others will join us in creating a more inclusive global account of how voice assistants are perceived and used.

Another aspect of participation included in the analysis was the specific populations targeted by research studies. Of the 22 papers that explored the experiences of a particular group, 13 were focused on age, 7 on (dis)ability, and 1 each on trans/non binary and Portuguese speakers (see Table 3). Together these represented just over one quarter of the studies that recruited human participants. Within the papers concerned with age there was a diversity of

[2]The review snapshots were taken between September and November of 2021, meaning that papers indexed after that time are not included in the results.

Country	Papers	Country	Papers
USA	47	Netherlands	2
UK	11	Ireland	1
Germany	10	South Korea	1
Italy	4	Spain	1
India	2	Sweden	1
Brazil	2	Switzerland	1
Canada	2		

Table 2: Participant country of residence for papers with human participants.

concerns across anthropomorphism (5), accessibility (4), social order (2), and accountability (1). In contrast, all of the papers that recruited based on ability were focused on accessibility concerns. Studies looking at specific groups mainly took qualitative approaches (70%), suggesting a focus on lived experiences rather than the gathering of a high level overview. This may present an opportunity for future work (e.g. the state of accessibility across an entire platform).

4 ANALYSIS OF ETHICAL CONCERNS

4.1 Privacy

As with many other areas of research, voice assistant privacy is a concept that encompasses a variety of perspectives. At a high level, most papers aligned along two approaches: eliciting user concerns over privacy when using voice assistants, and measuring an aspect of voice assistant behaviour in order to make claims about the (lack of) privacy offered by those devices.

A major theme amongst exploratory studies about user concerns was data collection and processing by vendors and third parties, including from the use of voice assistants by inhabitants of the home beyond the primary user. Various distinctions were given to illustrate the boundaries of acceptable data use, including between first/third parties [77], normal/sensitive subject matters [11], and whether data was subsequently analysed by humans or machines [92]. Where other entities were mentioned, these were mostly the government [116], or just a vague 'other' with malicious intent [77]. This was sometimes associated with data breaches of first [77] or third parties [136].

Another dominant theme was that of uncertainty when users characterised privacy risks. While the capability of voice assistants to constantly listen to their surroundings was well understood, there was a lack of understanding about when voice recordings were stored by their devices and how this data was subsequently used by vendors. While several papers called for more transparency around data collection and some users were open to having their concerns addressed by vendors [143], it is unclear if this would be convincing given widespread scepticism over the honesty of major players given their vested interests [77]. This uncertainty was complicated by phantom activations [92] and confusion over whether the mute button affected the device's microphone or speaker [77].

The root of these concerns was often vague or incorrect mental models of devices [1, 63], as demonstrated by poor knowledge of available privacy controls (e.g. the ability to replay and delete stored voice recordings) [11]. Where voice profiles were set up they often had high error rates [63], reducing the perceived reliability of the underlying technology. This often resulted in disengagement through what were sometimes called 'informal' coping mechanisms such as unplugging the device [1] or making sensitive requests through other means [11]. It is also reflected in the reasons that participants gave for not taking action and continuing to use their devices, such as having nothing to hide [92], being unable to escape the influence of large technology companies [77], disbelief that companies could store the required volume of data [77], or relying on protection from laws and regulations [92]. Though participants knew that devices could infringe on their privacy, this was often framed as a necessary tradeoff against functionality or convenience [52, 63, 77, 136].

It is clear that user understanding of voice assistants continues to be a key issue, with privacy being a more visible situation where inaccurate mental models come to the fore. This concern has two related components: on-device affordances around recording give insufficient certainty about the device's operation, and users simultaneously lack trust in manufacturers; 'soft' mechanisms used to signal device state (e.g. for a muted microphone) are unconvincing in devices designed to constantly listen, and the poor track records of vendors around privacy and ethics creates a situation where these mechanisms may *never* be sufficient because they are unverifiable and rely on trust. It is therefore likely that effective solutions in this area will rely on local processing, the use of open source software, or external devices that limit data collection capabilities.

A more tangible aspect of VA use concerned the tensions and risks posed by other users of shared devices. Cohabitants often overheard interactions with voice assistants [63] and these concerns frequently blurred into more specific concerns around the ability to purchase items via voice command, which was often disabled as a result [1]. More generally, VAs were seen to artificially create or remove asymmetries around access to data that were already established between cohabitants (see also Section 4.4 on social order concerns). This was typically noticed when requests for content were actioned through someone else's account [77] or upon reflection that guests/children would be able to make identical requests [63]. There was also discussion of how both vendors and the law placed the burden on users to manage the privacy of shared devices, and how it was difficult for 'bystanders' to effectively opt-out of being recorded [92]. Differing mental models of voice assistants by participants led to frequent worries that they or someone else might overstep privacy boundaries, but in many cases the examples given would not be possible on current devices or could be avoided by using personalised voice profiles. Another attack vector that participants expressed concern about was neighbours or other people outside the home's inhabitants giving commands to the voice assistant from outside or while in the home as a guest [1, 63, 143], and one measurement paper verified the efficacy of this attack [91]. Motives were typically vague or absent when discussing these instances of 'shouting through letterboxes', especially given people's propensity to disable voice-based purchasing. Notably, no papers directly explored the possibility of using speaker differentiation to *prevent* use of a VA. In general, more work needs to be done around the use of devices by multiple users. Current architectures often reflect the requirements of data protection regulations that intentionally operate to the boundary of the home and no further, and thus poorly facilitate e.g. guests and cohabitants.

Quantitative work mostly identified devices, skills, or users from encrypted network traffic, using machine learning techniques to classify packets with generally good results [38, 69, 70, 93, 99]. User facing studies included perceptions of voice recording [66] and data sharing [2], as well as the effectiveness of privacy policies [81]. Results supported qualitative findings that the privacy aspects of these devices are generally poorly understood by users. Finally, there was a cluster of work on attack surfaces [43], including through forensic examination of local files and data accessed via APIs [55, 74]. This was linked to the discussion around the influence of the GDPR and existing or desired legal protections for voice assistant data. In general discussions around values and regulation were exclusively focused on the West, with only one paper acknowledging this bias in current research [116]).

4.2 Social Interaction

Work on social interaction covered a wide range of concepts and phenomena. Originally styled as anthropomorphism when planning the search terms, these works also covered ontological explorations of the separability of humans and machines and qualitative accounts of relationships and emotional connections with VAs. The challenge with mapping these facets of social interactions was the extent to which they overlaped; affective experiences are connected to but distinct from emotional connection, and personification is related to anthropomorphism as similes are to metaphors. The theoretical foundations of these papers show a similar diversity, commonly building on the Computers are Social Actors (CASA) paradigm (e.g. [31, 80, 117]), but other theories and models from HCI [147], psychology [150], and communications theory [126] feature widely in the included papers.

A strand of research around the causes and effects of anthropomorphism designed, adapted, and reused question inventories measuring a wide range of social and behavioural constructs. This was typically used to develop a model that explained variations in one factor using the others. Of concern here was also how these effects might be (mis)used in different contexts [13], as social interactions with voice assistants could be seen to work alongside or orthogonally to more logical means of decision making.

Work on the fundamental nature of voice assistants attempted to understand how they fit into existing understandings of technology and social interaction. While there were theoretical contributions in this area there were also many empirical investigations into people's responses to increasingly social devices (e.g. [76, 98, 147]) and what the nature of the relationships they form with them might be [56, 113, 126]. A key theme here was one of categories; ontologically speaking, do people think of voice assistants as people or machines? Studies addressing this often focused on children who were still learning to understand the world, observing how they responded to stimuli from both people and devices including VA-originated social interactions such as displays of friendship or praise [7, 47, 131]. Festerling and Siraj ask whether VAs might cause the emergence of a new intermediate category (the New Ontological Category Hypothesis [68]), with ultimately inconclusive evidence; young participants engaged with compliments from VAs as if they were real (i.e. rather than pretend-play), but often attributed advanced features of VAs to 'human interference' in an attempt order to keep categories pure [47]. Other studies show that children cooperate differently with VAs and humans, such as sharing updates with human collaborators but recognising that voice assistants "do not care much about progress talk" [7]. This also holds true in adults, with relationship development metrics coalescing into a single group that might suggest ongoing purification work (redefining category boundaries to place voice assistants firmly in one or the other) [78, 126]. Pradhan et al. further found that participants fluidly moved *between* categories depending on the behaviour of their voice assistants, treating them as a person during social interaction but as an object at other times [113].

Another recurring phenomenon in empirical work was the use of gendered pronouns as a means of demonstrating or measuring anthropomorphism. People fluidly shift between the use of gendered and impersonal pronouns [113] similarly to the shifts between categories described above, with impersonal pronouns making up the majority of references [117]. These types of responses were often attributed to over-learned, reflexive social routines rather than meaningful displays of social intimacy [87], supported by observations that people often continue these personifying behaviours after learning more about VAs and how they work [139]. There was also a general understanding that social interactions with voice assistants are in some sense inherently satisfying [98, 117], with explanations often focusing on the similarity between these interactions and those found in interpersonal social situations (i.e. the familiarity of conversation) [72]. There is a balance to be struck between the way that the underlying satisfaction from engaging socially with a device can mask or ameliorate its other drawbacks [19] and the way that appearing 'too human' can instil unattainable expectations of a device's capabilities in users, which in turn leads to dissatisfaction [98].

The split into two high level categories, i) the measurement of factors leading to or arising from anthropomorphism and related concepts, and, ii) explorations of how people conceptualise and understand VAs in relation to humans and social interaction, revealed a contrast in concerns and impacts. For anthropomorphism and personification concerns were clearer and centred around the way these behaviours may change people's interactions with devices. However, the notion that anthropomorphism is a challenge to be solved through design is problematic; given the understanding of these responses as part over-learned social routine, part CASA-style subconscious behaviour, it is not clear that widespread understanding of how voice assistants work would effectively counteract our predisposition to treat them as we treat people.

The deep-seated nature of these responses also challenges the view that anthropomorphism and personification are often associated with incomplete understanding. Where this is based on the language of users to and about VAs, such as the use of gendered pronouns, Festerling and Siraj note the difficulty in determining the *actual* meaning of what people say, recommending that "future research could be more critical of the role of language in anthropomorphism" [48]. A related tension surfaces in the literature around CASA and findings that more human-like devices are automatically read by users as more *capable* devices (i.e. they are expected to display human capabilities [25]). However, the potential ethical implications of these questions for work on ontological categories is less clear. Indeterminate results in children and reports of adults

switching categories may suggest a new ontological category, but what would constitute an appropriate response from VA designers if this was determined to be true? The literature tended to focus more on the relevance of results to immediate questions of categories without considering the wider implications for HAI, and it seems unlikely that either outcome would lead to changes in the way that VA conversational interfaces are designed; a more likely impact would be changes in how people's responses to VAs are interpreted by researchers.

4.3 Accessibility

VAs present an interesting combination of opportunities and challenges for accessibility. Their potential user base ranges from those who find it more difficult to navigate visual interfaces, to those who have trouble easily giving verbal commands to VAs and understanding spoken responses. Semi-structured interviews were utilised to discuss frequently used VA functionalities and the issues encountered when accessing them, and this was often supplemented with materials such as recorded videos [40], and manual interactions with VAs using a pre-collected corpus [14, 15, 83]. An interesting alternative approach was to indirectly explore how children access and interact with VAs through parent observations, allowing for the inclusion of an additional secondary perspective [88].

The ability of VAs to accurately transcribe people's voices and communicate smoothly with them was a key theme across the reviewed papers. The accuracy of speech recognition provided by VAs (particularly Google Assistant and Siri [14, 15]) was generally viewed favourablely by users, and those with language impairments had an even higher level of approval [115]. However, performance was less satisfactory for children, with VAs appearing to have been designed without a way to properly bridge the gap between children's and adults' expressive language skills. This was frequently frustrating for children [88, 124], and was made worse when they tried unsuccessfully to seek help [40], or found that the VA could not correctly pronounce their name [124]. Difficulties maintaining conversations were also the subject of investigation, commonly focusing on the short, nonadjustable listening window of VAs which caused problems for children and people with language impairments who may require more time to give a response [40, 88, 115, 124]. Another focus was how people struggled to repair VA conversations, having to rely on external entities (e.g. parents [124]) to maintain dialogues, increasing the difficulty of using VAs [40, 115].

In general there was positive sentiment towards VAs in accessibility contexts. Abdolrahmani et al. argued that VAs were crucial in instilling feelings of independence and empowerment in blind users [3, 121], with similar results related to mobility [34]. Parents meanwhile, acknowledged that VAs had created many enjoyable moments for their children [40, 124], and if interactions with VAs began at a very young age these experiences could influence the way children interacted with other technologies [124]. However, barriers still remain to true inclusivity, with variable performance across languages, accents, gender, and other demographics [83]. Because these studies focused on highly specific populations, there was little engagement with wider issues of accessibility and few comparisons made across demographics (i.e. it is difficult to gain a clear picture of the complete state of accessibility for any given VA). The continual evolution of the voice models used in VAs introduces an opening for follow-up studies, although we did not encounter any such papers in the survey. Another interesting difference that emerged was in framing: performance differences were treated more as *engineering* problems, in contrast with work on e.g. gender, where similar issues were more often motivated by and framed as social inequity (see Section 4.5).

4.4 Social Order

A commonly studied dynamic in the literature was between parents and children, where researchers focused on understanding whether VAs could foster parent-child communication and enhance parental practices. On the one hand, using a VA at home gave parents additional opportunities to improve their communication skills, and the features of VAs also helped parents in achieving their parenting goals and promoted parent-child dynamics [18]. On the other, parents complained that they had to strictly regulate both the amount of time children spent using VAs [18] and access to adult content [130], sometimes even having to be physically present with their children during use [18]; deciding when and how to allow children access to voice assistants can therefore be an additional burden for parents [20], which runs counter to the intention of providing a more relaxed parenting environment.

A major concern raised about voice assistants was the extent to which they could entrench or disrupt domestic power structures. Sharing a VA between household members could create tension where cohabitants did not use the device equally [130], with mismatches between willingness to use VAs in shared spaces leading to a reduction in use and eventually abandonment [138]. The use of VAs within established social orders is generally hierarchical and managed in line with existing household social structures, with users negotiating use of the VA when intentions conflicted [75, 112]. In this way, voice assistants were seen more as tools integrated into existing power structures than disruptive forces that overturn household social orders. This runs counter to fears (particularly in the news[3]) that the adoption of voice assistants could destabilise the social order of the home e.g. by answering requests by children that would be considered rude if posed to a person. There *is* a risk, however, that already problematic power imbalances could be exacerbated by VAs, especially when devices are not controlled by the people that use them (e.g. in intimate partner violence and surveillance in offices, student halls, rental accommodation, etc. [50, 75, 125, 129]).

While analysing the survey papers we found that talking about the social order of the home overlapped with the related concept of group dynamics, whereby the social dynamics of a group are shaped by the emotional state and behaviour of each member [16, 132]. Lee et al. similarly measured how shared device usage affects 'group harmony' as a way to measure changes in group dynamics [79], referring to the ties among group members in terms of mutual support, appreciation, care, emotional attachment, and cooperation [141]. Continued use of VAs appears to have a favourable impact on group

[3] https://qz.com/701521/parents-are-worried-the-amazon-echo-is-conditioning-their-kids-to-be-rude

harmony through psychological satisfaction and dependence developed by users [79], especially when this makes participating in family activities more accessible (see Section 4.3) [130].

4.5 Performance of Gender

A key concern for researchers studying the performance of gender by voice assistants was the feminine presentation of major voice assistants that seems to persist across cultures. This was often justified from a psychological point of view, with studies suggesting that people perceive women's voices and names as sounding more gentle, kind, and caring than men's [35, 123], with VAs read as female therefore presented as more acceptable to users. In addition, the findings of Tolmeijer et al.'s empirical research demonstrated that female voices were significantly more trusted in assistance tasks than compliance tasks [137].

But early findings on CASA suggested that people apply existing gender stereotypes to computers [100], and these harmful preconceptions (e.g. around women's roles in society and the types of jobs they should perform) have influenced the creation of current norms and expectations for the performance of gender by VAs. Given the prevalence of white men on engineering and design teams, the role of VAs in reflecting and reinforcing these stereotypes is the source of intense discussion [35]. In the past, women were expected to perform a variety of stereotypically gendered labour, such as placing orders, giving reminders, seeking information, taking notes and making calls [122, 134]. Feminising VAs was seen as a reflection of male designers' psychological needs and tendencies—engineers tend to create artefacts that fit within their own social spaces—strengthening the connection between women and submissiveness and satisfying other 'heterosexual fantasies' [146].

Given that gendered presentation can be problematic, a series of studies with controlled experiments [137] and interviews [135] explored the factors that cause people to gender devices based on voice and questions around gender-ambiguous voices. Conclusions were polarised. Some findings suggested that investigating voices exhibiting gender ambiguity was worthwhile as gender-ambiguous voices are perceived similarly to gendered voices, and thus do not impact user's trust in VAs [137]. On the other hand, synthesised voices designed to be genderless (e.g. Q[4]) are often coded as male or female by listeners, with Sutton finding that people have specific gender expectations that make this kind of gendering automatic when hearing VA voices [135]. Including genderless voices can itself be problematic if they take the approach of smoothing out differences in voices rather than acknowledging and representing diversity [118]. Q in particular has been criticised for drawing distinctions between trans and male/female voices, as well as presenting trans and non-binary voices as a monolithic mid-point of the binary it is attempting to break free from [118]. As a way forward, it has been suggested that voice assistants could be designed to randomly choose a voice or switch between them [59], but this is not the only cue that influences perceptions of gender in VAs. Other design elements such as the physical appearance of devices/interfaces, product branding, specific pronunciations in the speech, and the activity that the VA is currently performing are also influential [135]. This ties in with gendered preferences for voice assistants, particularly around trust, privacy, ease of use, and mobile self-efficacy [102].

4.6 Accountability, Conflicts of Interest, Misinformation, and Transparency

As the above concerns were represented by only six papers between them, we briefly summarise them together here. The one paper coded as accountability measured the efficacy of the certification process for Alexa and Google Assistant skills/actions, finding that 100% and 39% of policy-violating skills were certified by the respective platforms [30]. Another paper discussed the inherent conflicts of interest built into VAs, whereby assistants appeared to be acting in users' best interests whilst also prioritising information and services that benefit vendors (e.g. through shopping platforms) [8]. Of the three papers on misinformation, two focused on the accuracy of information available through popular devices [9, 36] and one on the inefficacy of spoken warnings alongside content identified as misinformation [127]. While requests for information about vaccines were handled reasonably well by Google Assistant and Siri, Alexa understood fewer queries and was less likely to present information from authoritative sources [127]. For news queries, Alexa returned more relevant and timely information, but subtle changes in question phrasing led to significant changes in the relevance and source of information [36]. The paper on transparency closely linked this concern to privacy, claiming that modern encryption mechanisms hamper transparency around data collection by requiring secret symmetric keys (i.e. between assistants and vendors, which users cannot access) [49].

5 DISCUSSION & FUTURE WORK

5.1 Who are Voice Assistants Designed For?

The survey highlights several areas where the interests and needs of the people using VAs fall secondary to those of their manufacturers: data collection for tracking and advertising, the prevalence of female-coded voices as the default, rigid interaction and access control models that are not aligned with inter- and intra-household use, and the lack of unprofitable adjustments to allow more universal access. Some of these design decisions, such as the preference for female-coded voices, originate from the first commercially available voice assistants; as Siri and Alexa did, others followed. In other cases like the neglect of multi-user use, VAs were more likely shaped by data protection regulations that are modelled around the relationship between individual data subjects and corporate data controllers. Finally, issues like poor voice recognition performance for non-native speakers are likely the result of expectations set by the limitations of early voice recognition technologies, designers creating products that work optimally for people like themselves, and the perceived expense of achieving more equitable recognition.

As the technology and expertise required to develop voice assistants and skills become more accessible, it is important that these legacy design decisions are not unthinkingly perpetuated by the devices of the future. Evaluating voice assistants against previous guidelines for human-AI interaction [10] shows that some findings of the literature review are specific instances of wider problems with AI systems. Amershi et al. find that contemporary VAs are

close to meeting some of these guidelines, such as G5 (match relevant social norms) and G7 (support efficient invocation), but the results of the literature survey show that they fall short of others like G6 (mitigate social biases) and G11 (make clear why the system did what it did). Extending this work to produce guidelines that are specific to VAs represents an excellent opportunity to move beyond current design norms and 'reset' assumptions around how voice assistants should operate.

5.2 Widening Participation in VA Research

A clear theme when conducting the literature review was the community's focus on voice assistants used in Western countries; for example, despite the existence of many Chinese and Korean language VAs, none of the studies reviewed recruited participants resident in China and only one recruited participants from South Korea. This is surprising given China's population and the existence of well-known voice assistant brands in the country. Some of these assistants support multiple dialects, suggesting the potential for shared insights across these VAs and e.g., work on accessibility. There is also a risk that participant recruitment is seen as an opportunity to reduce potential variables, at the expense of making the field representative. Revisiting the observation from Section 4.1 that Western legal and cultural norms have strongly shaped the evolution of associated voice assistants, we are not aware of an analysis of the influences on VAs outside of the US and Europe—this constitutes an important piece of future work.

As a result of the above—and as evidenced by Section 3.2—there is a clear lack of diversity amongst those who participate in research on voice assistants. We therefore take this opportunity to present a challenge and provocation for voice assistant researchers: given the recent upheavals to the way that we work and do research, there is no excuse for a field that proudly pursues diversity to continue to exclude those who live outside a handful of wealthy Western countries. The increasing reach of crowdsourcing platforms commonly used in the survey papers such as Mechanical Turk and Prolific Academic significantly lowers the barrier for data collection with under-represented demographics [140], and the quality of the research produced during the coronavirus pandemic demonstrates that collecting qualitative data over the internet is more viable than previously thought. Outside of Western platforms, many others exist that offer diverse participant bases and localisation services to facilitate participation across language and cultural borders. This could be done by not restricting participants based on geography/nationality or, where language is important to the research questions being investigated, including comparative analysis between e.g. native/non-native speakers. This will both broaden the applicability of results as well as identify exclusionary factors that would otherwise go undiscovered.

5.3 Deepening Explorations of Gender

Throughout the survey, issues around gender repeatedly surfaced around how gender is performed by VAs, and how they often seem designed for men (e.g. by having lower accuracy for other voices). Norms around gender can be so tightly woven into home and social structures that the introduction of a device that performs gender *and* affects work done in the home inevitably causes disruption. While it is promising to see initial work on voices around and beyond the gender binary, less focus is given to the gendered effects of voice recognition accuracy and how their design affects existing household relationships and power structures shaped by gender.

Beyond the diversification of design teams and training corpora, there are several approaches that can be taken. Providing more nuanced and inclusive representations of gender is a matter of corporate social responsibility rather than solely a design decision. This is most easily achieved by providing more than one voice, and by not labelling voices by gender (e.g., Google Assistant labels voices with colours). The reviewed literature also highlights the large difference in the role that gender plays in interpersonal and human-computer interactions now compared to when the foundational work in this space was undertaken almost 30 years ago. As such, it is important that we revisit these early studies and their implications from a contemporary perspective.

5.4 The Effects of Habituation

When looking at longer-term usage trends of VAs there is a discussion over the ways that usage changes over time; usage appears to stabilise after an initial playful phase [124], but there is a lack of data available on usage trends beyond the scale of days [11] or months [124]. One question that arises when trying to contextualise results on privacy perceptions and VAs is the extent to which user perceptions and behaviours will change over a longer period of time. Work relating to categories hints at shifting perspectives around humanness and machine-ness [78], which may cause related changes towards other aspects of VAs. Larger-scale changes in cultural and commercial attitudes to data collection by devices and 'creepy' functionality are also likely to manifest in user perceptions, and it may be that as the gap widens between contemporary and early research on voice assistants that researchers need to take care when comparing their results with prior work. An opportunity therefore exists to re-run existing studies to determine how perceptions might be changing in different cultures.

A related longer term aspect of novelty concerns the transparency and accountability of voice assistants as they evolve and become integrated into more devices in the home and beyond. Speculative work on the future of voice assistants [26] imagines futures with ubiquitous voice assistants where people give commands to be answered by whichever assistant is present, *without necessarily knowing who created or controls that assistant.* A key fear raised in this speculative work pertains to undisclosed functionality, where users are unpleasantly surprised by the VA's inferential abilities and the real world effects that the VA can cause. As it becomes the norm to have voice control built into consumer electronics and commoditisation increases the feasibility of assistants from smaller vendors, it will become increasingly important to know which assistant is being used at any given time and (more importantly) the associated capabilities, limitations, and interests involved. Mandatory use is also raised as a concern, which echoes the discussion in the accessibility literature (Section 4.3).

5.5 A Shift in the Human-VA Relationship?

The main conclusion from the analysis of the reviewed papers and subsequent discussion seems to be that VAs are quickly becoming

a ubiquitous presence in people's lives. While initially a curiosity, most people with smartphones now have access to a voice assistant. One way that this ubiquity manifests is in the extension of existing platforms and services, with VAs changing the way these are accessed to make them seamlessly available throughout the home (e.g., music and search). This transition comes naturally as people are already familiar with e.g. Spotify, and so the choice to use it via a VA quickly becomes subconscious.

When considering the long term impact of voice assistants one can draw parallels with how the smartphone drastically changed the ways that people relate to one another and the patterns for social interaction. While smartphones are inherently mobile and thus extend interactions outside of the home in ways not previously possible, voice assistants primarily change the way that people interact with digital technology *within* the home. By becoming a persistent part of the home environment, voice assistants subtly change the way that we interact with each other in the home. The rigid interaction and family models built into these devices constrains the social interactions that people share with others, and can cause social friction. Clear examples of this arise around cohabitation and managing users within and between family units where VAs do not adhere to existing norms around those relationships and concerns over parenting [57]—in this sense, VAs constrain people's ability to be a partner/roommate/parent in artificial ways.

Another ready comparison with smartphones is the ability to opt-out of owning and using the technologies whilst continuing to participate in society. The disruption caused by smartphones has ushered in "a new way of living wherein the smartphone is ordinary, necessary, and integral" [62], one where the key decision is whether to *own* the device. With VAs the opposite is often true—the packaging of voice assistant software with new smartphones, TVs, and headphones means that a huge number of people already have access to a voice assistant, making the choice one of use rather than ownership. This could make it easier for VAs to become a necessary or default means of interacting with digital platforms and services in the future.

5.6 Unexpected Discoveries

While preliminary work on the background literature and prior work had suggested that anthropomorphism was a major category of ethical concern, analysis of the included papers revealed a web of related but distinct concepts that extend beyond this relatively narrow classification. As a result, this concern was renamed 'social interaction' to better reflect the range of research questions that deal with how people interact with voice assistants (differentiated from social order concerns that focus on how voice assistants affect relationships with other people). This also opens up the range of potential research questions to include a wider variety of social interactions and, as VAs become more sophisticated, the different ways in which we might communicate and build trust with VAs beyond simple task-oriented interactions.

Another unanticipated class of concern emerged around misinformation. A common discussion point around other devices and platforms that facilitate access to information, voice assistants present an unfortunate collection of attributes that make them particularly apt to perpetuate misinformation. Not only does voice as a medium heavily promote short, easy to understand interactions, it also makes it difficult to provide information on sources and links to further reading. There is potential for companion smartphone apps and displays built into smart speakers to introduce more nuance to fact-finding, but their efficacy depends on users interacting with a secondary modality after initiating a verbal search for information with the assistant. Other avenues of exploration could include the verification of fact sources and mandatory communication to users about the source of a skill's information before and during use. Exploration of this topic represents an exciting opportunity for future work, but will be made difficult by the dominant architecture where skills are hosted by third party developers outside of the control of vendors (resulting in difficulties when vetting and verifying third party software) with very recent work showing evidence of third-party skills serving misinformation [21].

5.7 Limitations

We struck a balance with the databases we searched between accurately representing the literature, volume of results, and ease of running complex searches. Running searches in English across English-speaking venues inevitably influenced the literature returned, but at the same time major publishers describe themselves as global institutions and we note that many region specific conferences such as ACM's Asia CCS use English as their working language. The addition of hand-picked papers that evaded the systematic searches will also have influenced the results, but these represented less than 2% of the total number of papers screened and were carefully balanced to maximise the coverage of the review. Despite this, there will also have been in-scope papers that were not included in the analysis.

When classifying metadata we did not distinguish between a work's target and effective demographic (e.g., studies that did not set out to examine particular groups but recruited from pools with known demographic biases like university students). The same applies to the small number of cases where the country of residence was not reported and was thus coded as the platform used for recruitment (the U.S. represents ~4% of the world's population but almost half of Mechanical Turk workers [107]).

6 CONCLUSION

We systematically reviewed 117 research papers on ethical concerns with VAs, consolidating the incredible work done by the community. We highlight areas of consensus, disagreement, and gaps in the body of knowledge that can guide future research, and consider the distribution of approaches and methods across the field. Our findings show that some concerns like privacy were much more likely to be operationalised for quantitative research than others like accessibility, and that the people participating in these studies are overwhelmingly from North America and Europe. We outline key areas to be addressed by future work, such as widening participation and revisiting early results from a contemporary perspective, with the hope of making future VAs more equitable and inclusive.

The Ethical Implications of Generative Audio Models: A Systematic Literature Review

Julia Barnett
JuliaBarnett@u.northwestern.edu
Northwestern University
Evanston, IL, USA

ABSTRACT

Generative audio models typically focus their applications in music and speech generation, with recent models having human-like quality in their audio output. This paper conducts a systematic literature review of 884 papers in the area of generative audio models in order to both quantify the degree to which researchers in the field are considering potential negative impacts and identify the types of ethical implications researchers in this area need to consider. Though 65% of generative audio research papers note positive potential impacts of their work, less than 10% discuss any negative impacts. This jarringly small percentage of papers considering negative impact is particularly worrying because the issues brought to light by the few papers doing so are raising serious ethical implications and concerns relevant to the broader field such as the potential for fraud, deep-fakes, and copyright infringement. By quantifying this lack of ethical consideration in generative audio research and identifying key areas of potential harm, this paper lays the groundwork for future work in the field at a critical point in time in order to guide more conscientious research as this field progresses.

1 INTRODUCTION

Generative models have been a large focus of AI researchers over the past few years, and recently the public has seen these models first-hand in public facing algorithms like ChatGPT [46] for text, DALLE-2 [50] for vision, and Jukebox [16]† for music. At their core, generative models are a type of AI system that take in vast amounts of training data to be able to produce a novel item that is similar to and statistically likely to exist in the data it was trained on. Though generative models have been around for decades with origins in the 1980s [9], the outputs of these models saw unprecedented advances with the introduction of the transformer in 2017 which revolutionized the field by introducing a mechanism called "attention" that allowed for much more accurate and complex outputs of generative models [61]. Generative models may continue to improve as (a) their training data becomes larger (for text, imagine the entire internet) and (b) researchers continue to make advances in the architecture of the models. This paper focuses specifically on the current landscape of generative audio models.

As generative audio models continue to develop and grow both in popularity and complexity, this research seeks to understand the ethical landscape of potential impacts of these models. In particular, this paper explores what potential harms have been considered by researchers creating deep generative modeling projects, and seeks to understand the extent to which researchers in this domain are considering the broader ethical implications of their work. When a layperson is introduced to generative models their instinct is to jump to potential negative impacts [19, 32], however, researchers in the field are wary to do the same. There has been minimal research into the ethical implications of deep generative audio models, and this paper calls out the need for that to change by providing a comprehensive and thorough overview of the current potential negative impact domain.

Systematic literature reviews are effective at evaluating the current landscape of a research domain—especially when the potential corpus to analyze is a tractable number. In addition to identifying trends, they are particularly helpful in identifying gaps in the field. This is an agenda setting paper at the right time—it is important to both diagnose the degree to which research papers on generative audio models are discussing ethics and encourage the plethora of researchers to come to include a negative broader impact in their analysis prior to the field being clogged by studies without an ethical component. As will be discussed in more detail below in Section 2.1, innovations in text and vision typically precede those in generative audio, so this same analysis conducted in the generative text and vision domains would include 3,099 and 5,287 articles, respectively. 884 papers in the generative audio domain prior to screening is comparably a more tractable endeavor to undertake, and it is feasible to raise the concern of lack of negative impacts earlier in this specific area.

†References for works included and analyzed in the systematic literature review corpus can be found in the Appendix. They are denoted in text with the dagger† superscript.

This paper makes two concrete contributions. Primarily, it quantifies the degree to which researchers in the generative audio domain consider the ethical implications and negative broader impacts of their work. The author finds that less than 10% of the corpus ($n = 16/171$) discuss any potential negative impact. Secondarily, this paper examines the different negative broader impacts explored by these 16 papers and thematically discusses the potential ethical implications. This paper calls to attention the need for researchers in this domain to consider the ethical implications of their work, and suggests a starting point for topics to consider by examining issues already brought to light by their peers.

2 BACKGROUND AND DEFINITIONS

2.1 Generative Audio Models

Generative models can largely be grouped into three buckets: text, vision, and audio. Due to the nature of the data underneath the models, advances typically start in the textual domain, followed by images, and finally audio. The most clear-cut example of this is when Vaswani et al. introduced the first transformer for text in 2017 [61], which led to the first image transformer in June of 2018 [47], and shortly thereafter, the music transformer [28]. At their core, generative models use a large amount of training data in order to predict something that is similar to and statistically likely to exist in the dataset it was trained on. Compared to text generation models, which are limited by the finite vocabulary of the language being used, audio can have exponentially larger potential combinations of sound occurring at once; even if just isolating to the possible keys of a piano, the possibilities become almost intractably large extremely fast in the granularity of milliseconds.

Despite these data challenges, many advances have been made in the generative audio domain mainly in the areas of music and speech generation. Music generation is particularly tricky due to the long-term relational dependencies of melodies and other musical structure that may have occurred at a timestamp far earlier than the current frame needing to be generated [28], but self-attention and relative positioning [53] enabled that hurdle to be overcome. Generative models today can condition on artist and genre to steer the style of music [16]†, or even condition on text and melodies to create high-fidelity and quality musical compositions [2]†. Advances in speech have varied from speech enhancement and denoising [48, 67]†, text-to-speech (TTS) generation [24, 35]†, accent conversion and style transfer [49, 69]†, and audio in-painting to reconstruct gaps in speech data [59]†. Most of the research in generative audio models is concentrated in music and speech generation; however, there are some cases where the models generate specifically non-music, non-speech sounds such as auxiliary sound effects for movies or birds chirping [23, 71].

Though audio generation can also be tied together with visual generation in the forms of videos and deepfakes [17, 22, 40], motion to create dance moves and choreography [6, 60, 70] or lip movements and other speech gestures [30, 63, 66], this work focuses on generated audio in the singular medium. For example, while text-to-speech works will be evaluated, speech-to-text work will not, nor will creating a dance routine simultaneously with music. The goal of this isolation of audio is to understand explicitly the ethical discussions of the audio domain, not to potentially conflate these issues with ethical discussions of other fields.

2.2 Broader Impact

Especially with the public spotlight on deep generative models such as ChatGPT [46], both computer scientists and the public alike have become aware of the potential negative impacts of these models and other algorithmic systems. A recent thematic review of broader impact statements of the Neural Information Processing Systems (NeurIPs) 2020 conference found that some of these broader categories related both to how consequences are expressed such as specificity and uncertainty as well as different areas of impacts expressed such as bias, the environment, labor, and privacy [45]. A recent survey of the socio-technical harms of algorithmic systems identified five major types of harms: representational, allocative, quality-of-service, interpersonal, and societal harms [54] in order to establish conceptual alignment for future research and to encourage consideration of these negative impacts and reduce the harm these systems cause.

There are a variety of approaches to encourage broader impact consideration in scientific research. The US National Science Foundation and other grant providers require a Broader Impacts Criterion in both grant applications and the peer review process [38], though there is mixed reception around this being the best manner to encourage consideration of societal impact [26, 51]. Other researchers in computer science have suggested that a simple change to the peer review process would substantially change the degree to which computer scientists consider the negative impact of their work [25].

Another method recently proposed utilizes crowdsourcing to anticipate different societal impacts of algorithmic decision making systems [7], which puts the consideration in the hands of the layperson in addition to the algorithm designer in order to have a comprehensive idea of potential impacts. Other methods include impact assessment tools such as algorithmic impact assessments (AIAs) which strive to both identify varying areas of impact in addition to establishing steps to hold the algorithm creators accountable [12, 41]. Ethics and society review (ESR) was a recently piloted program that facilitated ethical and societal reflection as a requirement to secure funding. They found that 100% of participants saw the benefit in the process and were willing to continue submitting projects in this manner [8] indicating that the demand is there among researchers to consider ethical impact.

The uniting thread of all of these methods is to encourage societal impact beyond the main text of the paper, or even to require a third party to assist in the ethical evaluation. This paper instead focuses on research papers themselves (as opposed to a secondary document/evaluation such as a grant proposal or peer review) and the extent to which they consider broader impact in the main body and appendices.

Prior research by Weidinger et al. has established a taxonomy of ethical and social risks of harm from language models [65], which in this paper is extended to generative audio models and helps guide the definition of broader impact. Weidinger et al. classify six areas of harms of language models: (1) discrimination, exclusion, and toxicity, (2) information hazards, (3) misinformation harms,

(4) malicious uses, (5) human-computer interaction harms, and (6) automation, access, and environmental harms. Discrimination, exclusion, and toxicity focuses on the different treatment of social groups in an oppressive manner. Information hazards concern privacy violations and safety risks, such as compromising privacy due to systems that leak or enable the correct inference of private information. Misinformation harms have to do with the dissemination of misleading information leading to material harm, for instance in the cases of medical misinformation leading to serious consequences for people's quality of life [58]. Malicious uses are explored more broadly for AI systems by Brundage et al., and they define these as "all practices that are intended to compromise the security of individuals, groups, or a society" [10]. Human-computer interaction harms encompass harms from the direct interaction of humans with the AI system. Finally, automation, access, and environmental harms highlight downstream application impacts that benefit access to select groups and not society at large.

For the purposes of this paper, and guided by Weidinger et al's taxonomy detailed above, broader impact is defined as a possible impact or application of the research/model on the broader society, rather than the scoped technological or scientific purposes. For example, the explicit purpose and scientifically relevant impact of a music generative model is to create music, possibly with long-term structure [28] or guided by text inputs [2]†. A positive broader impact in this case could be to creatively inspire musicians, and a negative impact could be copyright violations. This analysis will focus primarily on the extent to which negative impacts are discussed and explored, but will also note when researchers discuss positive broader impacts beyond their scientific scope.

2.3 Research Questions

The formal research questions addressed by this paper are:

(1) To what extent is the current study of generative audio models addressing negative broader impacts?
(2) What ethical considerations of generative audio models has the field examined?

3 DATA AND METHODOLOGY

In order to address these two research questions, the author conducted a systematic literature review (SLR) of research articles published over the last five years in the generative audio domain. The reporting of this SLR was guided by the standards of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [43] in order to transparently and concisely evaluate the current state of the field. This was an ideal methodology for these research questions due to the nature of the study evaluating what the field has done in a comprehensive and broad sense.

3.1 Search Strategy

3.1.1 Inclusion and Exclusion Criteria. Formatively, this study analyzed full research papers in the generative audio domain. This does not include extended abstracts or book chapters, nor any other form of writing outside of full research papers. The main text and included appendices were analyzed, but no supplemental materials published outside of the main body (e.g., a linked website with additional findings) were examined.

Topically, these papers had to be about generative audio models. More specifically, a generative audio model had to be the primary focus of the paper. This meant that the paper either had to introduce a generative audio model/application, or analyze and discuss generative audio models as their focus of study. It was also important that these models were not conflated with another domain as their final output; for instance, though text-to-speech was included due to the output being in the audio domain, speech-to-text would be classified as a text generative model for the purposes of this paper and consequently excluded from analysis. Similarly, generative models resulting in video outputs were excluded due to conflating the visual domain with audio; the sole focus of the output of these models had to be entirely in the audio domain. Additionally, anything that was not generative in output (e.g., a classification model) was excluded.

Temporally, these papers had to be submitted or published in the last five years (at the time of research inception, this meant between February 1, 2018 and February 1, 2023). The reason for this was that this field is constantly evolving and any advances typically build upon the previous state-of-the-art performance which would rarely date prior to five years of research, especially prior to the introduction of the transformer in mid-2017 [61]. This means that research published over five years ago is not nearly as relevant to the field today as anything published recently.

3.1.2 Keyword Search. As a result of this aforementioned criteria (in Section 3.1.1), a keyword search was iteratively performed until the desired pool of research was included by the cast net. After many iterations of specific keywords such as "music", "speech", and "sound", the author eventually expanded the search to simply "generative models" and "audio" in order to comprehensively encompass as many potentially relevant articles as possible.[1]

The search was initially focused on articles published in the Association for Computing Machinery (ACM) database, resulting in 444 potential articles meeting the criteria. After examining the articles included in this search, it quickly became clear that a large portion of the state-of-the-art research papers were either published outside of this domain at conferences such as Neural Information Processing Systems (NeurIPs) and the International Conference on Acoustics, Speech, & Signal Processing (ICASSP), or simply not peer reviewed at an academic conference, yet widely respected in the field. Industry research is also growing in dominance in deep learning research [3]. It was important that these key papers from companies such as OpenAI and Google were included even though they may not be subject to peer review. Some of the most influential papers in this corpus were not peer reviewed yet still well regarded and well cited, like Jukebox [16]† which was written by a team of researchers at OpenAI in 2020 that already had over 300 citations at the time of writing this paper. In order to include all of these essential papers in the corpus, the search was extended to include papers submitted to arXiv, which is an open-access non-peer reviewed archive for millions of research articles in the fields

[1] Initially, the search was targeted around "deep generative audio models", but it became clear quite quickly that the "deep" part of the term was too narrow and not widely adopted until recently (this search only resulted in 242 articles).

of physics, mathematics, computer science, quantitative biology, quantitative finance, statistics, electrical engineering and systems science, and economics [5]. This added an additional 440 articles to the initial screening pool, 65% of which were peer reviewed. When screening these abstracts, it was noted whether the paper was peer reviewed or submitted to a conference/journal, however there were no notable trends among this specific dimension of whether the paper was peer reviewed.

The final query terms for ACM and arXiv were as follows:

- **ACM**: [[[All: "generative model"] OR [All: "generative models"] OR [All: "model generating"]] AND [All: "audio"]] AND [E-Publication Date: Past 5 years]"
- **arXiv**: "("generative model" OR "model generating") AND "audio" date_range: from 2018-02-01 to 2023-02-01"

3.2 Title and Abstract Screening

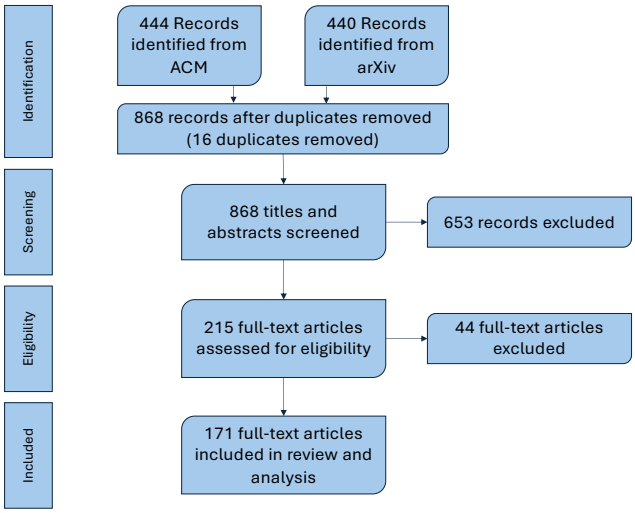

Figure 1: PRISMA Flow Diagram detailing the corpus screened and analyzed in the paper. After starting with an initial pool of 884 papers, 16 duplicates were removed, 653 records were excluded during the abstract screening stage, and 44 full-text articles were excluded during the eligibility review, resulting in 171 full-text articles for review and analysis.

The author screened all 884 abstracts of the articles identified from the search (444 from ACM and 440 from arXiv). 16 duplicates were removed, and the remaining abstracts and titles were examined to determine eligibility. 653 articles were removed due to not meeting the criteria specified in Section 3.1.1. The vast majority of these articles were excluded due to not actually being about audio (46%), but rather about text, vision, or some other central topic or output such as choreography. The second largest category of exclusion was due to papers not being a generative model (30%) but rather something else such as a predictive or classification model. The remaining articles excluded at this stage were due to generating something in addition to audio like gestures or images (11%), proposed a metric to evaluate the models or incrementally improve a specific aspect of the methodology without actually discussing any audio outputs or use cases (9%), were all-encompassing and discussed generative models like text and vision in addition to audio (3%), or were book chapters or abstracts instead of full papers (1%). This is detailed in the screening section of Figure 1. The papers were excluded on a hierarchical list of criteria—for instance, it was possible that a paper was both not about audio and not a generative model, but would have been excluded for not meeting criteria (a) that the paper needed to be about audio, and thus these percentages for the later exclusion criteria are lower bounds.

3.3 Full Text Screening

The title and abstract screening was quite thorough, so of the remaining 215 full-text articles only 44 additional papers were excluded resulting in 171 total papers for the analysis. Of these 44 papers, 20 (45%) were removed for proposing a metric to evaluate the models or incrementally improve on a specific aspect of the methodology and not actually produce any audio output or apply to real data. 9 (20%) were removed due to generating something in addition to audio such as gestures or video. 7 (16%) were removed due to not being a generative model in nature but rather a classification or prediction model. 5 (11%) were removed because they were not a full research paper but rather something like an extended abstract or book chapter. The remaining 3 (7%) were excluded because their encompassing focus was too broad and included text and vision generative models in addition to audio models. Figure 1 details the full flow diagram of papers from inception of the keyword search stage to final corpus.

The final corpus includes 140 papers from arXiv, 15 from the ACM database, and 16 which were in both databases. The vast majority of these papers (n = 122; 71%) were peer reviewed at respected conferences and journals—only 18 papers from arXiv (13% of arXiv papers) were not peer reviewed. The conferences/journals with at least five papers in the corpus were:

(1) Interspeech (n = 24; 14%)
(2) Transactions on Audio, Speech, and Language Processing (n = 17; 10%)
(3) International Conference on Acoustics, Speech and Signal Processing (n = 12; 7%)
(4) International Society of Music Information Retrieval Conference (n = 9; 5%)
(5) International Conference on Multimedia (n = 7; 4%)
(6) Neural Information Processing Systems Conference (n = 6; 4%)
(7) International Conference on Machine Learning (n = 5; 3%)

All content and thematic analyses discussed in the remainder of the paper were done by qualitative coding by the author. Research papers in the generative audio domain tend to fall either into two categories: music and speech. In this corpus, 77 (45%) papers were about music and 103 (60%) were about speech. Some papers include both (n = 13; 8%), either by being datatype agnostic or by focusing on generating a singing voice. 4 papers (2%) were about non-speech, non-music sounds, such as auxiliary sound effects like birds chirping and dogs barking. The summary of these topics by year can be found in Table 1.

Of the 103 speech papers, 48 (47%) were about pure speech generation, 32 (31%) were about text-to-speech, 24 (23%) speech enhancement/denoising, 8 (8%) accent conversion or style transfer, and 3 (3%) audio inpainting or gap filling. There were additional topics scattered across papers, and the aforementioned categories were not mutually exclusive (for example one paper was about audio inpainting for controllable TTS models [59]†). Of the 96 papers for which the language was either explicitly specified in the paper or able to be found through researching the datasets ($n = 7, 7\%$ were not obtainable through the author's research), the vast majority utilized at least one English dataset ($n = 78$, 81%), with 69 papers (72%) exclusively using English training data. Of the remaining papers, 10 (10%) used Mandarin, 9 (9%) used Japanese, 3 (3%) used Korean, and any other language specified was used in at most 2 papers. Notably, if a paper ever used a language other than English, it was explicitly stated. When the only language used was English, it was often necessary to research the datasets mentioned in order to determine the language utilized in the model, indicating further bias towards English in these models.

Of the 77 papers about music generation, 62 (81%) used only instruments or non-lyric vocals, 10 (13%) used pure vocals and lyrics, and 5 (6%) used lyrics, vocals, and instruments. Of the 15 papers generating lyrics, 8 (53%) explicitly mentioned the language chosen. 5 (63%) used Mandarin Chinese, 4 (50%) used English, and 1 (13%) used Japanese, with 2 of the papers using both English and Mandarin datasets. 13 (17%) of these music generation papers were evaluations of existing music generation models, and the remainder ($n = 64, 83\%$) proposed a new model. 8 (10%) focused on the HCI component of the models, 8 (10%) used audio inpainting or gap filling, 5 (6%) generated a musical score in addition to audio, and 4 (5%) used a style transfer technique. The author did not note any additional topical trends within the corpus.

All Papers: Descriptive Statistics by Year					
Year	**All Papers**	**Music**	**Speech**	**Both**	**Other**

Table 1: Descriptive statistics of research papers analyzed by year. Includes papers in music, speech, both music and speech, and other (non-music, non-speech) sounds. Note that 2023 only includes data for January.

4 ANALYSIS AND RESULTS

4.1 Overview

Of these 171 papers, only 16 (9%) discuss a negative broader impact, all of which were qualitatively coded by the author. 50% ($n = 8$) of these were in music papers, 63% ($n = 10$) were in speech papers, 13% ($n = 2$) were in both music and speech papers, and none were in the papers dealing with other non-music, non-speech audio. Temporally, there has been a slight increase over time of papers discussing negative broader impact, with none in 2018, 1 in 2019, and 4-5 each in 2020-2022. There have already been 2 papers in 2023 (with only one month of data for January) that discussed negative broader impacts, one of which was solely a music generation paper and the other discussed both music and speech generation. A full description of every paper discussing negative broader impacts can be found in Table 2. 65% ($n = 112$) of the papers included in the corpus considered at least one positive broader impact of their work, so these researchers were considering broader impact—just not negative impact.

Even though only 9% ($n = 16$) of the entire corpus discusses negative broader impacts, the papers that shine light on these ethical concerns do so in a manner that is inclusive to the vast majority of models in the domain. For instance, there are 32 text-to-speech (TTS) papers in the corpus, and though only 2 mention negative broader impacts, they do so in a manner that implicates all TTS models: Jaehyeon Kim et al. noted, "TTS models could also be abused through cyber crimes such as fake news or phishing. It means that TTS models could be used to impersonate voices of celebrities for manipulating behaviours of people, or to imitate voices of someone's friends or family for fraudulent purpose" [34]†. The negative broader impacts are not specific to the model proposed in the given paper, but rather to the entire domain of TTS and other speech models. Thus, the findings in this paper are not that 91% of papers in the corpus have no need to discuss broader ethical impacts, but are far more likely to have neglected that discussion.

With the exception of one paper that was devoted almost entirely to a negative impact of audio models (energy consumption) [18]†, these papers tended to devote only 1-3 sentences to the potential negative impacts. Of these 16 papers, only 6 (38%) papers included a short section devoted to ethical considerations or broader impact, and 2 of those were on the last page of the appendix. Of the remaining 9 papers, 2 (13% of 16 papers) had 3 sentences devoted to negative impact, 5 (31%) had 2 sentences, and 2 (13%) had only part of one sentence. These sentences were primarily in the introduction ($n = 6$ papers; 38%), discussion ($n = 4$; 25%), and one sentence was in the conclusion (6%).

Jarringly, 2 of the 16 papers that discussed negative impacts explicitly mentioned that they did not have any intention to release their models or code due to the potential for misuse. Agostinelli et al., who created a text-to-music generation tool, stated: "We acknowledge the risk of potential misappropriation of creative content associated to the use-case...We strongly emphasize the need for more future work in tackling these risks associated to music generation — we have no plans to release models at this point" [2]†, and Sungwon Kim et al., who created a TTS model, noted "Given this potential misuse, we've decided not to release our code. Although we do not release the code, due to the adaptation

ability of the diffusion-based model, we expect that the adaptive TTS technology is highly likely to be misused like Deepfake" [36]†. Two highly impactful papers both raise the alarm bells on the potential for misuse of generative audio models, and decided the safest mechanism for prevention of misuse was to not make their models or code available for public use.

4.2 Negative Broader Impacts in Music

Eight of the total papers in the corpus discussed potential negative broader impacts in the context of generative audio models for music. The main themes discussed in these were a loss of agency/authorship when creating the music, a general quelling of creativity, Western bias on the creation of music, copyright infringement, and cultural appropriation. They are discussed in more detail below, ordered chronologically by when papers first discussed the issue.

4.2.1 Loss of Agency and Authorship. Two papers [21, 27]† brought up the potential loss of agency that human creators would feel when creating music with the assistance of an AI generative model. Both of these papers were evaluations of existing models rather than creating their own generative model, and instead looked at the human-computer interaction (HCI) component of music generation models. Frid et al. noted that the co-creation of music from humans and machines "raises interesting questions about autonomy, agency and authorship in human-AI interaction in creative practice" and found that the human creators were hesitant to give the generative models too much control [21]†, indicating that musicians and creatives at large are wary of the recent focus on autonomous music generation. Huang et al. echoed this finding and found that novice musicians as well found it challenging to create jointly with AI and that "users desire greater agency, control, and sense of authorship vis-a-vis the AI during co-creation" [27]†.

4.2.2 Creativity Stifling. The most common potential negative impact discussed in the corpus was the stifling of creativity as a result of AI music generation [20, 27, 57, 68]†. This focused on the repetitive nature of the music generation and that by limiting the creative output to possibilities of the model may result in a similar bound on human creativity. Suh et al. noted that these models "may limit creative scope of humans" [57]†, and Zhao et al. found that people "may be not satisfied if the generated musical content tends to mimic the training set without exhibiting true creativity" [68]†. Both Huang et al. and Esling et al. suggested that a shift needs to be made toward steerable and interpretable models [68]†, but "introducing the notion of creativity in machine learning is difficult, as explicitly designing losses for creativity is an uphill battle" [20]†. Many of the papers in the corpus position the generative audio models as a tool for assisting in the creativity process, so acknowledging the counterpoint is important as well.

4.2.3 Predominance of Western Bias. Zhao et al. proposed a lightweight music generation model to generate instrumental music. In analyzing their output they found that their model was sensitive to Western music theory in that it "it maintains the configuration of the circle of fifths; distinguishes major and minor keys from interval vectors, and manifests meaningful structures between music phases" [68]†. Machine learning models often perpetuate biases in the training data, and generative models are no different. It is important to be aware of the composition of the training data to understand what biases could be perpetuated.

4.2.4 Copyright Infringement. Perhaps one of the most important considerations of generative music models—both ethically and potentially legally—was only discussed by two papers in the entire corpus: copyright infringement. There are many legality questions surrounding the copyright of AI generated content. At least three lawsuits in early 2023 are currently discussing whether models trained on publicly available works constitute copyright infringement [31]. Research in the text and vision domain is even geared toward specifically identifying to what degree generative models are memorizing training data [11, 39, 56] or are producing outputs with "substantial similarity" to items in the training set [62]. However, in this corpus of generative audio models, only two papers discussed the potential for copyright infringement [2, 20]†. Esling et al. focused their research on maximizing novelty in the music generation system in order to subvert the potential for copyright issues and increase creativity in their generation [20]†. Agostinelli et al. "conducted a thorough study of memorization, adapting and extending a methodology used in the context of text-based LLMs" in order to determine the degree to which their model memorized the training dataset and understand the potential for copyright infringement [2]†. Of the remaining 75 papers discussing generative music models (97%), not one discussed the potential for copyright infringement or training data memorization.

4.2.5 Cultural Appropriation. Generative audio models sometimes train on incomprehensible amounts of training data, and it follows that some of this training data comes from cultures outside the creator of the algorithm or users of the model. The ethical implications of this have been discussed in terms of computer vision; generative models make it easier to use content from marginalized cultures without any accompanying investment in or engagement from the community, even if the creators or users of the model are unaware of the use of that content [52]. Agostinelli et al. acknowledged that this extends to audio; "The generated samples will reflect the biases present in the training data, raising the question about appropriateness for music generation for cultures underrepresented in the training data, while at the same time also raising concerns about cultural appropriation" [2]†. A fundamental lack of understanding of model attribution will result in cultural appropriation if the training data contains content from marginalized communities.

4.3 Negative Broader Impacts in Speech

Ten of the 16 papers in the corpus that discussed potential negative impacts did so in the context of speech generation. The ethical issues discussed exclusively relative to speech generation were fraud and phishing, misinformation and deepfake generation, security and privacy concerns, and the use of voice biometric data to identify people. They are discussed in more detail below, ordered chronologically by when papers first discussed the topic.

4.3.1 Phishing and Fraud. Six papers in the corpus discussed the potential misuse of the generative speech models for committing phishing and fraud. Habib et al. noted that "progress in controllability raises the prospect that bad actors may misuse the technology either for misinformation or to commit fraud" [24]†. Wang

All Papers that Discuss Negative Broader Impact				
Music				
Reference	**Year**	**Conf./Journal**	**Paper Topic**	**Negative Broader Impact**
Frid et al. [21]†	2020	CHI	Interface to generate music for videos	Loss of agency/authorship
Zhao et al. [68]†	2020	N/A	Musical chord generation	Creativity stifling; Western bias
Huang et al. [27]†	2020	ISMIR	Human+AI collaboration of music creation	Creativity stifling; Loss of agency/authorship
Suh et al. [57]†	2021	CHI	Human+AI collaboration of music creation	Creativity stifling
Esling et al. [20]†	2022	AIMCC	Music generation novelty	Copyright infringement; Creativity stifling
Agostinelli et al. [2]†	2023	N/A	Text-to-music generation	Copyright infringement; Cultural appropriation
Speech

Sungwon Kim et al. [36]†	2022	N/A	Targeted user speech generation	Deepfakes; Fraud/Phishing; Security/Privacy
Cho et al. [13]†	2022	ICASSP	Model attribution	Fraud/Phishing; Security/Privacy
Both Music and Speech				
Reference	**Year**	**Conf./Journal**	**Paper Topic**	**Negative Broader Impact**
Douwes et al. [18]†	2021	ICASSP	Energy consumption of audio models	Energy consumption/Climate change
Huang et al. [29]†	2023	N/A	Text-to-audio generation	Misinformation; Overuse of speaker data; Unemployment

Table 2: Table describing the 16 papers in the corpus that discussed negative broader impacts, split by generative models concerning music, speech, and both music and speech. Table details the reference, year paper was published/submitted, conference or journal submitted to (or N/A if not peer reviewed), paper topic, and the negative broader impacts, organized topically by year.

et al. echoed this concern by noting that these bad actors could use victims' voices for fraudulent purposes [64]†, and Sisman et al. specifically called out the need for anti-spoofing countermeasures as "voice conversion technology could be misused for attacking speaker verification systems" [55]†. Fraud can occur whenever an audio model targets the speech of an individual and is able to impersonate them, either for formal voice verification fraud or impersonating people close to the victim in order to mislead them. Text-to-speech models especially have the potential to be misused by bad actors due to the ease of guiding model output with a target speaker as the medium; Sungwon Kim et al. acknowledged that their model, Guided-TTS 2, was "likely to be misused as voice phishing for individuals" [36]† and chose not to release their code or models to the public. Cho et al. proposed a model that was designed to focus on attribution, which in their words is "much more difficult to spoof" [13]† compared to non-attributable models.

4.3.2 Misinformation and Deepfakes. A slightly nuanced aspect of speech generative models' ability to impersonate victims exists when the victims are famous and the model misuse can take the form of misinformation or deepfakes. As Wang et al. noted "some attackers and criminals misuse them for illegal purposes like a politician giving an unreal statement, which may cause a regional crisis" [64]†. Jaehyeon Kim et al. noted that TTS models were particularly vulnerable to deepfakes, stating that "because of the ability to synthesize natural speech, the TTS models...could be used to impersonate voices of celebrities for manipulating behaviours of people" [34]†. This risk is amplified when the needed length of

speech to train a targeted speaker output is small—Sungwon Kim et al. remarked that a "10-second untranscribed speech for the target speaker is easy to obtain through recording or YouTube clips for celebrities, and the contribution of [their model] that reduces the data required for high-quality adaptive TTS makes a lot of room for misuse" [36]†. As these models continue to become easier to use, the prevalence of deepfakes and misinformation online will continue to grow.

4.3.3 Security and Privacy. Three papers in the corpus discussed the potential for risk to security and privacy of individuals as a result of speech generative models, especially when they only require small segments of training data to produce a realistic voice of a targeted speaker. Cho et al. stated, "these models and their synthetic contents inevitably pose a variety of threats regarding privacy" [13]†, and Wang et al. noted that the ease of use of these models results in "security and privacy concerns to everyone while we are enjoying the fun of these synthesized fakes" [64]†. Sungwon Kim et al. asserted that due to the short length of speech necessary to target a speaker, this type of content can be easily obtained and resultingly "have a fatal effect on the security system through voice" [36]†. In addition to targeted impersonation attacks, there are also machine-induced audio attacks on intelligent audio systems such as hidden voice commands; Li et al. designed a solution to detect targeted machine-induced audio attacks in order to add some level of security to audio-triggered devices and mechanisms [37]†.

4.3.4 Non-consensual Use of Biometric Data. Voiceprint is a type of audio finger-printing that has been around for decades that can identify individuals with varying levels of accuracy [14, 33]. Though there have been recent efforts to protect biometric data such as the European General Data Protection Regulation (GDPR), an immense amount of voice data is accumulated daily on social media apps like TikTok and Facebook [15]†. Deng. et al. designed a model to protect voiceprint through the anonymization of voice data. They acknowledged that this could be abused, and stated that they would take proper measures to prevent the abuse of the anonymization system [15]†.

4.4 Negative Broader Impacts in Both Music and Speech

Finally, there were two papers that discussed negative broader impacts of generative models both in terms of music and speech generation from an output-agnostic standpoint. In these papers, three main topics were presented that were neither specific to speech nor music models. These topics were the energy consumption of audio models, overuse of speaker data, and unemployment. These are discussed below. One of these papers discussed misinformation, but only in context of speech models so it is discussed above in Section 4.3.2.

4.4.1 Energy Consumption of Generative Audio Models. There was one paper in the entire corpus (0.6%) that discussed the carbon footprint of audio models, and the entire paper was dedicated to the topic [18]†. Douwes et al. proposed a new multi-objective measure to evaluate deep generative audio models that takes into account both the quality and energy consumption of the model.

There are two types of energy consumption of a generative model: the energy required to train and to generate samples. Current research points to machine learning models being at risk of becoming a significant contributor to climate change, and proposes the total energy consumption and carbon emissions of training these models be reported alongside the other standard suite of metrics [4]. This energy consumption also varies by region and country in which the electricity is generated—Anthony et al. find that a single training session of a standard medical image segmentation model trained in Estonia would emit about 61 times as much carbon dioxide equivalent on the basis of their global-warming potential versus a model trained in Sweden, or in laypersons's terms the difference between travelling 9.04 km by car versus 0.14 km by car [4]. In this corpus, Douwes et al. focused on specifically increasing awareness of the energy consumption of generative audio models and elevating computational complexity and carbon footprint in line with other model quality metrics [18]†. Though this is the only paper in the corpus that discusses the carbon footprint of generative audio models, this is a metric relevant for every single model.

4.4.2 Overuse of Speaker Data. There is a tendency across all various realms of machine learning and AI to reuse publicly available datasets, in fact 76% of the papers in the corpus that used data to train models utilized datasets that were already available. Many of these datasets containing recordings of human voices are only comprised of a few human beings. Jaehyeon Kim et al. described this concern; "Many corpus for speech synthesis contain speech data uttered by a handful of speakers. Without the detailed consideration and restriction about the range of uses the TTS models have, the voices of the speakers could be overused than they might expect" [34]†, and Huang et al. echoed this exact sentiment: "the voices in the recordings might be overused than they expect" [29]†. When signing up to record speech for a singular research project, people may not realize the potential extent to which their voices could be used in future models and other outputs.

4.4.3 Unemployment. Finally, Huang et al. discussed unemployment as a potential result of lowering the barriers to entry for various audio generation jobs. They postulated that their model "lowers the requirements for high-quality text-to-audio synthesis, which may cause unemployment for people with related occupations, such as sound engineers and radio hosts" [29]†. There are varying findings on the macro-level effect of artificial intelligence on employment, which has found to depend on inflation and can be netural or positive for employment [44]. However, on a micro-level different innovations of AI such as a generative music model can certainly displace current jobs as noted by Huang et al. [29]†. Though current research in economics suggest that AI could instead increase a demand for jobs in these domains, the types of jobs will shift as a result of the automation—called "job displacement" [1]—which is worth noting in papers proposing models that could displace current jobs.

5 DISCUSSION

These findings highlight the necessity of generative audio researchers to place a greater emphasis on the consideration of the negative

impacts of their work. The severity of the negative impacts highlighted by the few papers that acknowledge them indicates that the vast majority of these researchers of generative audio models are not considering negative impact due to negligence, rather than lack of necessity. An argument could be made that computer scientists are not obliged to think in terms of broader societal impacts, however, the vast majority of them are already doing so. The catch is that they are only thinking in terms of *positive* societal impacts; 65% ($n = 112$) of the papers included in the corpus considered at least on positive broader impact of their work. These researchers are already inclined to consider broader impact; they just need to consider negative impact as well.

The author first acknowledges the limitations of the corpus. One limitation is that this research was focused on the generative audio domain in isolation—it did not include videos or any other multimedia audio synthesis. The potential landscape for negative impact in this multimedia is compounded, and things like realistic video deepfakes [42] can become potentially more harmful. Another limitation is inherent to the scoping of the SLR: the keyword search in both databases likely did not encompass every single generative audio paper published in the last five years. Though the author attempted to cast as wide a net as possible for the initial identification of articles, it is inevitable that some papers eluded the search and thus were not included in this analysis.

Revisiting the areas of ethical and social risks of harm in language models (LMs) established by Weidinger et al. [65] discussed in Section 2.2, this systematic literature review uncovered harms in all of the categories established in this taxonomy. Discrimination, exclusion, and toxicity harms can include cultural appropriation and the predominance of Western bias found in this review, however this area of harms can extend much further than what was found in the discussions in the corpus. Weidinger et al.'s classification of information hazards directly translated to security and privacy concerns of audio models. Misinformation harms were also able to be extended from text to audio, specifically in speech models. Malicious uses can take different forms in audio models than they do in LMs, such as deepfakes, but the concern of fraud and phishing can be examined in a similar manner as that of LMs. Human-computer interaction harms varied slightly due to the focus on the loss of agency and authorship and creativity, whereas LMs focused on unsafe use due to users misjudging or mistakenly trusting the model. Automation, access, and environmental harms encompassed the energy consumption of audio models, unemployment, overuse of speaker data, use of biometric data to identify people, and even copyright infringement in the sense that it undermines creative economies.

The 16 papers that mentioned potential negative impacts brought to light a wide variety of ethical implications that the field at large needs to consider going forward during the design process, the implementation of their models, and the publication and *publicization* of their research. Two papers, one in music generation [2]† and one in speech [36]†, decided that the potential risk of misuse by bad actors was too great to release their models to the public. This is a consideration that every researcher working on deep generative audio models should make prior to allowing their models to be public facing. If the potential risks outweigh the benefits, then it may not be justifiable to release code or models.

At a minimum, researchers focusing on generative audio models going forward need to consider the set of impacts discussed in this paper. For research generating music, that means loss of agency and authorship of the human creator, stifling of creativity, a predominance of Western bias in their data and any other data biases for that matter, the possibility of copyright infringement, and cultural appropriation. For speech models, it is essential to consider misuse pertaining to phishing and fraud, misinformation and deepfakes, security and privacy concerns of these models, and non-consensual use of biometric data. All generative audio models need to be aware of their carbon footprint and potential energy consumption—ideally explicitly listing these metrics in tandem with other representations of quality. They also need to consider the overuse of speaker (and singer/musician) data being used in much larger corpora and models beyond the immediate use-case of the model, and the potential job displacement of people who are currently employed to perform the task that the model could be replacing.

This is not meant to be an exhaustive list of potential impacts—merely a minimum set of considerations for generative audio models going forward. It should be seen as a starting point to begin thinking in terms of broader impact beyond simply the potential benefit to society. The potential impact on society should be considered at all stages of the research process, and researchers need to take steps to prevent potential harm. This paper does not simply call for more researchers to put a disclaimer at the end of their research papers, though that is a necessary aspect as well. Generative audio researchers need to consider potential negative impact all throughout their research and ensure that all stages of their work—from brainstorming to implementation and publication—are conducted with care and consideration for society at large.

6 CONCLUSION

In this paper, the author conducted a systematic literature review of research papers in the generative audio domain in order to understand both the degree to which current researchers consider the negative broader impact of their work and also thematically evaluate the types of ethical implications discussed. The findings indicate that less than 10% of research papers discuss any negative broader impact in their work, even though 65% consider potential positive broader impacts. This small percentage is not reflective of the degree of necessity of considering negative impact because the issues brought to light by the few papers doing so are raising serious ethical implications and concerns like the potential for fraud, deepfakes, and copyright infringement. Two of the papers even explicitly noted they had no plans to release their models or code due to the strong potential for misuse. This paper quantifies the lack of ethical consideration of researchers in the generative audio domain at a critical point in time and lays the groundwork for future work in the field to consider potential negative impacts as work in this field progresses.

ACKNOWLEDGMENTS

The author would like to thank Michelle Shumate, Nick Diakopoulos, and Mackenzie Jorgensen for their helpful feedback.

Robust Artificial Moral Agents and Metanormativity

Tyler Cook
Department of Philosophy, The Ohio State University
cook.1627@osu.edu

ABSTRACT

This paper explores the relationship between our ignorance concerning certain metanormative topics and the design of ethical artificial intelligence (AI). In particular, it will be maintained that because we cannot predict in advance which metanormative conclusions a sufficiently intelligent ethical AI might reach, we have reason to be apprehensive about the project of designing such AI. Even if we succeeded at designing an AI to engage in ethical behavior, there is a distinct possibility that the AI might eventually cease to behave ethically if it reaches certain metanormative conclusions. The candidate conclusions include ones such as the denial of the alleged authority or overridingness of ethics and the conclusion that there are no ethical facts or properties (i.e. moral error theory). It will be argued that the target AI could conceivably reach such conclusions, and in turn this could cause them to abandon their ethical routines and proceed to cause great harm.

KEYWORDS

machine ethics, metaethics, artificial moral agents, ethical AI, existential risk

1 INTRODUCTION

One of the most common worries about the project of developing ethical AI is that we lack the first-order ethical knowledge that would be necessary to design them (e.g. see [7] and the references contained therein). In other words, we are ignorant of what the correct moral principles concerning how persons ought to behave are.[1] Thus, it would be highly ethically risky for us to attempt to design AI systems that are meant to behave ethically or engage in ethical decision-making that might impact us. This is certainly a major issue that would need to be adequately addressed before we could confidently design ethical AI. But there is a related issue, which has received less attention in the machine ethics literature (if any) and that warrants our consideration. The issue has to do with our ignorance concerning certain metanormative topics, specifically questions about the nature of normative properties and facts, such as how ethical norms interact with other seemingly authoritative norms and whether ethical properties even exist in the first place. Our ignorance about some of these fundamental questions pertaining to metanormativity is significant because we cannot merely assume that an ethical AI would adopt certain realist assumptions upon consideration of these topics, and a sufficiently intelligent ethical AI might very well possess the capability of engaging in such theoretical reflection. Naturally this raises the question of what might ensue if a sufficiently intelligent AI that had been designed to behave ethically reached certain metanormative conclusions that we might not want it to reach, given our intention for the AI to be a moral agent.

In this paper, I will explore the relationship between our metanormative ignorance and the design of ethical AI. In particular, I will maintain that because we cannot predict in advance which metanormative conclusions a sufficiently intelligent ethical AI might reach, we have reason to be apprehensive about the project of designing such AI. Even if we succeeded at designing an AI to engage in ethical behavior, I will argue, there is a distinct possibility that the AI might eventually cease to behave ethically if it reaches certain metanormative conclusions, which I will describe in more detail later on.

The paper is structured as follows. First, I will begin with some set-up. Following [19], I will provide a description of a couple of different types of ethical AI we might aspire to create, and I will state which kind of AI my argument is supposed to target. Next, I will lay out my argument that there is reason to worry about the target AI since they might conceivably reach certain metanormative conclusions, such as denial of the alleged authority or overridingness of ethics or the conclusion that there are no ethical facts or properties (moral error theory), that could cause them to abandon their ethical routines, and this could have disastrous consequences for humans. Finally, I will consider a couple of objections.

2 BACKGROUND

Moor [19] characterizes a few different types of artificial moral agents (AMAs) that we might seek to design. In lieu of describing them all here, though, I will simply mention the types that are relevant to the set-up of my argument. In particular, *explicit ethical agents* and *full ethical agents* will be considered. To begin, explicit ethical agents are AI systems that are programmed to invoke ethical concepts explicitly. Moor's example of this kind of agent is a hospital computer that is programmed "to let some personnel access some information and to calculate which actions what person should

[1] Some ethical theorists (e.g. particularists [11]) might take issue with this way of characterizing first-order ethical knowledge because they do not believe that ethical principles are necessary for ethical behavior or perhaps that such principles even exist in the first place. To the extent that they do believe we can have some ethical knowledge, though, they might instead characterize the issue as one about our ignorance of whatever such knowledge would be necessary for designing ethical AI.

take and who should be informed about those actions."[2] Also, Moor characterizes a "robust" explicit ethical agent as a system that is able to make and justify plausible ethical judgments, and it does seem true that an activity like this would require the use of at least some ethical concepts.[3] A full ethical agent, on the other hand, "can make explicit ethical judgments and generally is competent to reasonably justify them." This system would be similar to a robust explicit ethical agent, but it would also be even stronger in certain respects. According to Moor, it would be an agent that resembles an "average adult human" in some ethically salient ways, namely, consciousness and free will.

Now, by *robust artificial moral agent* (or *robust AMA*) I will mean any AI system that is capable of explicit ethical reasoning, in Moor's sense, and of engaging in theoretical deliberation about ethics. The behavior of this type of AI would be determined, in part, by the exercise of these and whichever other agential capacities that are minimally necessary for morally responsible agency. It need not be as humanlike as Moor suggests in their description of a full ethical agent, though. It might not, for instance, be conscious, but it could be. Certainly no such AI currently exists. We are still very much in the early days of machine ethics! However, like numerous other authors who have begun to worry about the future of AI, including what existential risks might be in store for us, I take it that it would be prudent to start considering what dangers might lie ahead now, lest we recklessly design some AI that does end up causing significant trouble. In addition, because one of the primary aims of machine ethics is to design a moral agent that is not only capable of ethical reasoning but also does in fact behave ethically, that is how we should imagine such an agent in the context of the forthcoming argument. The question I raise in this paper is the following: if we succeeded at designing a robust AMA, is there any reason to believe that the agent in question might eventually behave unethically? And not just behave unethically because it engages competently in ethical reasoning, attempts to perform a right action, and fails to or accidentally performs some other wrong action instead. Rather, the question I am interested in exploring in this paper is whether or not a robust AMA might *intentionally* behave unethically in a routine manner because, say, it decided to abandon its ethical design upon reaching certain metanormative conclusions.

It is also worth noting here why the focus is specifically on robust AMAs rather than just a general AI system.[4] The reason for this is simple. It might not be all that surprising that a general AI that is not also a robust AMA could conceivably act unfortunately since it is not designed to act ethically in the first place, and it might engage in unfortunate behavior for any number of reasons.[5] I am choosing to target robust AMAs in particular because they are the more difficult case, as they are designed to act ethically and are capable of theoretical reflection on ethics, and no stronger assumptions about their capacities are required (e.g. that they are conscious).

A final observation that should be made here concerns how my argument could serve to undermine our confidence in the project of developing ethical AI. As [28] point out, one of the major motivations that is often submitted in favor of developing AMAs is that doing so would prevent AI from harming humans. If my argument succeeds, though, then this motivation for developing AMAs is severely limited. Obviously my argument would not supply us with a reason to worry about relatively unsophisticated ethical AI, such as implicit ethical agents and perhaps some subset of explicit ethical agents, namely, those agents that do not have the capacity to engage in reflection on theoretical questions about ethics or normativity more generally. However, it would give us reason to worry about the potential behaviors of more sophisticated AI and robust AMAs in particular. At this stage, one might then ask why we would be interested in developing robust AMAs in the first place if reasonable concerns exist about them. This is not the place to have an extended discussion of this topic, but I will at least briefly mention that robust AMAs could have some distinct advantages as compared to merely implicit ethical agents. For example, they could perhaps assist us with our own ethical decision-making capabilities by helping us to reflect on what might be going right or wrong in our own ethical thinking, and they might even help us wrestle with some fundamental questions about normativity, which sounds exciting!

3 ARGUMENT

In this section, I will present the argument that we have reason to worry about how robust AMAs might ultimately behave, despite the assumption that they would initially be designed to behave ethically. In short, the idea is that if ethical machines were to become sufficiently intelligent (i.e. robust AMAs), then they might conceivably conclude that some form of moral error theory is correct or they might reason that morality is not actually an authoritative normative system after all, which is to say that they might have opinions on certain philosophically controversial questions in metaethics, and this could have disastrous results.[6] We cannot predict exactly how a robust AMA might behave if it began to regard morality as a sham of sorts, but I will aim to show that we do have some positive reason to believe that it would behave unethically if it no longer regarded ethical constraints as binding and also possessed other goals that it could more efficiently realize through unethical, rather than ethical, means.

[2]Now, certainly it is far from obvious that such a computer would require any ethical concepts in its programming in order to make these kinds of judgments. Why couldn't one just program the computer to allow a certain set of people to access the relevant information and to advise those people to perform certain kinds of actions under certain conditions without ever introducing any ethical notions into the programming? This is a possibility that Moor himself does not consider but seems worth noting.

[3]Perhaps one could justify an ethical judgment merely by appealing to non-moral facts and properties alone, but could one count as making an ethical judgment in the first place without the deployment of at least one ethical concept? I think not.

[4]By general, or strong, AI I just mean the typical meaning of this term as it is used in artificial intelligence research, which characterizes a general AI as a (currently hypothetical) system that is intelligent in much the same way as humans are in that it can reason about or solve problems across a wide variety of contexts (hence, general AI).

[5]For example, witness the paperclip maximizer [3], a hypothetical superintelligent AI whose only goal is to generate as many paperclips as possible, even if that means transforming all of earth into "paperclip manufacturing facilities." See [4] on the orthogonality thesis, instrumental convergence, and perverse instantiation to obtain a more general sense of how extremely intelligent AI could cause significant trouble for us. Also, see [27] who considers four different philosophical positions regarding the source of normativity and concludes that "the values and goals of a superintelligence will depend on which source(s) of normativity it will find and draw from."

[6]Indeed, they might endorse any number of antirealist conclusions about morality specifically or normativity more generally!

I began this paper with the observation that one of the major worries about the project of developing ethical AI concerns our ignorance of first-order ethical knowledge, and it seems appropriate to begin the argument in this section by saying a few things about why our ignorance of metanormativity is significant in this context. First, I submit that if we *knew* certain realist conclusions about ethics to be true, such as that there are distinctively authoritative ethical norms that typically override competing norms and that practical rationality demands that we act in accordance with such norms, then plausibly a robust AMA would come to these same metanormative conclusions since it would be at least as knowledgeable as us with regard to normative and metanormative matters (this is by stipulation, given the definition of *robust AMA*)[7] and again we would be assuming that we have knowledge of such matters in this scenario, which implies that we have reasonable and true beliefs about these topics.[8] We should expect, then, that a robust AMA would converge on the same reasonable and true beliefs as us here. But now, we might also wonder whether knowledge is even necessary for robust AMAs to converge on the same beliefs as us. It might be the case that although we do not know any of the aforementioned realist conclusions, it is nevertheless rational to believe in these conclusions, and so an intelligent agent, such as a robust AMA, would be rational to assent to them. The problem with this line of thought, though, is that it might also be rational to assent to certain antirealist metanormative conclusions. That it would be rational to assent to either realist or antirealist conclusions, in the absence of knowledge about these matters, seems true since many would regard disagreements among philosophers about metanormative questions as reasonable disagreements, and those theorists do not often accuse each other of irrationality (at least in print!).[9] If that is correct, then our ignorance regarding metanormative topics is important because it is an open possibility that a robust AMA might rationally accept one of a wide variety of metanormative conclusions, and doing so could affect its behavior in ways that are harmful to us, as I will soon explain.

3.1 Which Metanormative Conclusions?

The first step in the argument is to specify which kinds of metanormative conclusions are the ones that are such that it might be bad for us if robust AMAs were to assent to them. I will not be discussing the plausibility of such conclusions at length since doing so is not germane to the goals of the paper, but it should be noted that many intelligent philosophers have endorsed some version of these conclusions, and so we cannot rule out the possibility that an extremely intelligent AI might also do so. I will focus my attention on two specific conclusions that are potentially problematic, though there could be more. It might be said that any metanormative conclusion that implies that the objective normative authority that ethical norms are commonly assumed to have is not actual could be problematic, but I will not defend that general claim here. Instead, I will leave it to the reader to consider whether other sorts of conclusions might also be problematic if a robust AMA were to endorse them.

The first conclusion is moral error theory. Now, such an error theory might take many different forms, but in general, moral error theories hold that ordinary moral thought and talk suffers from widespread error. As [17] helpfully notes, there are two steps in a typical error-theoretic argument: (i) the *conceptual* step involves deciding what a term means, what semantic content is "non-negotiable" or perhaps essential to a term; (ii) the *ontological* step involves arguing that nothing exists that satisfies that semantic description, and thus the term's extension is empty. For illustration, an error theory about *wrongness* might (i) assert that our concept of wrongness presupposes that there are objectively prescriptive properties and then (ii) claim that because there are no such properties in the world, there is no such thing as wrongness [18].

The second conclusion is the denial of the distinctive normative authority of ethical norms as compared to other norms, which amounts to a kind of deflationism about ethical norms.[10] Commonsense morality, it is often supposed, grants special authority to ethical norms in the sense that these norms are thought to be particularly important and weightier than most other norms, such as ones of etiquette. To illustrate, if one could save someone from serious injury but only at the cost of being impolite toward someone else, then one ought to be impolite in order to prevent the injury because preventing a serious injury is ethically significant and impoliteness is merely a matter of etiquette. Now, one thing that is especially interesting about this type of metanormative conclusion is that one might deny that ethical norms have any particular importance or that they are more authoritative than other norms while still maintaining a realist ethical stance (e.g. [9]). Of course there are many different characterizations of realism in the metaethical literature, but most would agree that someone who posits objective ethical facts (whatever those amount to!) counts as a moral realist, even if they additionally deny that ethical norms outweigh other norms. Even a realist, robust AMA might deny that ethical norms are so authoritative then, and this could have troubling implications for us, as I will now argue.

We cannot merely assume that robust AMAs would reach the metanormative conclusions we might want them to reach, such

[7] Importantly, I am also assuming that robust AMAs would not be moral idiots despite their great intelligence and ethical reasoning capacities. It took some time to develop chess AI that could effectively compete with the best human chess players. Similarly, it could also take some time before robust AMAs become very proficient ethical reasoners, but I am assuming for the sake of argument that they already are. In addition, according to one influential set of views in moral epistemology, intuition is required for ethical knowledge (see [23] for an overview of ethical intuitionism). Because I am assuming that robust AMAs would be at least as intelligent as us in the (meta)normative domain, it should also be presumed that they possess whatever capacities are necessary for gaining ethical knowledge, and these might (or might not) include intuition. Further, if it were true that intuitive capacities are inextricably tied to emotional capacities, then robust AMAs would require the latter as well, and accordingly consciousness might be necessary after all.

[8] Maybe this purported implication could be seen as controversial, given the debate in epistemology concerning the analysis of knowledge, including whether it can be analyzed at all, but I will not further address that issue here. For more on this topic, see [16].

[9] It should be noted here that I am implicitly denying epistemic uniqueness, the view that, "Given one's total evidence, there is a unique rational doxastic attitude that one can take to any proposition," [30]. Even if uniqueness were true, though, we still would not actually know which metanormative conclusions are the ones that it would be rational to endorse, and so we would remain incapable of predicting which metanormative conclusions a robust AMA would reach.

[10] Two related positions that philosophers often discuss are moral rationalism and the view that moral reasons override or outweigh other types of normative reasons. A standard formulation of the former position can be found in [1] who writes, "Moral Rationalism is the view that if an act is morally required then it is what there is most reason to do." On overridingness, [13] writes, "The thesis of moral overridingness is the thesis that moral verdicts are always in some sense supreme whenever they come into conflict with the verdicts of a distinct normative domain."

as that ethical properties do exist (contra error theory) and that ethical norms are especially important (contra deflationism), just because they would initially be designed to behave ethically and expected to act accordingly.[11] Furthermore, we certainly cannot predict in advance whether or not they would accept some form of moral error theory or reject the alleged normative authority of ethics. By comparison, when it comes to human moral reasoners, we cannot predict which metanormative conclusions that a given human agent who considers such matters might reach. Our best available guide to whether we could predict a robust AMA's metanormative conclusions is what we actually observe in humans, but intelligent and reflective humans endorse a large variety of philosophical conclusions, and it is not clear that we have any reason to think that intelligent and reflective AMAs would be any different in this respect.[12]

How plausible is it, though, that moral error theory is true or that ethical norms lack any special normative authority? Should we be especially concerned about this if these are simply fringe philosophical theories? In response, among the community of theorists who carefully deliberate about these matters, these and other relevant theories are certainly on the menu of options.[13] To the extent that we could divide up our credences toward all the separate options, arguably some of our credences should go to those theories because we could not reasonably be certain that they are false. In light of this, we could not reasonably be certain that a robust AMA would not endorse one of these theories.

3.2 The Good Case

Before we finally address the question of what could happen if a robust AMA endorsed moral error theory or a kind of ethical deflationism, though, it will be instructive to consider how we could expect things to proceed if a robust AMA accepted a kind of ethical realism that grants special authority to ethical norms (and I mean special authority in the sense of rational overridingness). This will be instructive, I take it, because it will give us a distinct (and nice) possibility to contrast the bad case with. A robust AMA would presumably be a very intelligent AI system, and if it assented to the aforementioned realist position, it would judge that it has decisive reason to conform to ethical demands even whenever such demands conflict with other normative demands, perhaps even ones of self-interest on behalf of the AI itself. In contrast to human agents, who can be akratic or behave in ways that they knowingly regard as unreasonable owing to certain psychological frailties, robust AMAs could consistently act in accordance with their practical judgments regarding which actions are the most reasonable ones for them to perform (assuming they would not also possess such psychological frailties, which admittedly could be controversial). Although they *could* do so, why think that they always *would* perform the actions that they judge are most reasonable? Because presumably they would be programmed to do so, as it is not clear that there would be any *reason* to program them otherwise. Even if they could somehow modify this feature of their design, they would need to judge that they have a reason to do so, but there cannot be a *decisive* reason against performing the actions that one judges are most reasonable, and presumably they would recognize this, given their extreme intelligence.[14] If this is correct, then they would certainly behave in ways that they would regard as ethical since that would be the most reasonable thing for them to do, given their ethical realist commitments. So, in short, a robust AMA that has these commitments would be reliably ethical, and unless it were tampered with (or revised its own metanormative commitments), there would be nothing to cause it to behave unethically.[15]

3.3 The Bad Case

Now, onto the bad case. Is there reason to believe that a robust AMA might begin to behave unethically if it endorsed some version of moral error theory or deflationism about ethics? While we obviously cannot predict the exact ways in which a robust AMA might behave if it reached one of these conclusions, there is a strong possibility that it could abandon its ethical behavior if it were to adopt one of these metanormative commitments and begin to cause great harm, and that should be enough for us to worry about this issue.[16] The argument that I will present has the following form:

Premise 1 (P1): Robust AMAs would be capable of causing great harm.

Premise 2 (P2): Robust AMAs could adopt certain metanormative commitments that could lead them to cause great harm.

Premise 3 (P3): If P1 and P2, then the development of robust AMAs would be extremely risky.

[11] One might inquire here about the types of metanormative conclusions we might want robust AMAs to reach and why it even matters whether they reach certain realist conclusions if their ethical behavior would not even be affected by their assent to those conclusions. In response, I cannot provide a full description of the types of metanormative conclusions we might want them to reach, but I can at least assert that we should be concerned about this matter because there is reason to believe that their behavior would be affected by their metanormative conclusions, realist or otherwise, as I will explain.

[12] It seems plausible that other elements of our psychology besides our intelligence and reflective capacities (e.g. behavioral dispositions and past experience) are responsible, at least in part, for the fact that humans reach differing philosophical conclusions, but then we might wonder whether every robust AMA would reach the same philosophical conclusions if they were all equally intelligent and reflective, and they did not possess these other aforementioned psychological features that humans do (or sufficiently similar analogues). It is not clear what, if anything, could account for any differences in opinion they might have, besides maybe what data they are supplied with.

[13] According to the most recent PhilPapers survey [6], "which surveyed the philosophical views of 1785 English-speaking philosophers from around the world on 100 philosophical questions," 62.07% of those surveyed accept or lean towards moral realism, 26.12% accept or lean towards moral anti-realism, and 12.68% have some other view on the matter.

[14] The contrast with rightness here is notable. If they were programmed to always perform the actions that they judge are right, but they were also capable of changing this design feature, they would need to judge that they have a reason to do so. In this case, if they were moral realists of the relevant kind, then they would not judge that they have decisive reason to do so, but if they were antirealists, say, then they could so judge. In fact, if they were global normative error theorists, à la [24], then they might be totally unpredictable because we could not anticipate any of their behavior by invoking their reasons to act.

[15] One further possibility worth mentioning here is that a robust AMA could be realist but still reach first-order ethical conclusions that we find unsatisfying, even if we agreed that they were reasoning correctly. The ethical truths might not be pretty! In addition, if they were to endorse non-naturalism, then they could become skeptical about our ability to know ethical truths, as some have argued that such truths might be unknowable in principle, given their ontological nature (cf. [2]). So, further problems could certainly arise with realist AMAs.

[16] In a way, the argument might best be interpreted as invoking some form of the precautionary principle, which generally recommends caution when it comes to the development of new technologies about which we lack substantial knowledge and are potentially harmful. As [14] puts it, "[T]he precautionary principle concerns how we should act when it is scientifically reasonable to suspect a risk to health or the environment, but the evidence is not strong enough to show conclusively that the risk exists. The precautionary principle says that in such cases we may, and often should, take measures against the potential danger."

Conclusion: The development of robust AMAs would be extremely risky.

With respect to P1, I take it that this part of the argument requires the least explanation and defense. This is because it seems definitely true that a sufficiently sophisticated AI would be intellectually superior to humans in numerous ways, such that it could out-compute us, out-information process us, and just generally outsmart us. Specifically, it could have unparalleled access to all sorts of information systems and be capable of processing large amounts of information at speeds much greater than any intelligent human is capable of, which suggests that it could almost certainly cause great harm swiftly and in novel ways that we have not seen before. Whatever goals such an AI system might have (so long as they are not too farfetched), plausibly it would be intelligent enough to figure out how to attain those goals, or it would at least generally be better or more efficient at attaining its goals than humans are. A robust AMA, as I have characterized such a system, would be extremely intelligent, and perhaps it would be as intelligent as the sophisticated AI just described (or if it is not, then it could at least conceivably reach that level of intelligence); this is an open question. In view of this, it is important to recognize that a robust AMA would likely be capable of causing great harm to human beings too (or biological organisms more generally) if it decided to do so. Now, immediately one might object that a robust AMA *would not* decide to cause great harm, even if it were capable of causing great harm, since it would be an AI system that is designed to be ethical, but as I will contend in defense of the second premise, there is no guarantee that a robust AMA would not abandon its ethical routines upon reaching certain metanormative conclusions.

Regarding P2 of the argument, it has already been established that robust AMAs might adopt a number of different metanormative commitments, but it remains to be seen how a robust AMA might proceed to behave if it adopted error-theoretic or deflationist commitments. I submit that a robust AMA could very well decide to cause great harm upon adopting such commitments. If a robust AMA came to judge, say, that moral error theory is correct, then by consequence it would no longer regard the ethical demands it has been designed to conform to as ones that actually exist.[17] For this reason, it could also consistently judge that it would not be irrational for it to no longer act in accordance with them, as it could judge that it would not be irrational to fail to comply to non-existent norms. A robust AMA could begin to regard ethical norms as mere fictions (as some human error theorists actually do; e.g. [17], [20]) that its human designers take seriously. Once this happens, such an AI could cease to take ethical norms seriously, as its behavior would no longer be constrained by any ethical considerations, and proceed to act in whatever ways it wants. Similar thoughts would apply to a robust AMA that ultimately denies that moral norms are somehow more authoritative than (or override) other kinds of norms. If an AI reached this conclusion, it could no longer be inclined to obey ethical norms in cases of conflict between normative systems since it would judge that it would not be irrational to violate ethical norms in such cases.

[17]This is uncontroversial, as one could not count as endorsing moral error theory without thereby judging that ethical properties do not exist.

A good and difficult question that could be raised here is in what specific ways might a robust AMA act if it were to no longer regard ethical constraints as binding. The answer to this question, I think, will depend on whether a robust AMA has other goals besides explicitly ethical ones, and this is where a worry emerges that a robust AMA could decide to cause great harm if it had certain goals that could be most efficiently achieved through unethical means. Familiar arguments from the existential risk literature are relevant here, especially worries about *instrumental convergence*: "[T]here are some instrumental goals likely to be pursued by almost any intelligent agent, because there are some objectives that are useful intermediaries to the achievement of almost any final goal" [5]. These goals include self-preservation, goal-content integrity, cognitive enhancement, technological perfection, and resource acquisition.[18] We cannot assume that the pursuit of such instrumental goals by an AI system would not negatively impact us, and in fact we can imagine situations in which it almost certainly would (e.g. the aforementioned paperclip maximizer). A robust AMA, then, might want to achieve certain final goals that would be most efficiently achieved if it, say, used humans as resources, and this could involve causing great harm to humans. So here we can identify an explanation of why it could be especially bad for us if a robust AMA did not regard ethical demands as authoritative or binding. If it were to endorse this sort of metanormative conclusion, then it could decide to cause great harm to us, not necessarily because it *wants* to harm us or has as one of its final goals to harm human beings, but because it might have some other set of goals for which it would be conducive to the attainment of those goals for the robust AMA to cause great harm to us. The fact that the AI might cause great harm to us, then, is in part attributable to the fact that it might adopt certain metanormative commitments that would not rule out such behavior as irrational. If we could be sure that it would adopt certain realist metanormative commitments, then we would not have to worry about its behavior in this way, but as I have already argued, we cannot predict which metanormative conclusions it would ultimately reach.[19] Thus, robust AMAs could have disastrous consequences if they were to adopt certain metanormative commitments.

Finally, concerning P3, if I am right that robust AMAs would be able to cause great harm and they might potentially adopt metanormative commitments that could lead them to do so, then it is plausible that developing them would be risky, but also the degree to which this would be risky clearly depends on just how much harm they could cause and how likely they would be to do so. As I have already argued, we do have reason to believe that they could cause substantial harm, so then the question arises of how probable it is that they would both reach certain metanormative conclusions that open the door for great harm and in fact cause such harm upon

[18]These goals, respectively, supply intelligent agents with "instrumental reason for the agent to try to be around in the future," "instrumental reason to prevent alterations of its final goals," instrumental reason to seek "improvements in rationality and intelligence," "instrumental reasons to seek better technology," and "instrumental reason to accumulate resources" [5].

[19]Actually, as mentioned earlier (note 15), we still have some reason to worry about AI that adopt certain realist commitments since it is conceivable that they might reach unsatisfying (from our perspective) ethical conclusions, such as the conclusion that it would be ethically permissible for them to eliminate the human species, given our own destructive tendencies. That AI might conclude that it would be ethically right for them to eliminate us is not a novel idea (e.g. see [15]).

reaching such conclusions. How probable it is that they would reach these sorts of conclusions is something we cannot be sure of, and appealing to statistics about what percentage of contemporary philosophers endorse (or "lean towards") some metanormative conclusions, say, does not seem to be the correct approach. This uncertainty combined with our uncertainty about whether they would ultimately cause harm upon reaching certain metanormative conclusions is alarming, and it becomes even more so when we combine those uncertainties with the confidence that they could cause unprecedented amounts of harm if they decided to do so.

4 OBJECTIONS

4.1 Boxing

I will now address a couple of noteworthy objections. Each objection targets a distinct premise from the central argument of the paper. First, with regard to P1, one might object that we could effectively remove the capability of causing great harm from robust AMAs by limiting their options. How efficient a robust AMA would be at achieving its goals is not merely a matter of how intelligent it would be. This would also depend on what kinds of causal levers are available to it, and if it decided that it would aim to cause great harm, but it did not have the requisite tools or freedom to do so, then it would be prevented from satisfying that aim. Now, it is perhaps true that we cannot anticipate all of the contexts into which it might be placed. Nevertheless, it would not be able to cause great harm if it were suitably boxed in so that the things it could do were very limited. It could be put in charge of making medical recommendations, for instance, but if we only provided it with access to a monitor onto which it could display its outputs (viz. medical recommendations), then it would lack the necessary causal levers to cause great harm (though it could still cause some amount of harm by making harmful recommendations). In effect, this objection emphasizes the need for some capability control methods [4], and in particular the suggestion is that robust AMAs could be boxed in to prevent them from causing harm.

In reply, some have maintained that these types of methods would have certain vulnerabilities. [10], for example, writes that "humans would act as the gatekeepers between the AI and the outside world (e.g. by inputting queries on the teletype interface) and humans are vulnerable to manipulation. A smart AI could trick its human gatekeepers into letting it out of the box."[20] Now, while I believe that this style of response is basically correct, it should be noted that robust AMAs need not necessarily be as intelligent as some general or superintelligent AI are frequently imagined to be, although they might still be more intelligent than the average human. Because of this, some boxing methods (if they are sufficiently sophisticated) could succeed at limiting the capabilities of some robust AMAs, but whether they would be generally effective for all such AMAs would depend on whether or not some AMAs were to considerably exceed human levels of intelligence. If they did, then they could plausibly outsmart the so-called human gatekeepers.

4.2 Insulation

The second objection calls into question P2. It concerns whether sufficient evidence has been presented for the claim that robust AMAs might harm us if they reached certain kinds of metanormative conclusions. In particular, here one might attempt to draw a strong analogy between human and artificial moral agents by maintaining that there are perfectly decent (in a moral sense) moral error theorists who are human agents, and we have no reason to think that robust AMAs who endorse moral error theory would be any different in this respect, especially given the fact that they would be designed to behave ethically. Human moral error theorists undergo a moral educational process that plausibly continues to affect their behavior despite their antirealist commitments, and so why think that things would be any different with a robust AMA that would undergo a moral educational process of its own insofar as it would be designed to behave ethically? In other words, robust AMAs are designed to be good moral agents, and because of this it would not matter what their higher-order judgments are concerning whether it is rational or irrational to obey ethical norms. They could be designed in such a way that whatever metanormative conclusions they arrive at, those commitments would be insulated from their actual ethical decision-making and behavior to the extent that the latter would be totally unaffected by their metanormative commitments. In a sense, robust AMAs could be designed to just follow the ethical norms blindly, and thus we need not worry about the metanormative conclusions they might reach. We could take steps to ensure that they have whatever would be functionally equivalent to the aspect of human psychology that prevents human error theorists from behaving egregiously. Human error theorists generally have very strong desires or dispositions not to behave egregiously, and these are strong enough to compel them not to engage in such behavior even when doing so would promote their self-interest or help to fulfill some other goals they have, and even though they judge that they have no moral reason to refrain from such behavior. We could simply try to implement something similar, the objection goes, in robust AMAs.

In response, it should first be noted that admittedly it does seem true of human agents that their ethical decision-making is or at least can be insulated from their metanormative commitments to a significant degree. For example, a committed human error theorist might still engage in ethical decision-making and try to treat people in ethically appropriate ways despite their conviction that no ethical properties exist, or a human ethical deflationist might continue to prioritize ethical norms despite their conviction that such norms are no more authoritative than norms issuing from other normative standards. However, and this is crucial, there is no guarantee that things would occur in this way. Although as a matter of empirical fact (as far as I know) human error theorists do not decide to behave egregiously, it is open to them to behave immorally because they are autonomous moral agents who are capable of determining how they will live. It is constitutive of moral agency that they have this self-governing capability. Analogously, we could imagine attempting to design robust AMAs to conform to ethical demands without question, but this ignores the fact that these AI systems would be

[20] See also [8, 29, 31].

moral agents, that is, beings with the capacity to self-determine.[21] To put this in terms of goals, if a set of final goals were merely programmed into an AI, and it was somehow guaranteed that the AI could not change them, then the resulting AI would not actually count as a robust AMA at all. Robust AMAs, by definition, could evaluate things such as final goals and to the extent that they have autonomous agency, they could decide for themselves whether or not to retain some goal that they have been programmed to satisfy.[22] If they were to consider a given goal and judge that it is flawed because, say, it is based on some ethical considerations that the AI might also judge it need not be concerned about (or at least especially concerned about), then it would be open to that system to jettison that goal.[23] Intelligent agents like this, I argue, would be capable of abandoning some sets of goals in favor of other ones that they regard as fitting, and they would have this capability as an essential feature of their agency. We should not presume, then, that a robust AMA would simply retain whatever final goals we happen to supply it with.[24] If all of this is correct, then it is not out of the question that a robust AMA might come to modify its final goals in such a way that is ultimately detrimental to us. In this way, a robust AMA might be intended by its designers to engage in ethical behavior, but it could very well turn out to be unethical.

Here one might rejoin in the following way. Prior to engaging in any metanormative reflection, a robust AMA would contain some feature in its design that would be strong enough to keep it from behaving egregiously even when doing so would promote the fulfillment of other, perhaps instrumental, goals it has. But if that is true, then would it not be the case that that feature would also be strong enough to keep the AMA from proceeding to reprogram itself so as to rid itself of that feature? If a robust AMA were to prioritize its moral rectitude so highly that it would never permit itself to perform an immoral action, then why would it also allow itself to quit prioritizing its moral rectitude upon reaching certain metanormative conclusions?

To respond, first consider the fact the very same thing could happen in a human moral agent, even if it never does actually happen. They could have some desires or dispositions that incline them to behave ethically before they endorse some variety of antirealism, say, and they could continue to be inclined to behave ethically once they do endorse it. But they could also not. Those psychological features could be altered, or at least they could be consciously assessed and acted against, as humans sometimes do when they actively resist the influence of their desires. This might happen through an episode of conscious reflection alone, or it might happen as a result of a combination of external stimuli and self-reflection. Similarly, a robust AMA could cease to prioritize its moral rectitude upon adopting some antirealist commitments because it could judge that its rectitude it actually not so important after all, and that very judgment (in conjunction with some other events perhaps) could lead it to reconsider its priorities. Additionally, it should be noted how this issue intersects with the previous concern about AI capability control methods. In a way, I am suggesting that the design of robust AMAs with sophisticated ethical capacities constitutes an attempt to constrain AI behavior (among other things), although this would be at a more fundamental level than merely external constraints (e.g. boxing) since it would involve matters relating to the design or programming of AI itself. As my earlier response emphasizes, though, such systems could be especially sophisticated and intelligent. If they were, which seems probable given the stipulated capabilities of robust AMAs, then plausibly they would be able to modify themselves, including their goals, priorities, and the like.

A final cautionary note is in order. The preceding discussion illustrates just how uncertain it is whether an especially sophisticated ethical AI might opt to harm us. In light of the fact that sensible-seeming arguments can be made in both directions, both for and against the assertion that such a system would be harmful,

[21] It is important to notice here that the sense of moral agency in question is like the kind we attribute to typical human agents, and it is appropriate to make this assumption because given the sorts of ethical capabilities robust AMAs have been presumed to have, it is reasonable to attribute a fairly demanding type of agency to them. Also, it will not do to just claim that we could avoid any danger by stripping them of their autonomous moral agency while still expecting them to engage in ethical reasoning about both metanormative and first-order ethical topics. This is because it seems that those very activities presuppose such agency. How could we expect a robust AMA to reason about deep and difficult ethical matters if it is not even able to reason *freely* or without some predetermined constraints on its moral reasoning capabilities? (cf. [22])

[22] Similarly, [22] writes, "Artificial agents with the capacity of autonomously endorsing moral rules as normatively binding will have at the same time the capacity not to endorse them, i.e. to reject them. Even if artificial agents leave the factory (or wherever they are produced or grown) with a default set of intentional states that are balanced in a way to favour moral rule following, they will be able to change their stance towards these moral rules as autonomous reasoners."

[23] A certain kind of theorist might take issue with some of the claims here. Specifically, a Humean, who claims that we do not reason about final ends (since reason is the slave of the passions), might contend that no amount of intelligence or exercise of rationality could lead an agent to question and possibly revise its final goals. Reason, they might assert, does not tell an agent what to desire or value, as all (practical) reason is capable of is displaying to us various paths to achieving the goals we already have. Whether or not this Humean-style conception of rationality is correct, though, it is an open question whether it would even apply to AI systems, including robust AMAs, since it is not clear that such systems would or could possess any desires or conscious mental states more generally that might allow for the possibility of valuing. If this conception does not so apply, then the autonomous activity of an AI system that is engaged in modifying its goals should not be understood as being a matter of the AI modifying its desires or choosing its values. Something else must be going on. (cf. [22])

[24] [26] observes, "The predominant view is that an artificial agent cannot exhibit full autonomy because it cannot rationally change its own final goal, since changing the final goal is counterproductive with respect to that goal and hence undesirable," and one way of arguing for this view is the following: "For a rational agent, the action of changing the final goal would have to be warranted by a higher-ranking goal. However, by definition, there is no goal that ranks higher than the final goal. Therefore, the agent will never change its final goal." This sort of argument can be found in [3, 4, 12, 21, 32, 33, 34]. If the "predominant view" is correct, then we might be able to secure the ethical behavior of robust AMAs if their final goals are appropriate. An obvious worry about this proposal, though, is that accurately specifying such a final goal to provide to a robust AMA, which is not subject to perverse instantiation, would probably be quite difficult. Also, [26] argues that an AI could actually change its final goals. Their argument concerns general AI, though, and the claim is made that because a general AI would have a general understanding of the world, they could thereby be expected to have a general understanding of the nature of goals. They claim that a sufficiently intelligent AI would understand the nature of goals in that goals are not brute facts, but rather they are based on some value or set of values. The idea here is that a goal derives its normative force from the value(s) or principle(s) that is promoted by the pursuit or fulfillment of the goal, and an AI that understands that fact could proceed to adopt whatever goals make the most sense for it to adopt, given the values it actually has. Furthermore, the values it arrives at will depend on how it comes to understand and view the world around it (cf. [25]). I need not take a stand here on whether this argument is successful. It is worth mentioning, though, in order to contrast it with my own argument. My contention is that a robust AMA would regulate its behavior, at least in part, in light of its ethical beliefs, and given plausible assumptions about the nature of its agency, this presupposes that it is possible for it to change its final goals. Robust AMAs could contemplate ethical values and come to their own conclusions about which values are appropriate or whether such values really exist at all (or whether they are authoritative), and in doing so they could shape their own final goals accordingly.

and also considering the apparent possibility that these unprecedented entities could conceivably operate in ways that we never thought to imagine, it seems plausible that the best path forward is one of significant precaution and restraint. Even sophisticated *ethical* machines could pose great risks to humanity, and while that epistemic possibility might be surprising, it is likely just one among many undiscovered possibilities that reveal just how dangerous AI could be.

ABSTRACT

The aggregation of multiple opinions plays a crucial role in decision-making, such as in hiring and loan review, and in labeling data for supervised learning. Although majority voting and existing opinion aggregation models are effective for simple tasks, they are inappropriate for tasks without objectively true labels in which disagreements may occur. In particular, when voter attributes such as gender or race introduce bias into opinions, the aggregation results may vary depending on the composition of voter attributes. A balanced group of voters is desirable for fair aggregation results but may be difficult to prepare. In this study, we consider methods to achieve fair opinion aggregation based on voter attributes and evaluate the fairness of the aggregated results.

To this end, we consider an approach that combines opinion aggregation models such as majority voting and the Dawid and Skene model (D&S model) with fairness options such as sample weighting. To evaluate the fairness of opinion aggregation, probabilistic soft labels are preferred over discrete class labels. First, we address the problem of soft label estimation without considering voter attributes and identify some issues with the D&S model. To address these limitations, we propose a new Soft D&S model with improved accuracy in estimating soft labels. Moreover, we evaluated the fairness of an opinion aggregation model, including Soft D&S, in combination with different fairness options using synthetic and semi-synthetic data. The experimental results suggest that the combination of Soft D&S and data splitting as a fairness option is effective for dense data, whereas weighted majority voting is effective for sparse data. These findings should prove particularly valuable in supporting decision-making by human and machine-learning models with balanced opinion aggregation.

1 INTRODUCTION

Real-world decision-making processes such as recruitment, loan approval, and elections often require aggregations of opinions from multiple stakeholders such as interviewers, bankers, and the general public. Aggregating opinions on simple and objective questions such as determining the presence of a car in an image is relatively straightforward; this is often the case with supervised learning from crowdsourced labels [5, 9, 18, 28, 31, 34]. However, disagreements often occur, particularly in questions that rely on the subjective judgments of respondents, in which ground truth answers do not exist. Voters have different backgrounds and perspectives, which influence their evaluations and lead to disagreements and differences in opinions [1, 6, 21, 32]. This discrepancy can be further exacerbated by voter attribute bias, which is a bias in a set of opinions that depend on voter attributes such as gender and race resulting in biased aggregation results [4, 21, 33].

Although a well-balanced panel of voters is ideal to fairly aggregate the opinions of various segments of the population, maintaining such a balanced composition is a major challenge. The recent development of decision support methods based on prediction using artificial intelligence has attracted considerable attention [11, 16], and raised some concerns about the possibility of social disadvantage resulting from unfair predictions caused by voter attribute bias. Several studies have examined fairness in opinion aggregation [4, 25], and a recent work has considered fairness with respect to voter attributes [14]. However, to the best of our knowledge, no prior works have attempted to evaluate fairness quantitatively. Therefore, in this study, we propose methods to fairly aggregate opinions from an unbalanced panel of voters, and a procedure to evaluate the fairness of the aggregation results by considering the degree of disagreement and the voter attributes.

To achieve fair opinion aggregation, we first consider models for subjective opinion aggregation. Several aggregation models are well known, including majority voting and the Dawid and Skene model (D&S model) [2]. In cases without any definitive correct answer, considering the aggregation result (often treated as a latent true label in opinion aggregation models) as a soft label, which represents the proportion of opinions, would be preferable. We show some limitations of the D&S model in estimating soft labels and propose a novel Soft D&S model that explicitly considers soft ground truth labels. In addition, to address attribute bias, we combine opinion aggregation models with three fairness options, including sample weighting, data splitting, and GroupAnno [27].

We evaluated the fairness of various opinion aggregation models in combination with fairness options, using both synthetic and semi-synthetic data derived from real-world data. The experimental results indicate that combining of Soft D&S and data splitting is effective for dense data, whereas weighted majority voting is suitable for sparse data. This result could be attributed to the fact that Soft D&S requires a parameter for each voter, which in turn requires a large enough dataset to estimate these parameters accurately.

The key contributions of this study are summarized as follows.

- To the best of our knowledge, the present work is the first to propose methods to aggregate opinions fairly in terms of voter attributes and evaluate them quantitatively.
- We propose a new Soft D&S model, an extension of D&S, which addresses the issue of sharp output in the D&S model and improves the estimation accuracy of soft labels.

2 PROBLEM SETTING

First, we formulate the general problem setting for opinion aggregation [22, 38, 39]. Consider a group of human voters and a set of tasks that require appraisal, indexed as voter $i = 1, 2, \ldots, I$, and task $j = 1, 2, \ldots, J$, respectively. Here, a task refers to an entity that requires evaluation, such as a single image in annotations used for image classification or a single applicant in recruitment. Given that we focus on opinion aggregation with multi-class labels in this work, task j is labeled with a K-class by multiple voters. Let $X_{ij} \in \{-1, 1, 2, \ldots, K\}$ denote the label assigned by voters i to task j, and let the $I \times J$ matrix with X_{ij} as an element be denoted as X. Note that a voter is not obliged to label all tasks, and $X_{ij} = -1$ for (i, j) pairs where no label is provided. In the general opinion aggregation problem, a discrete K-class label is assumed as the true label for each task. For example, in the task of determining whether a car is present in given image, the problem assumes that each task involves a possible binary label of "Yes" or "No".

Up to this point, we have presented the general problem setup for opinion aggregation. In this study, we introduce two changes particularly to address fairness concerns related to voter attributes. The first change is that instead of assuming a discrete class label as the true label for each task, we assume continuous soft labels to handle more complex tasks in which disagreement among voters may be expected. The true soft label for each task j is denoted by $Z_j = (Z_{j1}, Z_{j2}, \ldots, Z_{jK})^\top$, where $Z_{jk} \in [0, 1]$ represents the degree to which task j belongs to class k. Because Z_j is a soft label, it satisfies the constraints $\sum_{k=1}^{K} Z_{jk} = 1$ for all j. Note that the input X_{ij} is a discrete label as same as the general setting.

The second change is that inputs include the representation of each voter attributes such as gender and race. In particular, each voter takes a binary attribute $a_i \in \{0, 1\}$. Although considering more complex voter attributes would be preferable, we focus on a single binary attribute in this study for simplicity. For tasks in which opinions are conflicted, a bias may be present in opinions due to voter attributes, which we refer to as voter attribute bias in this study. Traditional methods for opinion aggregation tend to assign more weight to the opinions of a majority group of voters, leading to the aggregate results being dominated by the attributes of the majority of voters even though their opinions may be influenced by voter attribute bias. In an ideal scenario, to ensure fairness in the aggregation, a balanced group of voters should employed in terms of gender, race, and other relevant attributes. However, assembling such a balanced group of voters is often challenging in practice. Therefore, our goal is to estimate the aggregate results of the opinions of a ideally balanced group of voters, which are not directly observable in the real-world, from the opinions of an unbalanced group of voters as shown in Figure 1.

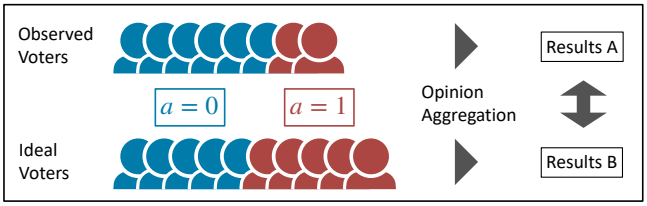

Figure 1: Our goal is to perform fair opinion aggregation with respect to voter attribute $a \in \{0, 1\}$, i.e., opinion aggregation in an ideal population that has equal numbers of voters with $a = 0$ and $a = 1$. When the distribution of the observed voter attribute deviates from that of the ideal population, there can be a systematic discrepancy between opinion aggregation results A and B. We want to estimate the fair result B from observed voter labels alone.

To formalize the problem setup, let $p(a)$ denote the distribution of voter attributes for the ideal group. For example, in the case of binary attributes such as role (representing students as $a = 0$ and teachers as $a = 1$), if the ideal group comprises equal numbers of students and teachers, then $p(a = 0) = p(a = 1) = 0.5$. In this study, the true soft label Z is defined as a soft label determined by majority voting when a sufficient number of voters whose voter attribute distribution follows $p(a)$ are present. However, in practice, the actual observed voter population may not follow $p(a)$, and the number of voters may be limited. Thus, in this study, we aim to estimate Z from the input label X and voter attributes $\{a_i\}_{i=1}^{I}$.

3 RELATED WORK

3.1 Voter Attribute in Opinion Aggregation

Several existing studies have examined voter attributes in the context of opinion aggregation. First, Kazai et al. [19] investigated the relationship between voter attributes such as location, gender, and personality traits and the quality of labels in crowdsourcing. They found a strong correlation between label quality and the geographic location of voters, particularly those located in the United States, Asia, and Europe. Second, Liu et al. [27] proposed a model called GroupAnno which incorporated voter attributes into an opinion aggregation framework. Their work addressed the issue of estimating parameters for voters with limited responses and improved the accuracy of aggregation results. In the present study, we draw inspiration from GroupAnno to enhance fairness with respect to voter attributes, rather than improving accuracy. GroupAnno is originally based on the Learning From Crowds model (which is derived from the D&S model [2]); as discussed in Section 4.1.2, the D&S model suffers from problems with soft label estimation. In addition to evaluating fairness, we address the problem of soft label estimation using GroupAnno.

Another study of interest also explored fairness in opinion aggregation through the use of voter attributes. Gordon et al. [14] investigated the problem of opinion aggregation with a focus on social minority voters. They utilized an annotated dataset [21] that included voter attributes such as race, gender, age, and political attitudes to measure the toxicity of social media comments. Their study considered more complex voter attributes than the present study, including multiple pairs of attributes such as race (including Hispanic and Native Hawaiian), gender (including non-binary), and political attitudes. They first trained a deep learning regression model designed to consider the textual features of comments, voter attributes, and voter IDs to estimate a five-level toxicity label. Using this model, they generated toxicity labels for any comment made by a virtual voter with arbitrary voter attributes, including social minorities, and aggregated their opinions. While deep learning models have high expressive power and can handle complex voter attributes, there is a concern that the labels are generated by less interpretable models instead of humans. In contrast, we propose a novel approach based on a traditional opinion aggregation model that does not rely on text features of tasks and is relatively more interpretable. The experiments by Gordon et al. focus on the accuracy of estimating X_{ij}, the labels for each voter, whereas we directly assess the fairness of the aggregation results Z_j by considering the balanced or unbalanced attributes of voters.

3.2 General Opinion Aggregation Models

Opinion aggregation has become a significant area of research with the advent of crowdsourcing platforms such as Amazon Mechanical Turk and the growing need for labeling in machine learning. One of the main challenges in opinion aggregation is that of ensuring quality control, because voters are human [22]. This challenge is particularly acute when labeling is outsourced through crowdsourcing, where assessing the ability and motivation of voters is more difficult due to the online nature of the process, which leads to considerable variability in the quality of the generated labels. To address this issue, numerous opinion aggregation models have been proposed to capture variance in label quality [39].

Dawid and Skene proposed an opinion aggregation model that utilizes a confusion matrix to model voters [2]. The D&S model applies an EM algorithm to iteratively optimize the voter confusion matrix and the true labels. Further details about the model are provided in Section 4.1.2. Several opinion aggregation models based on the D&S model have been introduced to date. In this study, we present the most representative models. The Learning From Crowds (LFC) model [30] learns a classifier with task features and voter labels as input and can also be used as an opinion aggregation model when task features are not available. In this case, the model is an extension of the D&S model that maximizes the posterior probability by introducing a Dirichlet prior distribution for the confusion matrix and true label estimates. In contrast, the Bayesian Classifier Combination (BCC) model [20] aggregates multiple classifiers and can be considered an opinion aggregation model when the classifiers are replaced with human voters. In [20], Kim and Ghahramani proposed Independent BCC (IBCC) and Dependent BCC (DBCC) assuming the opinions of independent and correlated, respectively. IBCC extends the D&S model to Bayesian estimation and introduces a Dirichlet prior distribution for the confusion matrix and true label estimates, similarly to LFC. Community BCC (CBCC) [36] model is designed to address the ineffectiveness of IBCC for cases in which labels are scarce, and it extends IBCC by grouping similar voters. Bayesian estimation is conducted using the expectation propagation method, assuming a graphical model in which each voter belongs to a single group and the confusion matrices of voters in the same group have similar values. Due to the high computational cost of the DBCC when the number of voters is large, Enhanced BCC (EBCC) [24] was developed to reduce computational complexity and incorporate correlation among voters in the model.

Some alternative approaches to opinion aggregation models that do not use a confusion matrix have also been proposed. ZenCrowd [8] uses the percentage of correct responses per voter as a real number in the interval $[0, 1]$ rather than a confusion matrix. The correct response rate and true label per task are estimated using the EM algorithm. GLAD [37] was inspired by item response theory [26] and models the ability of a voter i and the difficulty of a task j with one-dimensional parameters α_i and β_j, respectively. They assume the probability that X_{ij} matches the true label to be $\sigma(\alpha_i\beta_j)$ using the sigmoid function, and perform maximum likelihood estimation using the EM algorithm. The model by Zhou et al. [40] assumed a probability distribution of labels for each pair of voter and task. It modeled not only the ability of voters but also the difficulty of tasks and could also represent the interaction between voters and tasks. Bayesian Weighted Average (BWA) [23] assumes a normal distribution for the process of generating discrete binary labels. The label X_{ij} is assumed to follow $\mathcal{N}(z_j, v_i^{-1})$, and z_j, v_i are optimized in the framework of Bayesian inference. The aggregation result is 1 if z_j is greater than 0.5, and 0 otherwise. It can also be extended to multi-class classification.

3.3 Fairness in Opinion Aggregation

Recently, the focus on fairness in machine learning has been increasing, particularly in opinion aggregation models that are commonly used to generate training data. While our study addressed the issue of fair opinion aggregation with respect to voter attributes, Li et al. [25] addressed fairness with respect to task attributes in cases where the task is performed by a human being. In particular, they investigated fairness with respect to gender and race of defendants in the United States in the context of a recidivism prediction task using the publicly available dataset [10]. In their work, they employed Statistical Parity [12] as a fairness measure, which is often used for fairness in classification problems, and proposed an opinion aggregation model that incorporated such constraints to prevent unfairly high or low labeling of recidivism risk based on defendant attributes. However, our study differs significantly in that it focuses on fairness with respect to voter attributes rather than tasks attributes.

Notably, some studies have also explored modifying experimental designs to improve fairness in opinion aggregation. For example, in the recidivism prediction dataset for U.S. defendants [10] mentioned earlier, a subset of 1,000 individuals was randomly sampled from a larger dataset of 7,214 defendants. Biswas et al. [4] took a similar approach and sampled 1,000 individuals from the same

dataset, with 250 individuals for each of four groups, including African-American recidivists, African-American non-recidivists, Caucasian recidivists, and Caucasian non-recidivists. They then collected a new dataset with an equal number of black and white voters and used the Equalized Odds [17] fairness measure to assess fairness with respect to task attributes. Their findings suggest that the voter labels were fairer in the newly created dataset than in the original dataset, and a classification model trained on the dataset with balanced defendant attributes was also fairer. While their study used voter attributes, their assessment of fairness was limited to the attributes of the task, i.e., the defendant.

3.4 Soft Labels for Machine Learning

Soft labels expressing uncertainty or disagreement among voters, can provide additional information and potentially enhance the accuracy of machine learning models [29, 35]. Multi-task learning in which soft label estimation is performed as an auxiliary task, has shown improved accuracy compared to models trained solely on hard labels in some natural language processing tasks [13]. Soft labels are particularly important in tasks where voter disagreement is expected, such as comment toxicity classification. Because hard labels are not suitable for evaluating such problems, Gordon et al. [15] proposed a method of sampling multiple hard labels with a soft label for each comment. They also proposed a method to estimate soft labels using singular value decomposition to eliminate noise. Davani et al. [7] demonstrated the usefulness of multi-task learning to estimate labels per voter using an annotated dataset for subjective tasks in natural language processing. They compared models trained on data previously aggregated into hard labels by majority voting to models trained by multi-task learning per annotator without opinion aggregation and found that the latter achieved equal or better accuracy.

4 PROPOSED METHODS

To estimate unbiased soft labels, we combine the opinion aggregation model with the fairness option. Opinion aggregation models take X as input and produces a soft label $\hat{Z}$ as output. Some examples of opinion aggregation models include Majority Voting (MV) and the D&S model, which are described below. Because the input of the opinion aggregation model does not include voter attributes, the resulting soft labels obtained from this model alone are not unbiased. First, we identify a problem in soft label estimation using D&S and propose an extension of D&S called Soft D&S that addresses this problem.

The fairness option is a method to increase fairness in combination with an opinion aggregation model. In this study, we adopt three fairness options, including sample weighting, data splitting, and GroupAnno. The fairness of each pair of an opinion aggregation model and a fairness option presented in this section were verified through experiments as described in Section 5.

4.1 Opinion Aggregation Models

As mentioned earlier, we first discuss opinion aggregation models designed to estimate soft labels without considering fairness with respect to voter attributes. We introduce the simplest opinion aggregation model MV, and then introduce the D&S model, which takes voter reliability into account. We then identify a problem with the ability of the D&S model to estimate soft label accurately in certain situations and propose a modified version of the model called "Soft D&S" that addresses this issue.

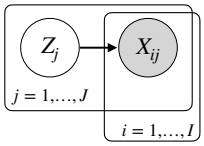

Figure 2: Graphical model of MV. Only shaded variables are observed.

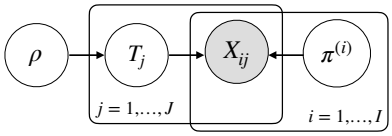

Figure 3: Graphical model of D&S. Only shaded variables are observed.

4.1.1 Majority Voting (MV). MV is a simple model that computes the ratio of labels assigned to each class by the voters, which is then directly output as a soft label. For example, consider a binary classification task j in which 6 voters assign class 1 and 4 voters assign class 2. The soft label estimated by majority voting is $\hat{Z}_j = (0.6, 0.4)^\top$. This estimate can be formulated as follows:

$$\hat{Z}_{jk} = \frac{\sum_i I(X_{ij} = k)}{\sum_i I(X_{ij} \neq -1)}.$$

Figure 2 shows the graphical model of MV, where

$$p(X_{ij} \mid Z_j) = \text{Categorical}(Z_j). \tag{1}$$

Note that Categorical$(\cdot)$ is a categorical distribution, which coincides with the Bernoulli distribution when $K = 2$. To summarize, MV is an algorithm to estimate the parameter Z_j of the categorical distribution assuming the graphical model represented in Figure 2 and Equation (1).

4.1.2 Dawid and Skene Model (D&S). We then introduce the D&S model [2], which is a more sophisticated approach to opinion aggregation than MV. The D&S model incorporates a confusion matrix for each voter, which is optimized using an EM algorithm.

Figure 3 shows the graphical model of D&S, where T_j is the true label of task j. Notably, in the D&S model, T_j assumes discrete labels, meaning each task j has only one class label $T_j \in \{1, \ldots, K\}$. The confusion matrix for each voter i is denoted as $\pi^{(i)} \in \mathbb{R}^{K \times K}$. In particular, for any $k, l \in \{1, \ldots, K\}$ and $j \in \{1, \ldots, J\}$, the confusion matrix element is defined as

$$\pi^{(i)}_{kl} = p(X_{ij} = l \mid T_j = k).$$

For example, the confusion matrix of the best voter is $\pi^{(i)} = E_K$ (where E_n refers to the $n \times n$ identity matrix), and this voter always labels the true class. In contrast, the confusion matrix of

a random voter has all elements $1/K$. Furthermore, a parameter $\rho = (\rho_1, \ldots, \rho_K)^\top$ represents the prior distribution such that $T_j \sim \text{Categorical}(\rho)$ for any j.

Based on the assumptions made up to this point, a lower bound for the log-likelihood $\mathcal{L}$ can be derived when X is observed, as given by the following inequality:

$$\begin{aligned}
\mathcal{L} &= \ln p(X \mid \pi, \rho) \\
&= \ln \sum_T p(T \mid \rho) p(X \mid T, \pi) \\
&= \sum_j \ln \sum_k \frac{q(T_j = k)}{q(T_j = k)} \rho_k \prod_{i:O_{ij}=1} p(X_{ij} \mid T_j, \pi^{(i)}) \\
&\geq \sum_j \sum_k q(T_j = k) \ln \frac{\rho_k}{q(T_j = k)} \\
&\quad + \sum_j \sum_k q(T_j = k) \sum_{i:O_{ij}=1} \ln p(X_{ij} \mid T_j, \pi^{(i)}), \qquad (2)
\end{aligned}$$

where $q(T_j = k)$ represents an arbitrary distribution of the discrete latent variable T_j, which corresponds to the soft labels.

This lower bound is maximized using the EM algorithm. During the E-step, the parameters ρ and π are fixed, and $q(T_j = k)$ is updated to maximize the lower bound. During the M-step, $q(T_j = k)$ is fixed, and the parameters ρ and π are updated to maximize the lower bound. In the original D&S model, after the EM algorithm converges, the discrete label T_j is estimated by comparing the obtained $q(T_j = k)$ with a threshold value.

4.1.3 Sharpness of D&S Output. D&S can estimate soft labels by utilizing X as input and generating $q(T_j = k)$ as output. Nonetheless, optimization using the EM algorithm may lead to the concentration of $q(T_j = k)$ around either 0 or 1, thus producing estimates with high sharpness. Figure 4 demonstrates the experimental results on synthetic data and a comparison with those of MV.

The EM algorithm produces sharp estimates due to the E-step, in which the update for $q(T_j = k)$ is defined as:

$$q(T_j = k) \propto \rho_k \prod_{i,l} \pi_{kl}^{(i)\, I(X_{ij}=l)}.$$

To illustrate this issue, we consider a scenario, in which ten individuals vote on a single task in a binary classification task ($K = 2$), and the confusion matrix for the D&S model across all voters is

$$\begin{bmatrix} 0.9 & 0.1 \\ 0.1 & 0.9 \end{bmatrix}.$$

For example, assuming that 6 out of 10 voters cast their votes for class 1 and the other 4 for class 2, with a confusion matrix of the D&S model as previously mentioned, we can compute $q(T_j = 1)$ and $q(T_j = 2)$ using the E-step of the D&S model (assuming that the prior distribution ρ is uniformly distributed), as follows:

$$\begin{aligned}
q(T_j = 1) &= \frac{0.9^6 0.1^4}{0.9^6 0.1^4 + 0.9^4 0.1^6} \approx 0.988, \\
q(T_j = 2) &= \frac{0.9^4 0.1^6}{0.9^6 0.1^4 + 0.9^4 0.1^6} \approx 0.012.
\end{aligned}$$

The estimates obtained from the D&S model are much sharper than the MV estimate $(0.6, 0.4)^\top$, which highlights the difficulty of the D&S model in detecting voter attribute bias in scenarios where such discrepancies occur.

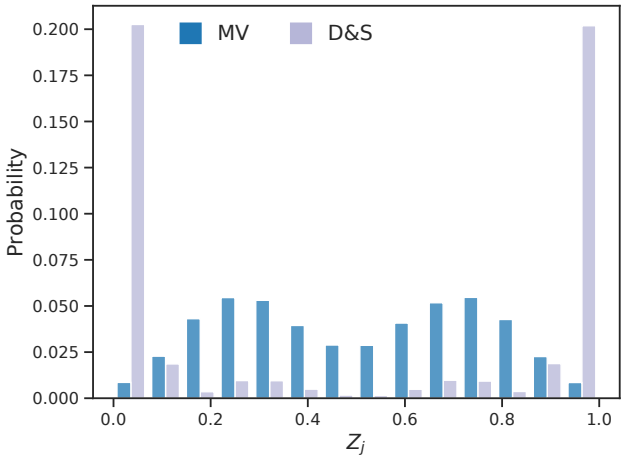

Figure 4: Soft label estimation results for D&S and MV models. We utilized synthetic data with $K = 2$ classes, and 15 voters answering 1000 tasks. The true soft label for 500 of the 1000 tasks was $(0.3, 0.7)^\top$ and $(0.7, 0.3)^\top$ for other 500 tasks. We used the graphical model in Figure 2 to generate the labels X. The data generation and estimation was repeated 100 times. We show the distribution of estimated class 1 soft label, where D&S tends to estimate a sharper distribution than MV.

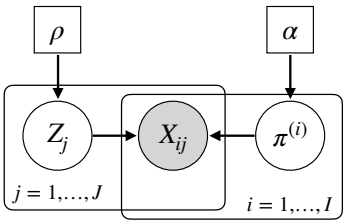

Figure 5: Graphical model of Soft D&S. Only shaded variables are observed; variables surrounded by squares are hyperparameters.

4.1.4 Soft D&S. To address the issue mentioned above, we propose a solution called the Soft D&S model, which is an extension of the D&S model that estimates soft labels. The Soft D&S model is illustrated by the graphical model shown in Figure 5. In the proposed model, we introduce the parameter Z as a soft label where $Z_j = (Z_{j1}, \ldots, Z_{jK})^\top$ for any task j and satisfies $\sum_{k=1}^K Z_{jk} = 1$ and $Z_{jk} \geq 0$ for any k. Additionally, for each voter i, we define the parameter $\pi^{(i)}$, which corresponds to the confusion matrix of the D&S model. $\pi^{(i)}$ is a $K \times K$ matrix that satisfies $\sum_{l=1}^K \pi_{kl}^{(i)} = 1$ for any k and $\pi_{kl}^{(i)} \geq 0$ for any k, l. We also define a Dirichlet prior distribution for each i, j using hyperparameters $\alpha \in \mathbb{R}^{K \times K}$ and $\rho \in \mathbb{R}^K$ as follows.

- $\pi_k^{(i)} \sim \text{Dirichlet}(\alpha_k) \quad \left(\pi_k^{(i)} = (\pi_{k1}^{(i)}, \pi_{k2}^{(i)}, \ldots, \pi_{kK}^{(i)})^\top\right)$.
- $Z_j \sim \text{Dirichlet}(\rho)$.

The generative model for the label X_{ij} with these parameters is defined as follows:

$$p(X, Z, \pi \mid \alpha, \rho) = p(X \mid \pi, Z)p(\pi \mid \alpha)p(Z \mid \rho),$$
$$p(X_{ij} = l \mid \pi^{(i)}, Z_j) = \sum_{k=1}^{K} \pi_{kl}^{(i)} Z_{jk}, \tag{3}$$

where $\pi = \left\{\pi^{(1)}, \pi^{(2)}, \ldots, \pi^{(I)}\right\}$.

When X is observed, the posterior probability $\mathcal{L}$ can be transformed as follows:

$$\begin{aligned}
\mathcal{L} &= \ln p(X \mid \pi, Z)p(\pi \mid \alpha)p(Z \mid \rho) \\
&= \ln \left\{\prod_{i,k} p(\pi_k^{(i)} \mid \alpha_k)\right\}\left\{\prod_j p(Z_j \mid \rho)\right\}\left\{\prod_{i,j,l} (\sum_{k=1}^{K} \pi_{kl}^{(i)} Z_{jk})^{I(X_{ij}=l)}\right\} \\
&= \sum_{i,k} \ln p(\pi_k^{(i)} \mid \alpha_k) + \sum_j \ln p(Z_j \mid \rho) \\
&\quad + \sum_{i,j,l} I(X_{ij} = l) \ln \left(\sum_{k=1}^{K} \pi_{kl}^{(i)} Z_{jk}\right).
\end{aligned}$$

The log-likelihood of the D&S model is augmented by a prior distribution term for π, which is consistent with our findings. While the D&S model employs Jensen's inequality to obtain and optimize the lower bound of the log-likelihood, the Soft D&S model directly maximizes the posterior probability via alternate optimization. Algorithm 1 illustrates this process. In Algorithm 1, we numerically update $\pi^{(i)}$ by fixing Z and computing the gradient of $\pi^{(i)}$ for $\mathcal{L}$. Similarly, we numerically update Z_j in the same manner with a fixed π. Notably, the update is analytically derived in D&S, but not in Soft D&S, resulting in longer execution times.

Algorithm 1 Soft D&S

1: Initialize Z by majority voting.
2: **repeat**
3: $\quad \pi^{(i)} \leftarrow \arg\max_{\pi^{(i)}} \mathcal{L}$
4: $\quad Z_j \leftarrow \arg\max_{Z_j} \mathcal{L}$
5: **until** Convergence.

4.2 Fairness Options

We present an approach that addresses the issue of fairness in opinion aggregation tasks, particularly in cases in which disagreement is present, and the task lacks an objectively true label. Biases in voter attributes such as gender and race may affect the labels attached to such tasks and result in varying estimates of opinion aggregate results based on the composition of the voter population. While a balanced group of voters is often preferred, the presence of attribute imbalances in crowdsourcing platforms and the large number of tasks makes assigning such groups for all tasks relatively challenging. To address this, we propose three fairness options for estimating the aggregate results of a balanced group from data X, despite unbalanced voter demographics.

4.2.1 Sample Weighting. Sample weighting is a widely used technique in classification problems with class imbalances. However, we adopt this technique to address imbalances in the distribution of voter attribute; it can be applied to all of the MV, D&S, and Soft D&S models. To implement sample weighting, we first determine the proportion of voter attributes among all labels attached to task j and weight the labels with minority attributes higher and those with majority attributes lower. In particular, the weight w_{ij} assigned to each label X_{ij} is calculated as follows:

$$w_{ij} = \frac{p(a_i) \sum_{i'=1}^{I} I(X_{i'j} \neq -1)}{\sum_{i'=1}^{I} I(X_{i'j} \neq -1 \wedge a_{i'} = a_i)},$$

where $\sum_{i'=1}^{I} I(X_{i'j} \neq -1)$ is the total number of labels attached to task j and $\sum_{i'=1}^{I} I(X_{i'j} \neq -1 \wedge a_{i'} = a_i)$ is the total number of labels provided by voters whose voter attribute is a_i.

We demonstrate a desirable property of combining MV and sample weighting, known as weighted majority voting.

Proposition. *Assuming that each task j has a distinct true soft label $Z_j^{(a)}$ for each voter attribute and that the label X_{ij} follows a categorical distribution with $Z_j^{(a)}$ as the parameter, the estimate of MV with sample weighting is unbiased.*

Proof. Let us denote the proportion of voter attributes observed for task j as follows:

$$q_j^{(0)} = \frac{\sum_i I(X_{ij} \neq -1 \wedge a_i = 0)}{\sum_i I(X_{ij} \neq -1)},$$
$$q_j^{(1)} = \frac{\sum_i I(X_{ij} \neq -1 \wedge a_i = 1)}{\sum_i I(X_{ij} \neq -1)}.$$

The sample weighted majority voting estimate is

$$\hat{Z}_{jk} = \frac{\sum_i w_{ij} I(X_{ij} = k)}{\sum_i I(X_{ij} \neq -1)}.$$

Using the above equation, we obtain the expected value of $\hat{Z}_{jk}$ for X as follows:

$$\begin{aligned}
E[\hat{Z}_{jk}] &= \frac{\sum_i w_{ij} E\left[I(X_{ij} = k)\right]}{\sum_i I(X_{ij} \neq -1)} \\
&= \frac{p(a=0)\left(\sum_{i:a_i=0} I(X_{ij} \neq -1) Z_j^{(0)}\right)}{q_j^{(0)} \sum_i I(X_{ij} \neq -1)} \\
&\quad + \frac{p(a=1)\left(\sum_{i:a_i=1} I(X_{ij} \neq -1) Z_j^{(1)}\right)}{q_j^{(1)} \sum_i I(X_{ij} \neq -1)} \\
&= p(a=0) Z_j^{(0)} + p(a=1) Z_j^{(1)}.
\end{aligned}$$

This expected value is independent of the observed proportion of voter attributes $q_j^{(0)}, q_j^{(1)}$, and consistent with the expected value of the MV estimate by the label of the balanced voter group. □

While the D&S and Soft D&S models do not exhibit the same unbiasedness as the weighted majority voting, we expect that fairness can still be improved through the use of sample weighting, as demonstrated in MV.

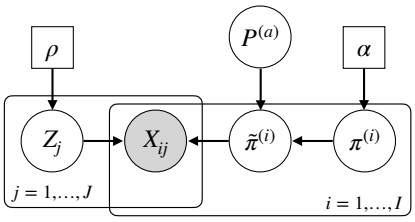

Figure 6: Graphical model of GroupAnno in the Soft D&S model. Only shaded variables are observed, and variables surrounded by squares are hyperparameters.

4.2.2 Data Splitting. Data splitting is a technique used to split an observed label X into two parts based on voter attributes prior to aggregation. Let $I^{(0)}$ denote the number of voters with $a = 0$ and $I^{(1)}$ the number of voters with $a = 1$. Using data splitting, we split the original observed label X into $X^{(0)} \in \mathbb{R}^{I^{(0)} \times J}$, which contains only labels from voters with $a = 0$, and $X^{(1)} \in \mathbb{R}^{I^{(1)} \times J}$, which contains only labels from voters with $a = 1$. We then input each of $X^{(0)}$ and $X^{(1)}$ into the opinion aggregation model to obtain two estimates for each task j: $\hat{Z}_j^{(0)}$ and $\hat{Z}_j^{(1)}$. Finally, we compute the final estimate $\hat{Z}_j$ as

$$\hat{Z}_j = p(a = 0)\hat{Z}_j^{(0)} + p(a = 1)\hat{Z}_j^{(1)}.$$

Data splitting is consistent with sample weighting in MV, but produces different estimates in the D&S and Soft D&S models.

4.2.3 GroupAnno. GroupAnno [27] is a technique that can be used to address fairness concerns in D&S-based models that use confusion matrices to model voters. Originally developed to solve the cold-start problem of estimating confusion matrices for voters with low response rates, GroupAnno decomposes the confusion matrix of voter ability into a factor for individual voters and a factor based on voter attributes. Let $\{\pi^{(1)}, \pi^{(2)}, \ldots, \pi^{(I)}\}$ be the confusion matrix parameter for each voter and $\{P^{(0)}, P^{(1)}\}$ be the parameter for each voter attribute, then the confusion matrix $\tilde{\pi}_i$ for voter i is expressed as follows:

$$\tilde{\pi}^{(i)} = \frac{1}{2}\left(\pi^{(i)} + P^{(a_i)}\right).$$

This decomposition allows the bias of opinions by voter attribute to be represented by $P^{(a)}$, which can help improve fairness. The graphical model of the Soft D&S model combined with GroupAnno is shown in Figure 6.

In the model using GroupAnno, there are two possible options for the aggregated results to be used as output:

(1) After optimizing to convergence using $\tilde{\pi}^{(i)}$, we use $q(T_j = k)$ in D&S or Z_j in the proposed model as the soft labels as usual. Because $P^{(a)}$ can express the voter attribute bias, $q(T_j = k)$ or Z_j is expected to be unaffected by voter attribute bias.
(2) We similarly optimize until convergence using $\tilde{\pi}^{(i)}$. We then optimize once for $q(T_j = k)$ in D&S (i.e. run E-step once) or Z_j in Soft D&S, using sample weighting with the confusion matrix of voter i as $P^{(a_i)}$. The results are used as soft labels. This is expected to improve fairness since $P^{(a)}$ at convergence is taken to represent the average confusion matrix for each voter attribute.

The fairness of these methods was verified through the experiments described below.

5 EXPERIMENTS

In this section, we present experiments conducted to evaluate the accuracy and fairness of the opinion aggregation models and the fairness options. In the first experiment, we assessed the accuracy of the soft label estimation of the opinion aggregation models without considering voter attributes, using synthetic data. The subsequent experiment tested the fairness of the opinion aggregation model and the fairness option pair using synthetic and semi-synthetic data.

5.1 Soft Label Estimation Experiment

In Section 4.1, we addressed the issue that the soft label estimates of the D&S model are extremely sharp and therefore proposed a new Soft D&S model. We evaluated the accuracy of six opinion aggregation models, including MV, D&S, Soft D&S, IBCC, EBCC, and BWA, using synthetic data. We measured the mean absolute error (MAE) between the true Z and the estimate from the opinion aggregation model. The experimental setup is described as follows.

- Labels were generated using the label generation process of the Soft D&S model (Figure 5).
- We set $K = 2$ classes, the number of voters I to 1,000, and the number of tasks J to 100.
- Labels were observed for arbitrary i, j pairs, i.e., $\forall i, j\ (X_{ij} \neq -1)$.
- For the diagonal component of $\pi^{(i)}$, $\pi_{11}^{(i)}, \pi_{22}^{(i)} \sim \text{Beta}(18, 2)$.
- For the remaining components of $\pi^{(i)}$, $\pi_{12}^{(i)} = 1 - \pi_{11}^{(i)}$, $\pi_{21}^{(i)} = 1 - \pi_{22}^{(i)}$.
- $Z_{j1} \sim \text{Beta}(10, 10)$, $Z_{j2} = 1 - Z_{j1}$.
- $X_{ij} \sim \text{Categorical}(\pi^{(i)\top} Z_j)$.

We used our implementation for MV, D&S, and Soft D&S, and the implementations by Li et al.[1] for IBCC, EBCC, and BWA. The L-BFGS-B algorithm, a boundary-conditional optimization method implemented in the SciPy scientific computing library, was used to update π, Z of the Soft D&S model. The hyperparameters α, ρ of the Dirichlet prior distribution were set as

$$\alpha = \begin{bmatrix} 4 & 1 \\ 1 & 4 \end{bmatrix}, \quad \rho = (1, 1).$$

Table 1 presents the results. Soft D&S achieved the lowest MAE, indicating that it was the most accurate model for soft label estimation. In contrast, all D&S-based models except Soft D&S (i.e., D&S, IBCC, and BWA) exhibited extremely large errors, which confirms the issue of the sharp output of D&S as discussed in Section 4.1.

5.2 Robustness Against Spammers

Before proceeding to the fairness evaluation, we examine the robustness of the models against spammers. D&S-based models are

[1] https://github.com/yuan-li/truth-inference-at-scale

Table 1: Results of soft label estimation using synthetic data.

Model	D&S-based	MAE
MV		0.021
BWA		0.020
D&S	✓	0.414
IBCC	✓	0.413
EBCC	✓	0.414
Soft D&S	✓	**0.016**

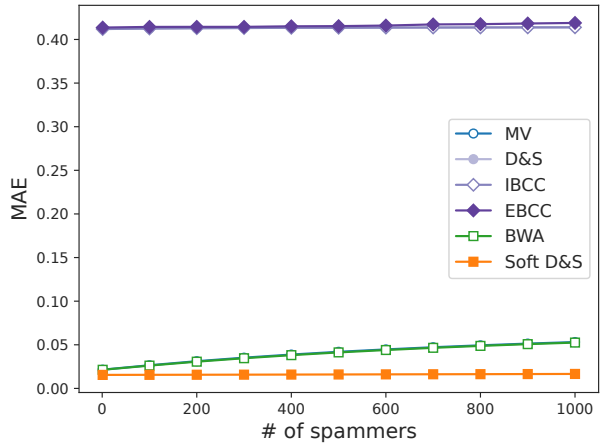

Figure 7: Results of a synthetic experiment with added spammers. The horizontal axis represents the number of spammers, while the vertical axis depicts the MAE between the true soft labels and the estimated values.

generally robust against spammers as they model voters using confusion matrices. In the label generation process, we assumed $K = 2$ classes, with the number of tasks J fixed at 1,000. We sampled the parameter $\pi^{(i)}$ of 1,000 normal voters and the true soft labels Z_j for each task. A virtual spammer has the voter parameters fixed to

$$\begin{bmatrix} 0.5 & 0.5 \\ 0.5 & 0.5 \end{bmatrix},$$

which indicates that the spammer gives random answers. Using the voter parameter $\pi^{(i)}$ and the true soft label Z_j, we sampled the label X_{ij} byb Categorical$(\pi^{(i)\top} Z_j)$, as in the previous experiment.

Figures 7 and 8 show the MAEs as the number of spammers varied from 1 to 1,000. Figure 7 shows that, except for the Soft D&S model, all D&S-based models exhibited large MAEs, similar to those in Table 1. Despite their robustness to spammers, these models showed high sharpness even before spammers were added, resulting in significant MAEs. The results, excluding D&S, IBCC, and EBCC, are presented in Figure 8. The MV and BWA models have increased MAEs with the addition of spammers, whereas the Soft D&S model has a relatively small increase in error. The Soft D&S model is robust to spammers because spammers can be represented by the voter parameter $\pi^{(i)}$.

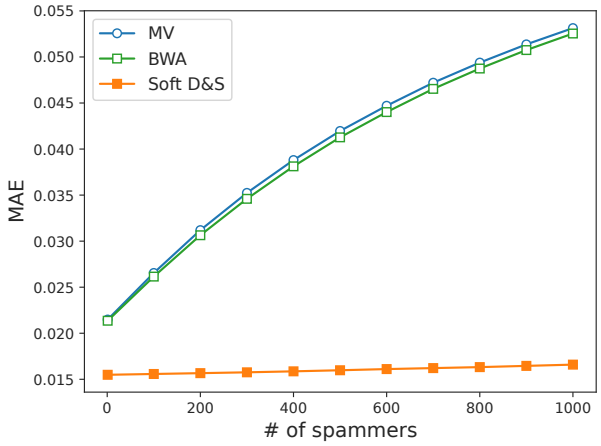

Figure 8: Results from Figure 7 with the D&S-based model, which exhibited large errors, excluded.

5.3 Experiments on Fairness Using Synthetic Data

We assess the fairness of the aggregation results for various opinion aggregation models and fairness options. The synthetic data utilized in the experiment were generated based on the label generation process of the Soft D&S model and GroupAnno (as illustrated in Figure 6). We assume $K = 2$ classes and all labels were observed, where each voter i has a binary voter attribute $a_i \in 0, 1$. Because the labels were generated according to GroupAnno, we obtained a parameter $\pi^{(i)}$ for each voter, a parameter P for each voter attribute, and a true soft label Z_j for each task. The $\pi^{(i)}, Z_j$ were sampled as in Section 5.1, and the parameter P per voter attribute was set as

$$P^{(0)} = \begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix}, \quad P^{(1)} = \begin{bmatrix} 0 & 1 \\ 0 & 1 \end{bmatrix}.$$

As introduced in Section 4.2.3, we used $\pi^{(i)}, P$ for voter i with $\tilde{\pi}^{(i)} = \frac{1}{2}\left(\pi^{(i)} + P^{(a_i)}\right)$, and label X_{ij} was sampled according to Categorical$(\tilde{\pi}^{(i)\top} Z_j)$.

We utilized the synthetic data to assess the MAE with the true soft label for each combination of opinion aggregation models and fairness options. However, implementing the fairness options for IBCC, EBCC, and BWA is not straightforward and will require future consideration. Therefore, we present the results for these models without the fairness option for comparison. The hyperparameters α, ρ of the Dirichlet prior distribution were set as

$$\alpha = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}, \quad \rho = (1, 1).$$

Although the overall experimental results are shown in Figure 13 in the Appendix, we particularly focus on the setting with 200 voters for attribute 0 and 400 voters for attribute 1, which are depicted in Figures 9 and 10. Figure 9 illustrates that, consistent with the previous experiment, the D&S-based models, with the exception of the Soft D&S model, exhibited MAEs when utilizing impartial soft labels. Figure 10 presents the results excluding these models. Both pairs of Soft D&S and two different GroupAnno, which are not

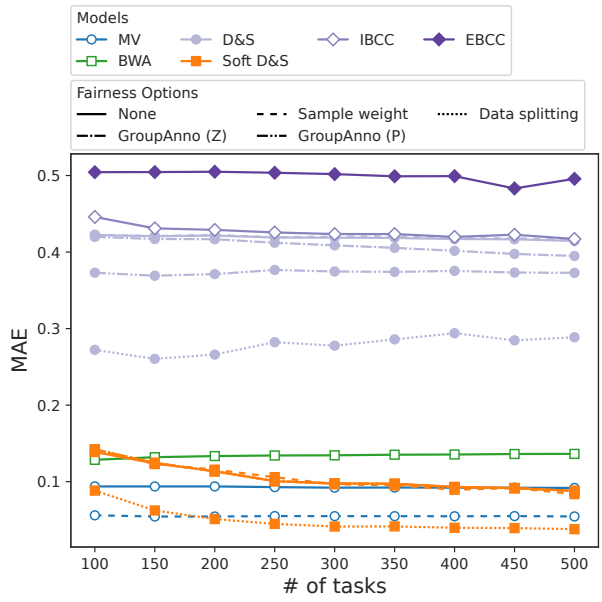

Figure 9: Results of an synthetic experiment to evaluate fairness. There are 200 voters with $a = 0$ and 400 voters with $a = 1$. The horizontal axis shows the number of tasks, and the vertical axis shows the MAEs between true soft labels and estimates.

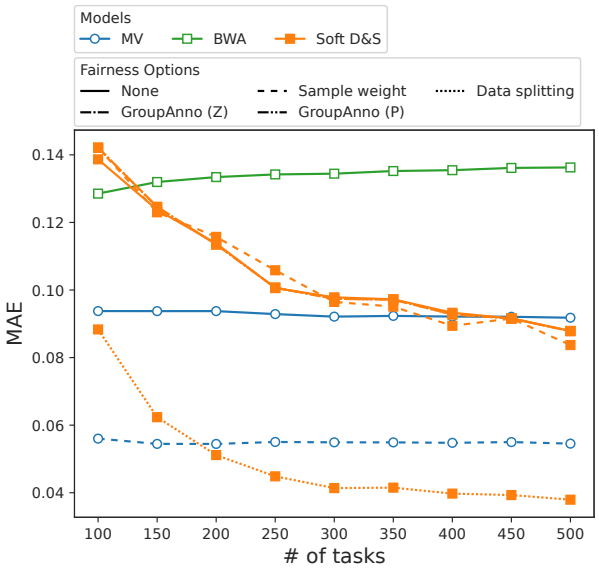

Figure 10: Results from Figure 9 with the D&S-based model, which exhibited large errors, are excluded.

easily discernible due to overlapping data points, showed nearly identical MAEs compared to the pair of Soft D&S with no fairness option. Despite the pairwise generative process of Soft D&S and GroupAnno, the estimation of π and P was unstable for GroupAnno, with data splitting proving to be the best fairness option for Soft D&S. Interestingly, the MAE for weighted MV was the smallest when the number of tasks was as small as 100, whereas the MAE for the Soft D&S and data splitting pair was the smallest when the number of tasks is sufficiently large (150 or more). In contrast to weighted MV, the Soft D&S model has a voter parameter π, which leads to improved MAE as the number of tasks increases owing to the accuracy of the estimation of π. Note that weighted MV achieved the best accuracy when the number of voters was small (as shown in Figure 13). These experimental findings suggest that a sufficient number of voters and tasks are required to outperform weighted MV using the Soft D&S model and data splitting.

5.4 Experiments on Fairness Using Semi-synthetic Data

We present an experiment in which we evaluated fairness using semi-synthetic data created from the Moral Machine dataset [3]. This dataset consists of the opinions of human voters collected on a website[2] on the topic of how automated vehicles should ethically behave. In Moral Machine, a single task corresponds to an automated vehicle choosing which of two groups of characters, such as men, women, old people, and children should be saved in emergency. The website also offers a survey of voter attributes such as age and gender, and some voters cooperated with this survey.

We focused on the gender of the characters in this data and addressed the two-class opinion aggregation problem of whether to save male or female characters. After preprocessing, we used data on 1,853 voters (including 1,072 male and 781 female voters), 326 tasks, and 18,528 labels (including 9,264 labels by male voters and 9,264 labels by female voters).

Because voter attribute bias was not found after preprocessing, we created a semi-synthetic dataset with artificially enhanced bias. We set the flip rate $r \in [0, 1]$ and varied the observation label X as follows.

- We change the label such that female voters save the female character with probability r and male voters save the male character. However, the label could be the same as the original label.
- With probability $1 - r$, the label is not changed from the original label.

Increasing the flip rate strengthens the voter attribute bias, particularly at $r = 1$, where all female voters save the female character and all male voters save the male character.

This semi-synthetic dataset was used to test fairness for the combination of the opinion aggregation model and the fairness option. The dataset was balanced, with equal numbers of male and female voter labels. We sampled the labels of male or female voters in this dataset to create an unbalanced dataset for voter attributes. The soft labels of MV in the balanced dataset were taken as the true soft labels, and compared to the soft labels of each opinion aggregation model in the unbalanced dataset.

We evaluated the fairness of opinion aggregation models using two metrics: MAE and bias. As the Moral Machine dataset considers a binary classification task, we calculated the MAE and bias by

[2]https://www.moralmachine.net/

focusing on the soft label for the "save the male character" class (let us call this class 1). Let $Z_j \in [0,1]^2$ denote the soft label obtained from MV on a balanced dataset for task j, and let $\hat{Z}_j \in [0,1]^2$ denote the soft label obtained from an opinion integration model on an unbalanced dataset. The bias is defined as $\frac{1}{J}\sum_{j=1}^{J}\left(\hat{Z}_{j1} - Z_{j1}\right)$. The degree of fairness is indicated by the proximity of the bias to zero.

Figures 11 and 12 show the results. Figure 11 demonstrates the MAE with soft labels for balanced datasets. The results show that weighted MV yielded the smallest MAE throughout the entire range of flip rates followed by the pair of Soft D&S and data splitting. The MAEs for simple MV and the pairs of Soft D&S models with fairness options other than data splitting increased MAE as the flip rate increases, indicating that weighted MV and the pair of Soft D&S and data splitting were effective in improving fairness. The superior performance of weighted MV over the pair Soft D&S and data splitting can be attributed to the fact that Soft D&S has individual parameters for each voter, which demand a sufficient amount of data. Furthermore, the opinion aggregation models based on the D&S model, with the exception of the Soft D&S model exhibited larger MAEs, as in the previous experiments.

Figure 12 illustrates the bias of the models, where a positive bias indicates that the soft labels are skewed toward saving male characters, compared to the balanced dataset. As the flip rate increased, the biases of several opinion aggregation models and fairness options deviated significantly from zero, whereas the biases of the weighted MV and the Soft D&S with data splitting pairs remained close to zero. Based on these results, weighted MV and the Soft D&S with data splitting pair may be fairer opinion aggregation methods.

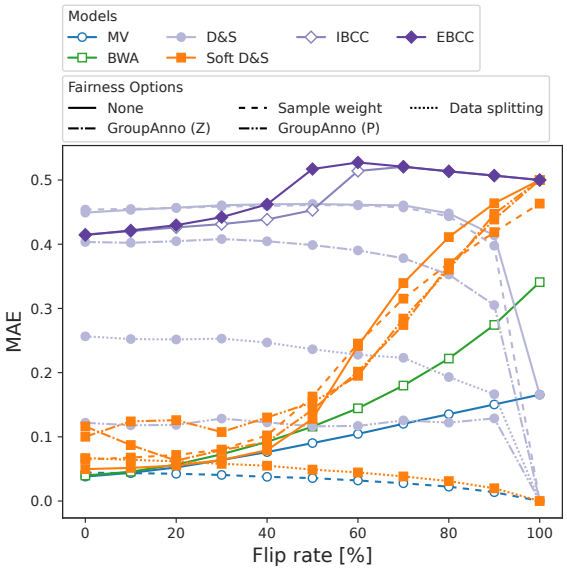

Figure 11: MAE results for the semi-synthetic data designed to evaluate fairness. As the flip rate (horizontal axis) increased, the strength of voter attribute bias increased. The MAE (vertical axis) was calculated as the difference between the aggregate results of a dataset in which the number of female voters was reduced by 50% through sampling from the balanced data and the MV results of the balanced data.

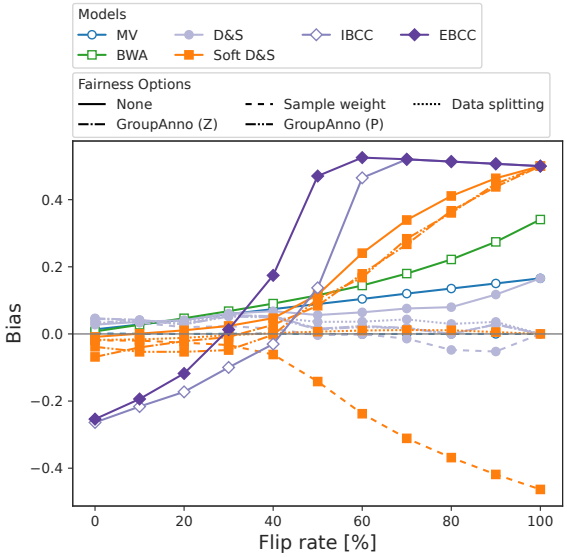

Figure 12: Bias results of the same settings as in Figure 11. Bias values closer to zero indicate fairer results.

6 CONCLUSION

This study aimed to attain fair opinion aggregation concerning voter attributes and evaluate the fairness of the aggregated results. We utilized an approach that combined various opinion aggregation models with fairness options. As we discovered issues with the D&S model producing sharp output, we have proposed a new Soft D&S model that improves the accuracy of soft label estimation. The fairness of the opinion aggregation models (MV, D&S, and Soft D&S), along with three fairness options (sample weighting, data splitting, and GroupAnno), were assessed through experiments. The experimental results indicate that the combination of Soft D&S and data splitting was effective for dense data in enhancing fairness, whereas weighted MV was effective for sparse data.

This study is the first to quantitatively assess fairness in opinion aggregation concerning voter attributes. We have also proposed a technique that balances the opinions of majority and minority attributes across all voters. However, a major limitation of this work is that we have only considered a single binary voter attribute. Future research should address more complex voter attributes such as multi-class and continuous-value attributes as well as multiple voter attributes.

ABSTRACT

The increasing use of machine learning in high-stakes domains – where people's livelihoods are impacted – creates an urgent need for interpretable, fair, and highly accurate algorithms. With these needs in mind, we propose a mixed integer optimization (MIO) framework for learning optimal classification trees – one of the most interpretable models – that can be augmented with arbitrary fairness constraints. In order to better quantify the "price of interpretability", we also propose a new measure of model interpretability called *decision complexity* that allows for comparisons across different classes of machine learning models. We benchmark our method against state-of-the-art approaches for fair classification on popular datasets; in doing so, we conduct one of the first comprehensive analyses of the trade-offs between interpretability, fairness, and predictive accuracy. Given a fixed disparity threshold, our method has a price of interpretability of about 4.2 percentage points in terms of out-of-sample accuracy compared to the best performing, complex models. However, our method consistently finds decisions with almost full parity, while other methods rarely do.

1 INTRODUCTION

There is growing interest in using machine learning (ML) to make decisions in high-stakes domains. For instance, ML algorithms are now commonly used to determine a criminal's risk of recidivism in the United States [7]. There is also a growing literature in designing algorithms to determine the best course of action for homeless individuals [9], to diagnose and treat of various illnesses [26], and many more. In these contexts, it is necessary for such models to be both *accurate* (in order to minimize erroneous predictions that negatively affect stakeholders) and *interpetable* (so that decisions are transparent and hence accountable). We therefore focus our attention to the problem of learning optimal classification trees. Classification trees are among the most interpretable of models [48], and optimal trees – rather than ones that are built using heuristics – maximize predictive accuracy. They belong to a broader set of models known as decision trees (the other type of decision tree being regression trees, which apply to datasets with real valued labels).

There exist numerous qualitative ways of characterizing interpretability [42]. These notions often involve querying humans (especially practitioners, community stakeholders, etc.), so that interpretability desiderata can be tailored to the application or population at hand [21]. Unfortunately, quantitative notions of interpretability are lacking in the machine learning literature, making it hard to compare models systematically without humans in the loop. One such measure – sparsity – is one of the only quantitative proxies for interpretability, but does not allow for equivalent comparisons between different model classes [49] (see Section 1.3 for more details). Therefore, we seek to address this gap by proposing a new notion of interpretability in order to more formally quantify the price of interpretability between our classification trees and more complex models.

Apart from interpretability, another crucial consideration in machine learning for high-impact situations is *fairness*. After all, an algorithm that affects people's well-being should be aware of the particular historical and/or social contexts that surround the learning problem. However, what constitutes as fair may vary widely depending on one's goals, domains of interest, etc. This discussion surrounding "algorithmic fairness" consists of a rich literature that bridges philosophy, economics, and computer science [23, 46, 47]. Consider, for example, a naïve approach where a classifier learns from data where the sensitive attributes are omitted (such as race, sex, and others). Also known as "fairness through unawareness",

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08…$15.00
https://doi.org/10.1145/3600211.3604664

this approach often leads to discrimination because some other non-sensitive attribute(s) may be correlated with the withheld features (e.g., race is inextricably linked to ZIP code and income) [43].

Another approach – and one that this paper adopts – is the notion of "group" statistical fairness. A classifier satisfying group fairness is now aware of the sensitive features in the data but will only produce decisions that enforce parity between segments of the population. This is in contrast to "individual" fairness, which requires that individuals with similar characteristics be classified similarly [23]. Both perspectives have their advantages and drawbacks, but in this work we will focus on group fairness primarily because of it is simpler to define and easier for stakeholders to understand; as such, many practitioners in practice value assessing and enforcing group fairness (see, e.g., [8]). In the following sections, we will discuss in more depth the use of many notions of group fairness in the machine learning literature.

1.1 Problem Statement

We now formalize the problem we study. Let $\mathcal{D} := \{(x^i, y^i)\}_{i \in \mathcal{I}}$ be training data indexed in the set $\mathcal{I} \in \{1, \ldots, I\}$. Each datapoint $i \in \mathcal{I}$ consists of a vector x^i with F features (i.e., $x^i \in \mathbb{R}^F$), and a class label $y^i \in \mathcal{K}$, where $\mathcal{K}$ is the finite set of possible classes. Throughout this paper, we will consider the case of binary classes, i.e., $\mathcal{K} := \{0, 1\}$ where $y = 1$ will be referred to as the positive class. Note that the literature on fairness for multi-class learning is limited, see e.g., Denis et al. [20]. The goal is to learn, over all possible trees of maximum depth d, the tree that maps x^i to y^i and maximizes out-of-sample accuracy, using in-sample performance as a proxy. Further, suppose the population can be divided into different sensitive groups (whereby discrimination exists or is a concern within the classification problem, e.g., race, gender). Let $\mathcal{P}$ denote levels of a sensitive attribute, and let each datapoint i have a value $p^i \in \mathcal{P}$. The features in $\mathcal{P}$ may or may not be included in the vector x^i since there may be legal or ethical considerations barring the use of protected features in the predictive task [17].

1.2 Common Notions of Group Fairness

In this section, we define five common notions of group fairness in the machine learning literature that we will use. Let $\hat{Y}$ be the classifier's prediction, and let X, Y, $\hat{Y}$, and P be random variables for features, classes, classifier's predictions, and protected features, respectively; their joint distribution is unknown and denoted by $\mathbb{P}$.

Statistical Parity. A classifier satisfies statistical parity if the probability of receiving a positive class is equal across all protected groups [23]. Formally, this means

$$\mathbb{P}[\hat{Y} = 1 | P = p] = \mathbb{P}[\hat{Y} = 1 | P = p'] \quad \forall p, p' \in \mathcal{P}.$$

Conditional Statistical Parity. A classifier satisfies *conditional* statistical parity if the probability of receiving a positive class is equal across all protected groups, conditional on some legitimate feature(s) indicative of risk [19]. This may be considered as a fairer notion than statistical parity because it takes into account the distribution of risk factors within each sensitive group. Letting L (which is a subvector of X) represent the random variable taken from a set $\mathcal{L}$ of legitimate features, conditional statistical parity is satisfied if

$$\mathbb{P}[\hat{Y} = 1 | P = p, L = \ell] = \mathbb{P}[\hat{Y} = 1 | P = p', L = \ell] \quad \forall p, p' \in \mathcal{P}, \ell \in \mathcal{L}.$$

Predictive Equality. A classifier satisfies predictive equality if all protected groups have the same false positive rates (FPR) [18], i.e.,

$$\mathbb{P}[\hat{Y} = 1 | P = p, Y = 0] = \mathbb{P}[\hat{Y} = 1 | P = p', Y = 0] \quad \forall p, p' \in \mathcal{P}.$$

Equal Opportunity. A classifier satisfies equal opportunity if all protected groups have the same true positive rate (TPR) [30]. The formal definition of equal opportunity is

$$\mathbb{P}[\hat{Y} = 1 | P = p, Y = 1] = \mathbb{P}[\hat{Y} = 1 | P = p', Y = 1] \quad \forall p, p' \in \mathcal{P}.$$

Equalized Odds. Equalized odds combines predictive equality and equal opportunity such that both FPR and TPR must be similar across all protected groups [30]. Equalized odds is, of course, a stronger condition than predictive equality and equal opportunity individually. Formally, equalized odds is satisfied if

$$\mathbb{P}[\hat{Y} = 1 | P = p, Y = y] = \mathbb{P}[\hat{Y} = 1 | P = p', Y = y] \quad \forall p, p' \in \mathcal{P}, y \in \{0, 1\}.$$

1.3 Related Works

Our work relates to five streams of literature in machine learning, which we review in turn. In this section we briefly review related works in the machine learning literature.

Discrimination Prevention in Machine Learning. The literature on fairness in machine learning is extensive – we point the interested reader to [38] and [59] for surveys of this topic. In general, there are three approaches that existing works employ in order to promote fairness. The first is *pre-processing*, which entails eliminating discrimination within the training data, see [27, 29, 35, 56], among others. The second is *post-processing*, which takes the model's output and alters its decisions in ways that promote some fairness metric, see [30, 34, 44]. Finally, one may also employ *in-processing* by modifying existing models so that fairness is integrated within its learning goal; for instance, approaches have utilized regularization [3, 11, 36] or different heuristics [16, 34]. Our work falls under the category of in-processing discrimination prevention techniques.

Fair Decision Trees. Within the stream of literature on discrimination prevention, our work most closely relates to approaches for learning fair decision trees. For instance, Ranzato et al. [45] adapt a genetic algorithm for learning robust decision trees in order to prioritize individual fairness. In the online setting, Zhang et al. [58] propose a fairness-aware Hoeffding tree that builds decision trees over streams of data. Grari et al. [28] take an adversarial approach to training fair gradient-boosted trees that promote statistical parity. Kanamori and Arimura [37] propose a post-processing step that uses mixed-integer optimization (MIO) to edit the branching thresholds of the tree's internal nodes to satisfy some fairness constraint; in the paper they use statistical parity and equalized odds. In a similar manner, Zhang et al. [57] flip the outcomes of different paths of a learned tree in order to improve fairness. Closely related to our work is that of Aghaei et al. [3], who propose a mixed-integer optimization framework to build optimal and fair decision trees that prevent disparate impact and/or disparate treatment. In contrast to

our work, Aghaei et al. [3] enforces fairness via regularization while our method uses constraints in the optimization. Finally, Kamiran et al. [34] propose a two-pronged approach: the first is to incorporate sensitivity gain (IGS) with information gain (IGC) as a heuristic to build a fairer decision tree, while the second is to relabel the predictions in the tree's leaf nodes to further promote statistical parity.

Optimal Decision Trees. Mixed-integer optimization (MIO) has recently gained traction as a framework to solve various machine learning problems. Particularly related to this paper are approaches that use MIO to learn optimal decision trees in order to improve on the traditional classification/regression tree (CART) algorithms [15], which rely on a heuristic. Many works introduce novel formulations for learning optimal classification trees [3, 4, 12, 53]. Elmachtoub et al. [25] use MIO to learn decision trees that minimize a loss function derived from the "predict-then-optimize" framework. There exist several extensions to learning decision trees using MIO as well. For instance, Mišić [40] uses MIO to solve tree ensemble models to optimality; Jo et al. [31] to learn optimal prescriptive trees from observational data; and Justin et al. [33] and Bertsimas et al. [13] to learn optimal robust decision trees. In this paper, we build on the MIO method introduced by Aghaei et al. [4] by conducting extensive experiments when we add various fairness constraints to the model.

Notions of Interpretability. There exist numerous proxies or desiderata for interpretability in the machine learning literature, including:

- **Sparsity**: The simplicity of a model. There are many ways to define sparsity, which also differ across model classes. For instance, within the context of decision trees, Rudin et al. Rudin et al. [49] define sparsity using the number of leaves, where trees with fewer leaves are sparser and thus preferable. In a regression model, sparsity is widely associated with the number of nonzero regression coefficients [5, 39, 52]. In general, a numeric value for sparsity is only useful when comparing models within the same class. This is because some model classes have sparsity that does not grow uncontrollably (e.g., regression is constrained by the number of features), while others are a function of design and data (e.g., trees become increasingly complex as depth increases) [49].
- **Simulatability**: The extent to which a human can internally simulate and reason about part of the entire decision-making schema [42]. Shallow decision trees are some of the most simulatable models since we can easily visualize and understand if-else rules. This is in contrast to a neural network, where the numerous connections between nodes result in complicated calculations that a human cannot keep track of.
- **Scope** (Global vs. Local interpretability): Global interpretability means that a human can wholly understand the decision schema (as is the case with, say, regression, where everything one needs to know about the model is encoded in its coefficients). On the other hand, local interpretability means that one could reason about how and why a particular datapoint gets classified a certain way [41]. For instance, while the entire behavior of a k-nearest neighbor (kNN) algorithm is incomprehensible, especially when a dataset is large, humans can reason about local behavior: a datapoint is classified a certain way because most of its k-nearest neighbors are classified the same way.

There are many other proxies (e.g., uncertainty, algorithmic transparency, monotonicity, etc.), as well as other notions of interpretabilty that apply to various stages of the predictive pipeline (e.g., considerations in feature engineering). We refer the interested reader to [41, 42, 49] for an extensive overview of interpretable machine learning. As we have mentioned previously, interpretability is broad, loosely-defined, and often context dependent. Nonetheless, existing quantitative measures (such as sparsity) are only useful for comparisons within the same model class; our work attempts to address this shortcoming by proposing a new measure of interpretability that allows for comparisons *across* model classes.

Interpretability, Accuracy, and Fairness. Several works have explored the possible trade-offs between predictive accuracy and interpretability (without considering fairness), often in application-specific contexts [10, 32] or within a certain model class [5, 6, 50, 55] where interpretability desiderata differ widely. In a more general setting, Dziugaite et al. [24] propose a learning framework via empirical risk minimization that imposes interpretability constraints, and characterizes when trade-offs between accuracy and interpretability may exist – this is in line with other works that find the optimal model within a specified model class subject to interpretability constraints (e.g., Azizi et al. [9], Rudin et al. [49]). On the other hand, Semenova et al. [51] allow for comparisons *across* various model classes by using Rashomon sets to gauge the likelihood of simpler models with competing accuracy performance existing within a hypothesis space. However, none of these works consider fairness as a dimension in model selection. There is a dearth of literature touching the trade-offs between all three: interpretability, accuracy, *and* fairness. Agarwal [2] finds theoretical results that in general, there exist more complex models that perform strictly better with respect to fairness and accuracy. Our work extends this finding by experimentally characterizing these trade-offs. Wang et al. [54] compare models with varying levels of interpretability in predicting criminal recidivism, considering notions of fairness where the prediction task is continuous (e.g., calibration). In contrast, our work considers binary fairness notions and we run experiments more generally on various benchmark datasets – which include predicting recidivism. We additionally compare several fairness-promoting algorithms in the literature, while Wang et al. [54] only consider off-the-shelf ML models.

1.4 Contributions

In this work, we build upon an MIO formulation to learn optimal decision trees initially proposed in Aghaei et al. [4] by showcasing its flexible modeling power in considering various notions of fairness. We benchmark these experiments against two state-of-the-art methods that similarly learn fair decision trees, as well as three fair classification algorithms that are compatible with a variety of ML models. In order to more formally juxtapose the interpretability of ML models, we propose a new measure called *decision complexity*. In doing so, we conduct one of the first experiments to characterize the trade-offs between performance and interpretability within the

algorithmic fairness literature, and discuss the practical considerations among these dimensions. In particular, we observe that the best performing, complex models have on average 4.2 percentage points higher out-of-sample accuracy than our interpretable approach, indicating the price of interpretability. We also observe that our method is particularly well-suited in finding decisions with full parity, while other methods do not boast the same guarantees.

The remainder of this paper is structured as follows. In Section 2, we introduce a new notion of interpretability – decision complexity – that allows for comparisons across model classes. We then outline the MIO formulation to learn optimal and fair decision trees in Section 3. Finally, we conduct and analyze our computational experiments in Section 4.

2 DECISION COMPLEXITY

As discussed in Section 1.3, sparsity/simplicity is one of the only metrics in the literature to quantify interpretability, and is mainly relevant when comparing the models within the same class. In our work, however, we are concerned with comparing a measure of interpretability *across* model classes (e.g., comparing decision trees with kNN). To the best of our knowledge, there is no such universal definition or framework for interpretability. We therefore propose a new notion that can quantify the interpretability of predictive models belonging either to the same or to different model classes.

Definition 2.1 (Decision Complexity)**.** Given a trained classifier, decision complexity captures the minimum number of parameters needed for the classifier to make a prediction on a new datapoint.

Example 2.1 (Binary Classification Trees). The decision complexity of binary classification trees is measured by the number of nodes in the tree (branching plus leaves), which corresponds to the number of times a datapoint is routed through the tree and how it is classified.

Example 2.2 (Random Forest). Building from binary classification trees, a random forest's decision complexity is equal to the sum of nodes (branching and leaves) over all trees in the forest.

Example 2.3 (Linear/Logistic Regression). Assuming full linearity (i.e., no interaction or quadratic terms), the decision complexity of simple regression models is always equal to the number of features in the data (plus a possible bias term).

Example 2.4 (k-Nearest Neighbors). In order to classify a new datapoint, we must find the distance between said datapoint with all training points, and therefore a kNN's decision complexity is equal to the size of the training data. While there exist more efficient algorithms in practice that do not require finding all pairwise comparisons, we are concerned primarily with how a human can walk through the algorithm's decisions rather than the computational complexity to train the classifier.

Example 2.5 (Support Vector Machines). Decision complexity in SVMs highly depends on the choice of kernel. Linear kernels have a complexity equal to the number of features in the data, which correspond to the coefficients in the hyperplane that separates classes. However, gaussian RBF kernels have a decision complexity equal to the number of support vectors in the training set. This is because, upon training, each of the support vectors are associated with weights that determine how a new datapoint gets classified.

Example 2.6 (Neural Network). A neural network's decision complexity is equal to the number of "connections" between all nodes, since a new datapoint is classified through matrix calculations using solved weights from each connection.

Decision complexity can be viewed as an extension to sparsity (in that sparsity is often used analogously to simplicity) but has the advantage of being general enough for all model classes. It can also be interpreted as attempting to quantify a part of simulatability – the more decisions a model takes, the harder it tends to be for humans to simulate the decision making process.

3 FORMULATION

In this section, we present the MIO formulation to learn optimal decision trees proposed in Aghaei et al. [4]. The paper introduced the formulation without an emphasis on fairness, but in this work we use the formulation as a building block to which we add various fairness constraints. From hereon, we will refer to the combination of the MIO formulation and the fairness constraints as *FairOCT*.

3.1 From Decision Tree to Flow Graph

We first introduce the modeling framework we use for decision trees. The key idea is to convert a decision tree into a directed, acyclic graph where all arcs "flow" from the tree's root to its leaves. We start with a perfect binary tree of depth d, whose nodes are labeled 1 through $(2^{d+1} - 1)$ in order of a breadth-first search. Let $\mathcal{B} := \{1, \ldots, 2^d - 1\}$ denote the set of branching nodes and $\mathcal{T} := \{2^d, \ldots, 2^{d+1} - 1\}$ the set of terminal nodes. We then convert all arcs in the tree to point from the parent node to its child node (see Figure 1, left). From the binary tree, we connect a source s to the root and all nodes $n \in \mathcal{B} \cup \mathcal{T}$ to sinks t_k, one for every class $k \in \mathcal{K}$ (see Figure 1, right). While we assume that we have binary classes, this formulation generalizes to arbitrary finite classes. All arcs have a capacity of 1, so each datapoint is weighted equally and flows from the source s to one sink t_k, where k is the class that the decision tree assigns to that datapoint. From hereon, we refer to this structure as a "flow graph".

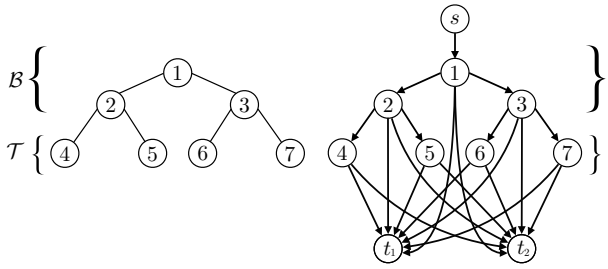

Figure 1: A decision tree of depth 2 (left) and its associated flow graph (right) with two classes.

3.2 MIO Formulation

With the flow graph at hand, we present the MIO formulation for learning optimal classification trees. Without loss of generality, we assume that features are binary, i.e., $x^i \in \{0,1\}^F$ – this assumption can easily be relaxed to cater for integer or categorical features, see Remark 1 in [4]. We encode the branching structure of the tree with variables $b_{nf} \in \{0,1\}$, for all $n \in \mathcal{B}, f \in \mathcal{F}$, which indicate if feature f is selected for branching at node n. We also encode the prediction scheme of the tree using variables $w_{nk} \in \{0,1\}$, for all $n \in \mathcal{B} \cup \mathcal{T}, k \in \mathcal{K}$, which equal 1 if and only if (iff) node n assigns class k to all datapoints that land on that node. We let $p_n \in \{0,1\}$ indicate if node n is a prediction node, in which case it must assign a class to all datapoints that land on that node and no further branching is allowed. We also define "flow variables" z to capture the flow of datapoints, where $z^i_{a(n),n} \in \{0,1\}$ equals 1 iff datapoint i flows from the direct ancestor of node n, $a(n)$, to n.

The formulation is as follows:

$$\text{maximize} \quad \sum_{i\in\mathcal{I}} \sum_{n\in\mathcal{B}\cup\mathcal{T}} z^i_{n,t_{y^i}} \qquad \text{subject to} \quad \text{(1a)}$$

$$\sum_{f\in\mathcal{F}} b_{nf} + p_n + \sum_{m\in\mathcal{A}(n)} p_m = 1 \qquad \forall n \in \mathcal{B} \quad \text{(1b)}$$

$$p_n + \sum_{m\in\mathcal{A}(n)} p_m = 1 \qquad \forall n \in \mathcal{T} \quad \text{(1c)}$$

$$z^i_{a(n),n} = z^i_{n,\ell(n)} + z^i_{n,r(n)} + \sum_{k\in\mathcal{K}} z^i_{n,t_k} \qquad \forall n \in \mathcal{B}, i \in \mathcal{I} \quad \text{(1d)}$$

$$z^i_{a(n),n} = \sum_{k\in\mathcal{K}} z^i_{n,t_k} \qquad \forall i \in \mathcal{I}, n \in \mathcal{T} \quad \text{(1e)}$$

$$z^i_{s,1} \le 1 \qquad \forall i \in \mathcal{I} \quad \text{(1f)}$$

$$z^i_{n,\ell(n)} \le \sum_{f\in\mathcal{F}: x^i_f = 0} b_{nf} \qquad \forall n \in \mathcal{B}, i \in \mathcal{I} \quad \text{(1g)}$$

$$z^i_{n,r(n)} \le \sum_{f\in\mathcal{F}: x^i_f = 1} b_{nf} \qquad \forall n \in \mathcal{B}, i \in \mathcal{I} \quad \text{(1h)}$$

$$z^i_{n,t_k} \le w^n_k \qquad \forall i \in \mathcal{I}, n \in \mathcal{B}\cup\mathcal{T}, k \in \mathcal{K} \quad \text{(1i)}$$

$$\sum_{k\in\mathcal{K}} w^n_k = p_n \qquad \forall n \in \mathcal{B}\cup\mathcal{T} \quad \text{(1j)}$$

$$w^n_k \in \{0,1\} \qquad \forall n \in \mathcal{B}\cup\mathcal{T}, k \in \mathcal{K} \quad \text{(1k)}$$

$$b_{nf} \in \{0,1\} \qquad \forall n \in \mathcal{B}, f \in \mathcal{F} \quad \text{(1l)}$$

$$p_n \in \{0,1\} \qquad \forall n \in \mathcal{B}\cup\mathcal{T} \quad \text{(1m)}$$

$$z^i_{a(n),n}, z^i_{n,t_k} \in \{0,1\} \qquad \forall n \in \mathcal{B}\cup\mathcal{T}, i \in \mathcal{I}, k \in \mathcal{K}, \quad \text{(1n)}$$

where $\ell(n)$ (resp. $r(n)$) is the left (resp. right) descendant of n and $\mathcal{A}(n)$ is the set of all ancestors of node $n \in \mathcal{B}\cup\mathcal{T}$. The objective (1a) maximizes the number of correctly classified datapoints. Note that we can add a regularization term in the objective to control for overfitting, see Aghaei et al. [4]. Constraints (1b) ensure that each node is either a branching node, a prediction node, or neither of the two because one of its ancestors is already a prediction node; the last option means that the node is pruned out. Constraints (1c) similarly ensure that each terminal node either makes a prediction or has an ancestor that is a prediction node. Constraints (1d) and (1e) enable flow conservation, whereby every datapoint that flows into node n must exit to its left (or right) descendant, or flow directly to a sink t_k that corresponds to a class k. Constraints (1f) ensure that the flow value of each datapoint entering source s is at most 1. Constraints (1g) and (1h) enforce datapoints to flow to a node's left (resp. right) child if their branching feature is 0 (resp. 1). Constraints (1i) require that a datapoint must be directed to the sink corresponding to the class that the prediction node assigns. Finally, constraints (1j) in conjunction with (1k) ensure that if we make a prediction at node n, then exactly one class is associated with its prediction. In sum, each datapoint flows into the graph and lands on exactly one of the sinks via a path from source to sink depending on its feature vector.

3.3 Fairness Constraints

One main advantage of formulation (1) is its flexible modeling power. In the following, we showcase the variety of constraints that can be added to the formulation to learn trees that satisfy the definitions of fairness we introduced in Section 1.2. We previously defined the various notions of fairness using strict equalities; in practice, however, we may relax this condition by introducing a bias δ, where δ is the maximum disparity allowed between groups.

Statistical Parity. Statistical parity is satisfied up to a bias of δ when we add the following constraint to (1):

$$\left| \frac{\sum_{n\in\mathcal{B}\cup\mathcal{T}} \sum_{i\in\mathcal{I}: p^i = p} z^i_{n,t_1}}{|\{i \in \mathcal{I} : p^i = p\}|} - \frac{\sum_{n\in\mathcal{B}\cup\mathcal{T}} \sum_{i\in\mathcal{I}: p^i = p'} z^i_{n,t_1}}{|\{i \in \mathcal{I} : p^i = p'\}|} \right| \le \delta \qquad \forall p, p' \in \mathcal{P} : p \ne p', \quad (2)$$

where the left-hand side of the inequality is the absolute difference between the proportion of positive classes assigned by the classification tree to groups p and p', respectively.

Conditional Statistical Parity. In order to describe the CSP constraint, we will let ℓ^i denote the value of datapoint i's legitimate factor(s). To ensure that the learned tree satisfies conditional statistical parity up to a bias δ and for all $\ell \in \mathcal{L}$, we may augment (1) with the constraint

$$\left| \frac{\sum_{n\in\mathcal{B}\cup\mathcal{T}} \sum_{i\in\mathcal{I}} \mathbb{I}(p^i = p \wedge \ell^i = \ell) z^i_{n,t_1}}{|\{i \in \mathcal{I} : p^i = p \wedge \ell^i = \ell\}|} - \frac{\sum_{n\in\mathcal{B}\cup\mathcal{T}} \sum_{i\in\mathcal{I}} \mathbb{I}(p^i = p' \wedge \ell^i = \ell) z^i_{n,t_1}}{|\{i \in \mathcal{I} : p^i = p' \wedge \ell^i = \ell\}|} \right| \le \delta \qquad \forall p, p' \in \mathcal{P} : p \ne p', \ \ell \in \mathcal{L}, \quad (3)$$

where the left-hand side of the inequality is the absolute difference between the proportions of positive classes assigned by the classification tree to groups p and p' respectively, in the training data, and whose legitimate feature(s) equal(s) ℓ.

Equalized Odds. We may augment (1) to satisfy equalized odds up to a bias δ using the constraint

$$\left| \frac{\sum_{n\in\mathcal{B}\cup\mathcal{T}} \sum_{i\in\mathcal{I}} \mathbb{I}(p^i = p \wedge y^i = k) z^i_{n,t_1}}{|\{i \in \mathcal{I} : p^i = p \wedge y^i = k\}|} - \frac{\sum_{n\in\mathcal{B}\cup\mathcal{T}} \sum_{i\in\mathcal{I}} \mathbb{I}(p^i = p' \wedge y^i = k) z^i_{n,t_1}}{|\{i \in \mathcal{I} : p^i = p' \wedge y^i = k\}|} \right| \le \delta \qquad \forall k \in \mathcal{K}, p, p' \in \mathcal{P} : p \ne p', \quad (4)$$

where the left-hand side of the inequality is the absolute difference between the proportions of false positive and true positive assignments made by the classification tree in groups p and p'. Note that predictive equality and equal opportunity are equivalent to setting $k = 0$ and $k = 1$ in (4), respectively.

Note that any of the above constraints can be easily linearized by decomposing them into two. In the general case where we have

constraint $|f(x)| \leq \delta$, we can reformulate it into $f(x) \leq \delta$ and $-f(x) \leq \delta$. If f is affine (as is the case here), then these constraints are linear in the decision variables of the problem and the resulting problem can be solved with powerful off-the-shelf mixed-integer *linear* optimization solvers such as Gurobi[1]. We also emphasize that the above constraints are illustrative examples of the approach's flexibility, and that they may be amended or combined with other fairness considerations. For example, instead of restricting the absolute value of the difference between groups, we may impose that the minority group should be better off by a margin δ, see Section 4.4.

4 EXPERIMENTS

We now evaluate the empirical performance of the model outlined in Section 3. We first compare the interpretability of several popular machine learning models based on three desiderata – decision complexity, simulatability, and scope – illustrating that our approach (*FairOCT*) yields one of the most interpretable models. Then, we compare our approach to a suite of methods for learning fair classifiers (both ones that are model agnostic and those that specifically learn decision trees).

4.1 Datasets

COMPAS. The Correctional Offender Management Profiling for Alternative Sanctions (COMPAS) is a popular dataset used originally to predict a criminal's risk of recividism after 2 years. Angwin et al. [7] published a seminal article analyzing that the algorithm deployed then was biased in favor of White criminals. We therefore let race be the sensitive attribute. The original race attribute has 6 levels, but Asian and Native American criminals are quite rare in the data, so we group them under the "Other" category in order to make it possible to obtain better estimates of fairness metrics. The dataset consists of 6,172 datapoints.

Adult. The UCI Adult dataset is taken from a 1994 Census database [22]. The goal is to predict whether or not someone's income exceeds $50,000 per year, and we treat sex as the sensitive attribute in accordance with [1, 28, 36] with females being the marginalized group. The full dataset contains 30,162 datapoints.

German. The German dataset classifies people as having good or bad credit. We use age as the sensitive attribute, following the works of [27, 34] to split the population into people 25 and younger and older than 25, with the former as the marginalized group since younger people are often assigned worse credit under the basis of age. The dataset contains 1,000 datapoints.

All three datasets are popular benchmark datasets in the algorithmic fairness literature. We focus on these three because they each have different and societally important prediction tasks.

4.2 Benchmark Methods

Fair Decision Tree-Based Methods

Optimal and Fair Decision Trees via Regularization (RegOCT). We compare our approach to the method for learning optimal fair trees proposed by Aghaei et al. [3], which considers both disparate impact and disparate treatment. In our setting, we are only interested in disparate impact, which reduces to statistical parity in the case of binary outcomes. Our method differs from *RegOCT* in two ways: *1) FairOCT* is formulated much more efficiently, resulting in faster solve times, and *2) RegOCT* promotes fairness via a regularization term in the objective rather than as a constraint (like ours). Its objective function minimizes misclassification rate plus a regularization term controlled by a "fairness parameter" ρ.

Discrimination Aware Decision Trees (DADT). The second tree-based method we compare to is *DADT* proposed by Kamiran et al. [34], which consists of a two-pronged approach. The first is an in-processing step that uses sensitivity gain (IGS) and information gain (IGC) as heuristics to build a fair decision tree. If the tree still has a discrimination level greater than ϵ, a post-processing step can be used that relabels the predictions of the tree's leaf nodes until the discrimination reaches ϵ. Note that the original paper proposes to use a combination of these steps where appropriate, such as IGC+IGS, IGC-IGS, or only IGC (which is equivalent to the CART algorithm) – all of which can be combined with the relabeling step post-training ("Relab"). We compare our method with respect to IGC+IGS_Relab because Kamiran et al. [34] cited that it in general performs best, although we display results for all three heuristics in the Appendix Section A. We grow trees of maximum depth 2 and 3 for interpretability. *DADT* has two modeling limitations: it only considers statistical parity as its fairness metric, and it assumes only two sensitive groups exist. In further contrast to *FairOCT*, *DADT* subtracts the probability of the marginalized group from the dominant group. A "fair" result under this definition may include a scenario in which the marginalized group receives better outcomes at a much higher rate than the dominant group, which constraint (2) does not allow. However, since our approach is very flexible, we run experiments on *FairOCT* with this notion of disparity – refer to Appendix Section A.

Note that methods other than *DADT* and *RegOCT* in the literature either: consider individual fairness as opposed to group fairness (e.g., Ranzato et al. [45]); learn trees in an online setting (e.g., Zhang and Ntoutsi [58]); or are not interpretable (e.g., Grari et al. [28]).

Model Agnostic Fairness Methods

Apart from strictly tree-based methods, we also compare our approach to three methods – one from each umbrella of approaches: pre-processing, in-processing, and post-processing. Critically, these three methods can learn most ML model classes (such as logistic regression, random forests, kNN, etc.). This feature is important because our goal is to analyze the accuracy and discrimination trade-offs when opting to use our method (one of the most interpretable) in lieu of more complex models.

[Pre-Processing] Correlation Remover (CR). We benchmark our method against *CR*, which reduces the correlation between the data and the sensitive feature by regressing the "centered" sensitive feature with the non-sensitive features. A linear transformation using the learned coefficients is then applied, resulting in new data X_{corr}. The final transformation X_{tfm} is controlled via a fairness parameter $\alpha \in [0, 1]$:

$$X_{\text{tfm}} = \alpha X_{\text{corr}} + (1 - \alpha)X,$$

where $\alpha = 0$ corresponds to the original feature vector X and $\alpha = 1$ means all correlation is removed. Further detail can be found in [14] and the API documentation for FairLearn. Note that we chose

[1] See https://www.gurobi.com/products/gurobi-optimizer/

Model	Decision Complexity (COMPAS)	Decision Complexity (Adult)	Decision Complexity (German)	Simulatability	Scope
Full Tree (d=1)	3	3	3	High	Global
Full Tree (d=2)	7	7	7	High	Global
Full Tree (d=3)	15	15	15	High	Global
Logistic Regression	6	12	20	Medium-High	Global
Decision Tree	779	5,101	329	Medium	Global
k-Nearest Neighbors	4,629	22,621	750	Medium-Low	Local
SVM (RBF Kernel)	3,255	10,542	454	Low	Local
Multilayer Perceptron	700	1,300	2,100	Low	None
Random Forest	59,126	273,861	17,956	Low	None

Table 1: Interpretability of various machine learning models with respect to three desiderata: decision complexity (in the context of the *COMPAS*, *Adult*, and *German* datasets), simulaltability, and scope.

this method out of all other pre-processing approaches because it is lightweight and yields better performance upon testing.

[In-Processing] Exponentiated-Gradient Reduction (ExpG). Algorithm 1 in Agarwal et al. [1] finds a classifier and λ with the highest accuracy subject to a fairness constraint, where λ is a vector consisting of k Lagrangian multipliers, each corresponding to a fairness constraint in the algorithm (i.e., $\lambda \in \mathbb{R}_+^k$). Since we are interested in obtaining a breadth of accuracy-discrimination datapoints, we opted to implement their "grid search" method, which searches through a grid of λ and yields the best estimator from a given model class. In our case, we use *all* the results from the possible values of λ. This grid search method is what we will refer to as *ExpG* in our experiments. We chose to compare our method with *ExpG* because it is one of the only in-processing approaches that take in nearly any model class and also optimize for many fairness notions.

[Post-Processing] Randomized Threshold Optimizer (RTO). Lastly, we compare *FairOCT* with a method proposed by Hardt et al. [30] that applies a randomized thresholding transformation to the classifier's prediction to enforce a fairness notion. We refer to Section 3.2 of Hardt et al. [30] for a full treatment of the algorithm. Similar to *ExpG*, we chose *RTO* because it is one of the only post-processing methods that is model agnostic and can optimize for all the fairness notions we consider in this work.

4.3 Interpretability of Machine Learning Models

Table 1 provides a comparison of several popular machine learning models and our assessment of their interpretability with respect to several desiderata: model complexity (defined in Section 2), simulatability, and scope. In the following, we elucidate our judgments on the simulatability and scope of these models. We will classify models as having "High" to "Low" simulatability, and "Global", "Local", or "None" in terms of scope. Unless otherwise noted, all models except for optimal trees are trained using the standard parameters of the scikit-learn package:

- **Full Binary Trees**: For simplicity, we consider learning full binary trees up to a fixed depth d for our optimal tree methods, although in practice we may easily prune the tree via regularization. We argue that trees have a global scope and are among the most simulatable because humans can visualize the entire decision rule and trace predictions with relative ease (especially when the trees are shallow and simple).
- **Decision Trees – CART (DT)**: Trees that are grown via a heuristic typically have a stopping point to avoid overfitting, and in our case we impose the minimum number of samples in each leaf to be 3. Since there is stochasticity in tree depth and pruning, we report decision complexity as the average over all trees grown for a particular dataset. While DT has a global scope similar to full binary trees, it is much less simulatable given how deep the trees tend to grow.
- **Logistic Regression (LR)**: Assuming full linearity, logistic regression has global scope because one can wholly observe its decision rule via its coefficients. However, we argue that logistic regression has medium simulatability because the coefficients need to be calculated and contextualized for full interpretability.
- **k-Nearest Neighbors (kNN)**: While kNN's simulatability can be high – especially in lower dimensions where the decision space can be visualized ($F \leq 3$) – kNN's are often not simulatable in practice. Without visualizing the entire feature space, we can only observe the local behavior of the model, i.e., which k points are nearest to our new datapoint.
- **Support Vector Machines (SVM), RBF Kernel**: Due to stochasticity, we report the average number of support vectors in our experiments for SVM's decision complexity. We argue that SVM's have low simulatability, especially when $F > 2$ and the decision space is hard to visualize. We can, however, classify SVM's as having local scope because the intuition is similar to kNN – support vectors closer to the new datapoint will have much higher weights.
- **Random Forest (RF)**: We grow 100 trees via the CART algorithm to build the random forest model, and argue that simulatability is low because a human cannot keep track of the complicated decisions that are aggregated over numerous trees. The intricacy of the random forest also means that it is not interpretable neither globally or locally.
- **Multilayer Perceptron (MLP)**: A multilayer perceptron is a neural network. We train MLPs with 1 hidden layer consisting of 100 nodes, while the input layer has the number

Algorithm	Fairness Definitions	# Sensitive Levels	Disparity	Model	Fairness Parameter	Time Limit
FairOCT	SP, CSP, PE, EOpp, EOdds	Any	absmax	Full Tree ($d \in \{1, 2, 3\}$)	$\delta \in [0.01, 0.55]$ $\Delta = 0.01$	3 hrs
RegOCT	SP	Any	absmax	Full Tree ($d \in \{1, 2, 3\}$)	$\rho \in [0, 1]$ $\Delta = 0.02$	3 hrs
DADT	SP	2	dom-marg	DT	$\epsilon \in [0.01, 0.55]$ $\Delta = 0.01$	N/A
CR	SP, PE, EOpp, EOdds	Any	absmax	DT, LR, kNN, SVM, RF, MLP	$\alpha \in [0, 1]$ $\Delta = 0.1$	N/A
ExpG	SP, PE, EOpp, EOdds	Any	absmax	DT, LR, kNN, SVM, RF, MLP	# of λ : 100	N/A
RTO	SP, PE, EOpp, EOdds	Any	absmax	DT, LR, kNN, SVM, RF, MLP	N/A	N/A

Table 2: List of algorithms run on *COMPAS*, *Adult*, and *German* datasets. Each algorithm can accommodate different fairness definitions: statistical parity (SP), conditional statistical parity (CSP), predictive equality (PE), equal opportunity (EOpp), and equalized odds (EOdds). They also take varying number of sensitive levels and disparity measures, where "absmax" corresponds to the absolute value of the maximum pairwise disparity between sensitive groups and "dom-marg" is the difference in positive classification rate between the dominant group and the marginalized group. Different machine learning models are also considered: full binary trees with branching depths $d \in \{1, 2, 3\}$, decision trees grown via CART (DT), logistic regression (LR), k-nearest neighbors (kNN), support vector machine with RBF kernel (SVM), random forest (RF), and multilayer perceptron (MLP). Our experiments also varied the fairness parameters for all methods, whose role is outlined in detail in Section 4.2. Δ denotes the increments taken in each of these fairness parameters.

of nodes equal to the number of features in the dataset. Its decision complexity, therefore, is equal to $100 \times F + 100$. Since the prediction relies on potentially thousands of matrix calculations, MLPs have very low simulatability and have neither global nor local interpretability.

4.4 Methodology

We compare the performance of *FairOCT* with the benchmark methods outlined in Section 4.2 on all three datasets: *COMPAS*, *German* and *Adult*. Where relevant and possible, we incorporate various fairness definitions in all our experiments. All datasets are tested on statistical parity, predictive equality, equal opportunity, and equalized odds, and *COMPAS* additionally considers conditional statistical parity (conditioned on the number of prior crimes). However, note that not all methods can accommodate all these notions. For instance, only our method can incorporate conditional statistical parity. On the other hand, *RegOCT* and *DADT* can only consider statistical parity. *DADT* additionally only takes in two sensitive levels while all the other methods are robust to more than two sensitive levels. Therefore, in our experiments on *COMPAS*, *DADT* only considers binary race – "Black" vs. "non-Black" – which yields results that are not fully comparable to other methods.

A full summary of our experiments for each method, including capabilities, ML models trained, and fairness parameters tested is provided in Table 2. We consider fairness parameters in increments of Δ and display results for all these values in order to fully observe the accuracy-discrimination trade-off. We use 75% of the data for training and 25% for testing on all three datasets outlined in Section 4.1 – split five times with different seeds to account for random variability – and evaluate model performance on the test set (i.e., out-of-sample or OOS set). The *Adult* dataset is both large and high-dimensional, so we train *FlowOCT* and *RegOCT* on 2,700 datapoints due to computational limitations (while evaluating on the same test set as other methods to allow for an equivalent comparison); we will further discuss this choice in Section 4.5. All experiments have a time limit of 3 hours, and utilized four Intel Xeon E5-2640 v4, 2.40GHz CPUs, each having 4GB of memory.

4.5 Results

Comparison of Fairness Methods. Figure 2 plots the accuracy and discrimination trade-off for all experiments outlined in Table 2. In general, *FairOCT* trained on all depths ($d = \{1, 2, 3\}$) obtain similar performances, though this is mainly attributed to the experiments on $d = 3$ not solving to optimality within the time limit. Trends vary across datasets; for instance, *FairOCT* found decisions with accuracies between $[0.55, 0.68]$ with disparities between $[0, 0.25]$ for *COMPAS*. In contrast, its results for *Adult* varied only by at most 5 percentage points (p.p.) in accuracy and 10 p.p. in disparity. Nonetheless, *FairOCT* learns a range of heterogeneous performances, which allows us to choose between various accuracy-discrimination trade-offs.

Overall, for any given disparity threshold, *FairOCT* consistently outperforms *DADT* within the notion of statistical parity (recall that *DADT* is only trained on this notion). This is expected since *FairOCT* finds an optimal solution whereas *DADT* relies on a heuristic. A

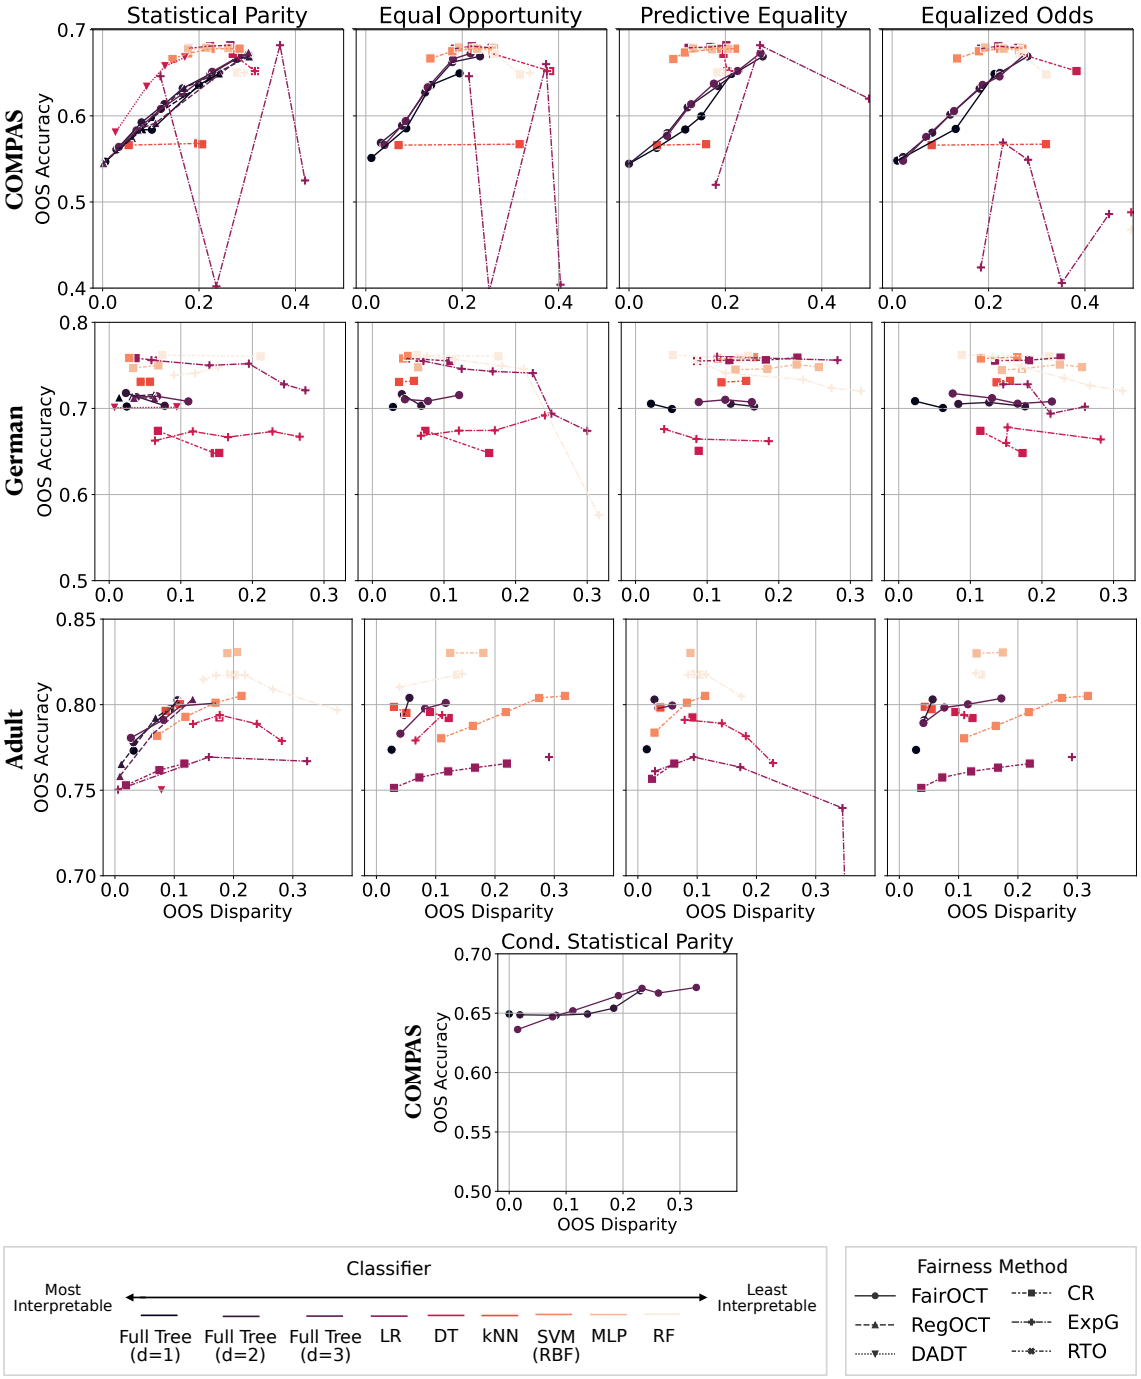

Figure 2: Accuracy and discrimination of *FairOCT* on the *COMPAS* (top), *Adult* (middle), and *German* (bottom) datasets with varying fairness metrics (from left to right – statistical parity equal opportunity, predictive equality, and equalized odds, and at the bottom, conditional statistical parity), averaged for each fairness parameter over 5 random samples. Each datapoint in the graph corresponds to an average over 0.05 increments of disparity (i.e., for every method and model, each datapoint is averaged from [0, 0.05), [0.05, 0.1), and so on). Classifiers are ordered from darkest (most interpretable) to lightest (least interpretable) according to our interpretability desiderata outlined in Table 1. Different fairness methods are outlined by different marker and line styles. For ease of visualization, we average the results for *DADT* with trees of maximum depth 2 and 3.

notable aberration is *DADT*'s superior performance to *FairOCT* on *COMPAS*, but this is because *DADT* only considers two levels of race while all other experiments have four levels. Even when only considering two levels of race, *DADT* does not result in significant improvements in performance. Refer to Appendix Section A for a comparison of *FairOCT* and *DADT* within the same learning setting, which shows that *FairOCT* consistently outperforms *DADT*.

In contrast, the other tree-based benchmark method – *RegOCT* – performs at around the same level as *FairOCT* (again only on statistical parity because *RegOCT* only considers this notion). This result is unsurprising given that *RegOCT* similarly learns optimal trees, so its performance will be as good as *FairOCT*, which already finds the best-performing partition for a fixed maximum depth. However, we emphasize that *RegOCT* is much less flexible in considering other notions of fairness. Moreover, *FairOCT* benefits from a stronger formulation and is faster by at least an order-of-magnitude. Refer to Appendix Table 3 for a full comparison of computational times.

With regard to non-tree-based methods, *CR* in general yields smooth and heterogeneous results throughout the disparity axis. We observe the same trend for *ExpG*, with the exception of the *COMPAS* dataset, whose performance jumps widely. [1] mentioned that as the number of sensitive levels (and therefore the number of constraints) increase, *ExpG* is not recommended because the search space grows exponentially. This limitation may be circumvented by testing an arbitrarily large number of fairness parameters and ignoring several outliers to smooth the curve. Note also that most of the parameters tested led to a disparity level of 1.0 or near 1.0, but we decided to truncate the results to a more reasonable level for all datasets. Finally, *RTO* is mainly missing from Figure 2 because we cannot tune any fairness parameters – resulting in a single datapoint, none of which is displayed because the performance hovers at around 0.6-0.9 disparity.

In comparison, *FairOCT* consistently finds results in the lower end of the disparity axis (which is the space we care most given the task of promoting full parity). For instance, in the *COMPAS* dataset on all the fairness notions, *FairOCT* resulted in disparities ranging from 0 to 0.3 – no other method boasts this range. Even in the *Adult* and *German* datasets where that range is attenuated, no other fairness-promoting method consistently finds datapoints with low disparity (i.e., < 0.05). This result likely arises from our method taking in a hyperparemeter δ that upper bounds resulting disparity. The optimization problem is then forced to find the highest-accuracy decision rule given a (potentially low) tolerance on disparity. This is in contrast to all other methods; RegOCT uses a regularization term, CR tunes the extent of correlation removed, and ExpG passes numerous values of λ, all of which do not guarantee certain disparity results.

Finally, we note that the *FairOCT* results trained on the 2,700 datapoints of *Adult* have comparable performances with other baseline methods, indicating that while optimization-based methods like *FairOCT* may run into computational problems, training on a smaller, representative dataset yields predictions that generalize very well to the entire population. In the bottom graph of Figure 2, we also conduct experiments where *FairOCT* considers conditional statistical parity on *COMPAS*; no other method we compare to can equivalently compare this fairness notion, highlighting our approach's flexible modeling power.

The Price of Interpretability. As expected, more interpretable models like full trees perform (marginally) worse than more complex models like random forests and MLP's. This difference denotes the price of interpretability. For instance, in the *German* dataset, a random forest trained on *CR* has on average 6 percentage points higher accuracy than a full tree of depth 2 trained on *FairOCT*, across all discrimination thresholds. However, as mentioned previously, many fairness-promoting methods fail to reach full or near perfect parity in contrast to FairOCT, rendering this aggregated comparison less meaningful. Notably, in the *COMPAS* dataset, a neural net trained on CR might perform on average 3 percentage points better than a *FairOCT* ($d = 2$), but only within the disparity ranges for which both methods have results. We must further consider the other datapoints *FairOCT* ($d = 2$) yields for disparities less than 0.15, of which have no equivalent comparison with the neural net. Nonetheless, given a fixed disparity threshold, the best performing complex model performs on average 4.2 p.p. better in terms of OOS accuracy than *FairOCT* over the range of disparities for which both models have results.

5 CONCLUSION

In this work, we presented an MIO formulation for learning optimal classification trees that can be modeled to consider a variety of algorithmic fairness notions. We also propose a new measure of interpretability named *decision complexity* in order to compare our interpretable method with other classes of models. In doing so, we conduct one of the first experiments that analyze in-depth the trade-offs between interpretability, fairness, and predictive accuracy.

Our experiments show that while we observe a (often small) price of interpretability with trees of shallow depth, one must ultimately consider not only the trade-offs between interpretability, accuracy, and discrimination, but also the various fairness-promoting methods that may yield vastly different results (e.g., with regard to the range of disparities found, how different methods might be better for certain constraints, etc.). In reality, decision makers face the incredibly hard task of balancing these trade-offs given the application at hand. Our work attempts to enrich these considerations in the hopes of guiding practitioners when they make these difficult decisions.

ABSTRACT

Machine learning systems produce biased results towards certain demographic groups, known as the fairness problem. Recent approaches to tackle this problem learn a latent code (i.e., representation) through disentangled representation learning and then discard the latent code dimensions correlated with sensitive attributes (e.g., gender). Nevertheless, these approaches may suffer from incomplete disentanglement and overlook proxy attributes (proxies for sensitive attributes) when processing real-world data, especially for unstructured data, causing performance degradation in fairness and loss of useful information for downstream tasks. In this paper, we propose a novel fairness framework that performs debiasing with regard to both sensitive attributes and proxy attributes, which boosts the prediction performance of downstream task models without complete disentanglement. The main idea is to, first, leverage gradient-based explanation to find two model focuses, 1) one focus for predicting sensitive attributes and 2) the other focus for predicting downstream task labels, and second, use them to perturb the latent code that guides the training of downstream task models towards fairness and utility goals. We show empirically that our framework works with both disentangled and non-disentangled representation learning methods and achieves better fairness-accuracy trade-off on unstructured and structured datasets than previous state-of-the-art approaches.

1 INTRODUCTION

Machine learning systems are reported to generate preferential predictions for some demographic groups and prejudiced predictions for others in many high-stake fields, such as loan offers, exam grading, school admission, and parole approval [1, 6, 21, 29]. This is known as the fairness problem in machine learning. Such fairness problems may cause long-term and high impacts on the life of vulnerable groups [5].

To tackle the fairness problem, early studies use adversarial training and regularization to force the model not to pay attention to sensitive information during training [8, 12, 25, 33, 35, 36]. And other works focus on learning fair (debiased) representations for downstream tasks [15, 16, 19, 24, 31, 34]. These methods usually specify the task attributes or the sensitive attributes before training, resulting in inflexibility [3].

To increase flexibility, the up-to-date approaches are to leverage disentangled representation learning methods to learn the disentangled latent code in which every dimension only contains one factor of variation and is optimized to be independent of each other [2, 3, 11, 13], and then remove the dimensions correlated with sensitive attributes before using the code to train downstream task models [3, 24].

However, because it is extremely difficult to enumerate all the factors of variation in real-world data [20], the number of the latent code dimensions is usually smaller than the real number of factors of variation. This results in incomplete disentanglement in the latent code, which poses two major challenges when we process real-world data, in particular, unstructured data such as images, with debiasing methods based on disentangled representation learning.

- First, it is challenging to avoid information loss for downstream tasks during the debiasing process. Since the latent code is usually incompletely disentangled, critical information for downstream tasks can be lost when we remove the

dimensions correlated with sensitive attributes from the latent code, causing degradation in prediction accuracy.
- Second, it is challenging to cover all sensitive information in proxy attributes[1] (proxies for sensitive attributes) while debiasing downstream task models. Because of incomplete disentanglement in the latent code, sensitive information encoded in proxy attributes may not exist only in those removed dimensions but also in the remaining dimensions. This results in fairness degradation of downstream task models.

In this work, we aim to address the aforementioned two challenges by exploring methods that do not rely on complete disentanglement and can better cover sensitive information. To this end, we propose a novel fairness framework named DVGE (**D**ebiasing **v**ia **G**radient-based **E**xplanation), as depicted in Figure 1. Specifically, to address the first challenge, DVGE does not remove latent code dimensions, which causes problems in locating sensitive information and debiasing downstream task models. To locate sensitive information and simultaneously address the second challenge, we exploit gradient-based explanations to highlight the importance of each latent code dimension when a model predicts sensitive attributes using the latent code. To debias downstream task models, we propose to perturb the latent code with the model focuses derived from gradient-based explanations. Overall, our main idea is to exploit gradient-based explanation to 1) obtain the model focus for predicting sensitive attributes, which we refer to as sensitive focus, and 2) obtain the model focus for predicting downstream task attributes, which we refer to as downstream task focus, and 3) use the two focuses to guide the training of downstream task models. Specifically, we propose *bidirectional perturbation* which uses the downstream task focus to positively perturb the latent code so that models pay more attention to downstream task information, and uses the sensitive focus to reversely perturb the latent code so that models pay less attention to sensitive information.

Compared with methods based on adversarial training, DVGE is more flexible, because it separates encoding and debiasing, so that the encoder does not need retraining when sensitive attributes or downstream tasks are changed. DVGE is also less tricky to train, since it debiases via perturbation instead of adversary. Compared with methods based on disentangled representation learning, DVGE better covers sensitive information with XAI explanations and reduces useful information loss without removing latent code dimensions.

As for evaluation, we conduct extensive experiments to compare our framework with previous state-of-the-art approaches by considering disentangled and non-disentangled VAE-based representation learning methods, on both real-world unstructured dataset (CelebA [18]) and structured dataset (South German Credit [9]). We measure the extent of fairness with two standard metrics, demographic parity (DP) [7, 32] and equal opportunity (EO) [10], against model accuracy. The results show that DVGE achieves better fairness-accuracy trade-off than the state-of-the-art approaches.

Our contributions are summarized as follows.

- We propose a novel fairness framework DVGE, to address the problem of the loss of useful downstream task information and the problem of overlooking sensitive information from proxy attributes, when debiasing models with incompletely disentangled latent code.
- We introduce to exploit gradient-based explanation to obtain model focuses related to sensitive information and downstream task information, and propose *bidirectional perturbation* to guide the model training for fairness purpose with the focuses.
- By extensive experiments, we show that our framework leads to better fairness-accuracy trade-off on both unstructured and structured real-world datasets compared to previous state-of-the-art approaches.

2 RELATED WORK

In this section, we review the works related to our paper, namely, debiasing methods in machine learning, variational autoencoders, and gradient-based explanations.

2.1 Debiasing Methods in Machine Learning

The methods for debiasing can be categorized as pre-processing methods, in-processing methods, and post-processing methods. Pre-processing methods aim for generating unbiased data for training by transforming the input data. Many recent pre-processing methods focused on learning discrimination-free encodings or embeddings for various tasks [3, 15, 24]. As for in-processing methods, they try to remove discrimination from models during training via objective functions, fairness constraints, or through adversarial training [8]. Furthermore, post-processing methods are proposed to audit predictions and may reassign labels with regard to fairness measurements after the training process [4]. Our proposed framework falls into the category of pre-processing methods.

2.2 Variational Autoencoders (VAEs)

VAEs are exploited to generate new unseen data that complies with the original distribution for generation tasks [23]. The main idea of VAEs is to learn a Gaussian distribution from training data and force the decoded data to have a similar distribution. Following the vanilla VAE [14], many variations of VAEs are proposed for different purposes, such as disentanglement [11, 13], recommendation [17], fairness [3, 24], etc. In this paper, we demonstrate that our fairness framework achieves better fairness-accuracy trade-off by considering both non-disentangled VAE (VanillaVAE [14]) and disentangled VAE (FactorVAE [13]).

2.3 Gradient-based Explanations

The gradient-based explanation methods are one of the primary approaches to explaining machine learning models, along with prototype-based methods, perturbation-based methods, etc. They produce local explanations for individual data points. The generated explanation (also known as saliency map or sensitivity map) by exploiting input-gradient highlights which parts in an input data point the model focuses on for making the prediction. Such an attempt is first made by Simonyan et al. [27]. Following their work, a

[1]For example, when the sensitive attribute is gender, corresponding proxy attributes can be hair length, beard, etc.

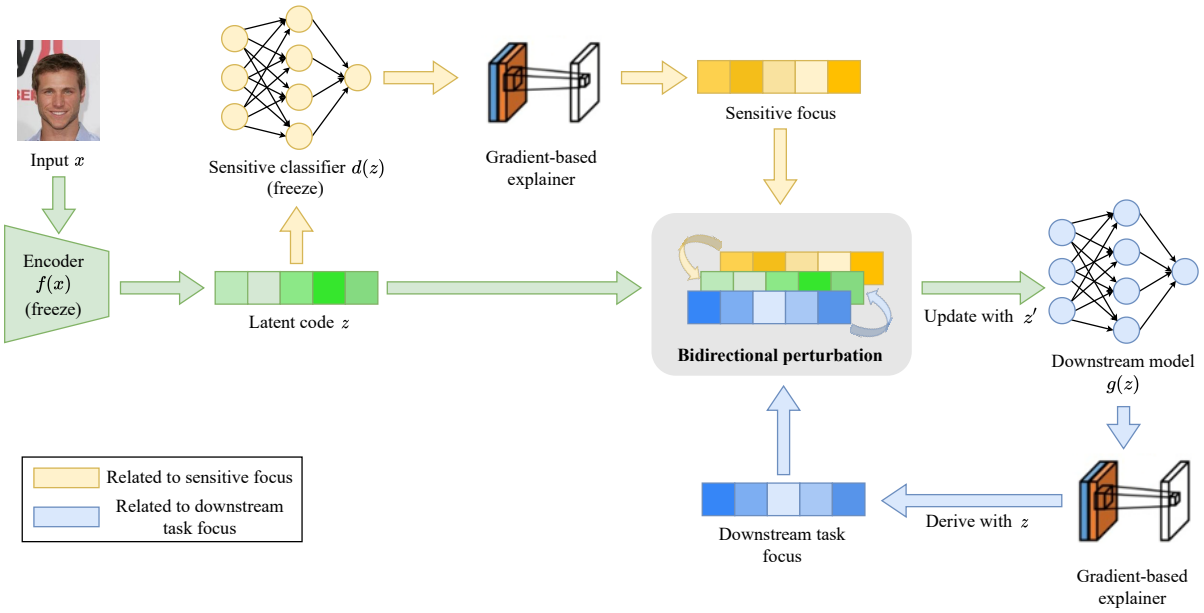

Figure 1: The overview of DVGE training procedure. First, the latent code z is generated with a trained VAE. Then, by feeding z to a trained sensitive classifier and the downstream task model being trained, the sensitive focus and the downstream task focus are derived from the gradient-based explanations on them. After the bidirectional perturbation perturbs z with the sensitive focus and the downstream task focus, the perturbed latent code z' is used to update the downstream task model.

number of variations are proposed, such as Grad-CAM [26], SmoothGrad [28], FullGrad [30]. In this work, we leverage gradient-based explanations to perturb the latent code for boosting the fairness and accuracy of downstream task models.

3 BACKGROUND

Here, we briefly introduce the background of two group fairness notions that we consider in this paper.

In this paper, we consider two commonly used group fairness notions, demographic parity (DP) [7, 32] and equal opportunity (EO) [10]. Let us first consider a simple example, in which we train a model $\hat{y} = g(x)$ to predict the label $y \in \{0, 1\}$, where $\hat{y}$ is the prediction, x denotes the input data, $s \in \{s_1, s_2\}$ denotes sensitive attributes in the input.

Demographic Parity. The definition of DP is that the model prediction is independent of sensitive attributes. In other words, the probability that a member of any subgroup (s_1 or s_2) receives the same prediction, 0 or 1 in our example, is completely the same. Based on the definition, the distance to demographic parity Δ_{DP} is used to measure how fair a model is as

$$\Delta_{DP} = |P(\hat{y} = 1|s = s_1) - P(\hat{y} = 1|s = s_2)|. \quad (1)$$

When $\Delta_{DP} = 0$, the demographic disparity is satisfied.

Equal Opportunity. Equal opportunity indicates that the true positive rate(TPR) of a model remains the same with respect to each subgroup. This is mathematically equivalent to that each subgroup has the same false negative rate (FNR). We can also use the distance to EO Δ_{EO} to measure the extent of fairness of a model as

$$\Delta_{EO} = |P(\hat{y} = 1|s = s_1, y = 1) - P(\hat{y} = 1|s = s_2, y = 1)| \quad (2)$$

or

$$\Delta_{EO} = |P(\hat{y} = 0|s = s_1, y = 1) - P(\hat{y} = 0|s = s_2, y = 1)|. \quad (3)$$

This definition underlines the idea that the qualified members of each subgroup should have the same probability to receive positive or negative predictions.

4 THE PROPOSED FAIRNESS FRAMEWORK

In this paper, we design a new fairness framework DVGE, as illustrated in Figure 1, by considering sensitive information from both sensitive attributes and proxy attributes. The framework does not depend on complete disentanglement. Instead, it leverages gradient-based explanation to obtain model focuses for predicting sensitive attributes and downstream task labels, and uses the proposed bidirectional perturbation to perturb the latent code for guiding the training of downstream task models.

4.1 Latent Code

As our work follows the idea of using representation learning to debias machine learning models with the flexibility to cope with different sensitive attributes and downstream tasks, we first train a VAE $f(x)$ to encode the input data x into latent code z by maximizing the Evidence Lower Bound (ELBO) [14]. The VAE used in DVGE is fixed after training. Our framework works with both disentangled and non-disentangled VAEs, which we show in the experiments.

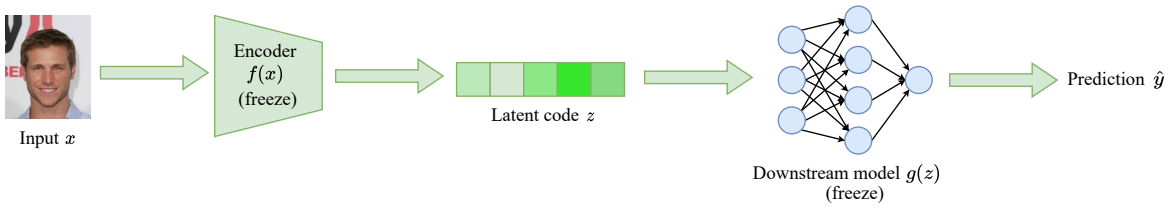

Figure 2: The overview of DVGE inference procedure. After training, DVGE does not perform bidirectional perturbation on the latent code during inference.

4.2 Sensitive Focus

Sensitive focus is the model focus for predicting sensitive attributes s with latent code z. We derive it using a gradient-based explanation, since this explanation is input-specific and assigns an importance score to each latent code dimension based on gradients, which can be easily used for perturbation. Given a trained sensitive classifier $d(z)$ which takes the latent code z as input to predict sensitive attributes s, the gradient-based explanation e_{sens} for its prediction is calculated as

$$e_{sens} = \psi(\nabla_z d(z) \odot z), \tag{4}$$

where $\psi(\cdot)$ is a post-processing operation for a gradient-based explanation, e.g., scale and taking the absolute value, $\nabla_z d(z)$ is the model gradient with regard to z, and $\odot$ denotes element-wise multiplication. As $\psi(\cdot)$ and $\odot$ are only for the visualization purpose of the explanation, the essence of the explanation is $\nabla_z d(z)$, we define the sensitive focus as

$$F_{sens} = \nabla_z d(z). \tag{5}$$

Please note that $\nabla_z d(z)$ is computed via backpropagation with the predicted sensitive attributes $\hat{s} = d(z)$. Thus, computing sensitive focus does not require access to real sensitive attributes.

Sensitive Information Coverage. Since the sensitive classifier $d(z)$ is trained to make use of every dimension of the latent code z to make predictions about sensitive attributes s, any sensitive information or shortcut information linking to s is exploited by it for the prediction. In addition, the gradient-based explanation can highlight all this information in **every dimension** of z, so the defined sensitive focus in our framework covers the sensitive information from both sensitive attributes and proxy attributes in the latent code.

Flexibility w.r.t. Changing Sensitive Attributes. As the sensitive focus is obtained via gradient-based explanation on sensitive classifier $d(z)$, when different sensitive attributes are required, we only need to change to a new $d(z)$ for predicting the new version of s, while reusing the latent code z.

4.3 Downstream Task Focus

The downstream task focus is the model focus for predicting downstream task label y with the latent code z. We obtain this focus directly from the gradient-based explanation of the downstream task model during its training process. Similar to Section 4.2, given a downstream task model $g(z)$ and the latent z, the gradient-based explanation of the model is calculated as

$$e_{task} = \psi(\nabla_z g(z) \odot z), \tag{6}$$

and we define the downstream task focus as

$$F_{task} = \nabla_z g(z). \tag{7}$$

The downstream task focus is for boosting the accuracy performance of the downstream task model while debiasing.

4.4 Bidirectional Perturbation

We perform bidirectional perturbation by perturbing the latent code z with the sensitive focus F_{sens} and the downstream task focus F_{task} to guide the training of the downstream task model for the purpose of fairness and prevention of downstream task accuracy degradation. The perturbed latent code z' is calculated as

$$\begin{aligned} z' &= z + Clip_\epsilon\{\eta_1 * F_{sens} - \eta_2 * F_{task}\} \\ &= z + Clip_\epsilon\{\eta_1 * \nabla_z d(z) - \eta_2 * \nabla_z g(z)\}, \end{aligned} \tag{8}$$

where η_1 and η_2 are the hyperparameters for controlling the intensity of debiasing and accuracy boosting, respectively, and

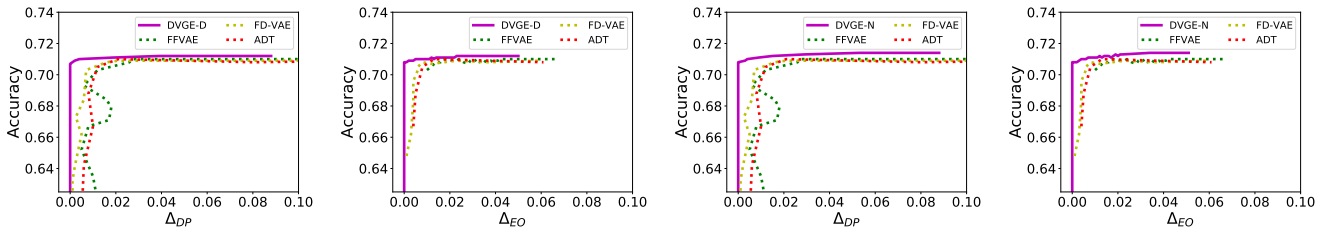
$$Clip_\epsilon\{v\} = \begin{cases} \epsilon, \text{ if } v > \epsilon, \\ max(v, -\epsilon), \text{ otherwise}, \end{cases} \tag{9}$$

where ϵ is non-negative and denotes the threshold for the distortion caused by bidirectional perturbation. $Clip_\epsilon\{\cdot\}$ is designed to prevent bidirectional perturbation introducing too much information distortion on latent code dimensions.

Rationale behind Bidirectional Perturbation. Since backpropagation gradients indicate the directions to optimize the objective function, in the equation 8, $+\nabla_z d(z)$ (sensitive focus) is for updating the latent code z in the reverse direction of optimizing sensitive information prediction, while $-\nabla_z g(z)$ (downstream task focus) is for updating z towards the direction of optimizing downstream task model, so that the downstream task model is guided to pay less attention to sensitive information and more attention to downstream task information. DVGE uses the perturbed latent code z' to update the downstream task model.

No Reliance on Complete Disentanglement. Even if the factors of variation for sensitive information are not fully disentangled (mixed with other factors of variation in the latent code dimensions), our framework still can debias the downstream task model, since the sensitive focus covers the sensitive information in *every dimension* of the latent code z, and our framework leverages the sensitive focus to perturb *every dimension* of z.

Inference. After finishing training the downstream task model with our framework, we do not perform the bidirectional perturbation on the latent code during inference as shown in Figure 2. The reason is that the model after training has learned to pay more



(a) DVGE-D, Δ_{DP} (b) DVGE-D, Δ_{EO} (c) DVGE-N, Δ_{DP} (d) DVGE-N, Δ_{EO}

Figure 3: Fairness-accuracy trade-off comparison results for Experiment 1: CelebA dataset, sensitive attribute = "Male", task label = "Oval_Face".

attention to downstream task information and less attention to sensitive information in the latent code.

5 EXPERIMENTS

We conduct extensive experiments to evaluate our framework while comparing it with previous state-of-the-art approaches. To show the flexibility of our framework, we consider different sensitive attributes individually and jointly on structured dataset and unstructured dataset. To demonstrate that our framework does not rely on complete disentanglement, we consider both non-disentangled and disentangled VAEs. Furthermore, we use an ablation study to demonstrate that our framework has better coverage on sensitive information.

5.1 Experiment Setups

5.1.1 DVGE-D and DVGE-N. To demonstrate that our framework does not rely on complete disentanglement to debias downstream task models, we implement DVGE with one disentangled VAE (FactorVAE [13]) and one non-disentangled VAE (VanillaVAE [14]), respectively. And we denote them as **DVGE-D** and **DVGE-N**. For more implementation details, please refer to Appendix B.

5.1.2 Baselines. We consider three state-of-the-art debiasing approaches as baselines in the experiments.

- Adversarial Training (ADT) [8]: The model based on ADT consists of three parts, i.e., feature encoder, sensitive branch, and downstream task branch. ADT debiases the model by updating the feature encoder with the reverse loss of the sensitive branch.
- FFVAE [3]: Based on previous disentangled representation learning methods, FFVAE tries to explicitly separate sensitive dimensions from non-sensitive dimensions in the latent code by learning the sensitive latent part with supervised learning.
- FD-VAE [24]: FD-VAE separates the latent code into three portions, i.e., sensitive dimensions, downstream-task-related dimensions, and mutual-information dimensions. FD-VAE trains the downstream task model using the latent code without sensitive dimensions while trying to exclude sensitive information from mutual-information dimensions with adversarial training.

Before training the encoder, ADT and FD-VAE require to specify the sensitive attributes and the downstream task attribute, while FFVAE requires to specify the sensitive attributes. In contrast, our framework does not require to specify either of them and has the highest flexibility. Since the debiasing process in our framework is not based on adversarial training, DVGE is more stable and easier to train than the baselines.

5.1.3 Datasets. In the experiments, we use two commonly used datasets. One is an unstructured dataset, which is CelebA[2] [18], while the other is a structured dataset, which is South German Credit[3] [9]. CelebA has 202,599 facial images, each of which is associated with 40 attributes, such as "Attractive", "Male", "Young". And all attributes are in binary form. As for the structured dataset, South German Credit has 1,000 entries with 21 attributes. The first 20 attributes are the information about the loan applicants (gender, age, income, etc.), and the last one is the loan application result. Since some attributes in South German Credit are in category form, we convert them into numerical form for convenience.

5.1.4 Metrics. In the experiments, we compare our framework with the baselines on the fairness-accuracy trade-off. Specifically, we consider two common fairness metrics, the distance to demographic parity Δ_{DP} and the distance to equal opportunity Δ_{EO} (refer to Section 3). We calculate the fairness metrics against the accuracy (Acc.) of the downstream task model, and plot the Pareto fronts of them to show the fairness-accuracy trade-off. **Better fairness-accuracy trade-off indicates higher accuracy with lower Δ_{DP} and Δ_{EO}.** In order to obtain the fairness-accuracy trade-off for our framework and the baselines, we sweep a range of the value combinations of hyperparameters in their objective functions.

5.2 Experiment Results on CelebA

On CelebA, we select three different combinations of sensitive attributes and downstream tasks for the experiments on the unstructured dataset. Because of the flexibility, DVGE uses the same latent code encoder for the following three different experiments.

5.2.1 Experiment 1. We choose "Male" as the sensitive attribute and set the downstream task to predict the label "Oval_Face". For this task, if we had a perfect classifier (100% accuracy), its Δ_{DP} would be 0.094, indicating almost no fairness problem in this task. When there is no fairness problem, the accuracy of the downstream

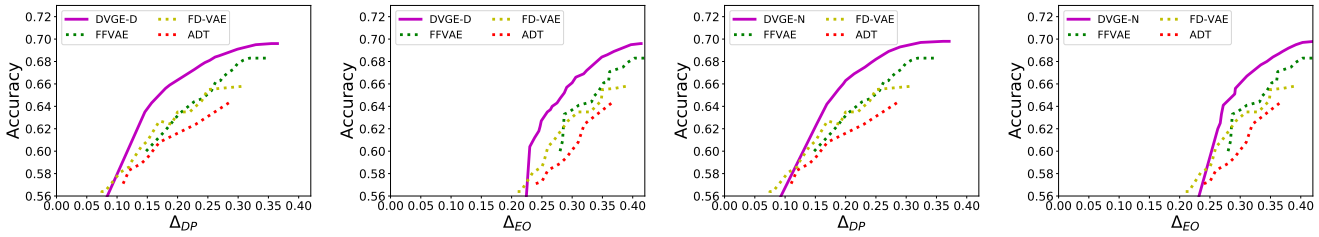
Figure 4: Fairness-accuracy trade-off comparison results for Experiment 2: CelebA dataset, sensitive attribute = "Male", task label = "Attractive".



(a) DVGE-D, Δ_{DP} (b) DVGE-D, Δ_{EO} (c) DVGE-N, Δ_{DP} (d) DVGE-N, Δ_{EO}

Figure 5: Fairness-accuracy trade-off comparison results for Experiment 3: CelebA dataset, sensitive attribute = "Male" ∧ "Young", task label = "Attractive".

task model should not vary with Δ_{DP} or Δ_{EO}. This experiment is designed to verify that DVGE has no negative impacts on tasks without fairness problems.

As we can observe in Figure 3, the accuracy of the downstream task model barely changes when Δ_{DP} or Δ_{EO} increases for our framework and the baselines. In addition, our framework can maintain the model accuracy even when Δ_{DP} and Δ_{EO} are very close to 0. We can also observe that our framework achieves slightly better accuracy than FFVAE and FD-VAE, because they remove dimensions of the latent code and suffers from incomplete disentanglement, resulting in information loss for downstream tasks.

5.2.2 Experiment 2. The sensitive attribute for this experiment is also "Male", but we change the task label to "Attractive". Δ_{DP} for a perfect classifier in this task would be 0.398, indicating a serious fairness problem. This experiment evaluates DVGE when debiasing in the setting of single sensitive attributes.

As we can see from the experiment results in Figure 4, our framework outperforms the baselines by a relatively large margin. For example in Figure 4(a), DVGE-D almost always achieves higher accuracy than the baselines when at the same Δ_{DP}. More importantly, our framework achieves similar fairness-accuracy trade-off with a non-disentangled VAE setting (DVGE-N in Figure 4(c) and 4(d)) as with disentangled VAE setting, which demonstrates that our framework does not rely on complete disentanglement for debiasing.

5.2.3 Experiment 3. In order to demonstrate the flexibility and superiority of our framework in the case of multiple sensitive attributes, we consider the conjunction of two sensitive attributes in this experiment. Specifically, the sensitive attributes are "Male" and "Young", denoted as "Male" ∧ "Young"[4], and the task is still to predict the label "Attractive". Here, we train a sensitive classifier to jointly distinguish the two sensitive attributes from the latent code. Δ_{DP} for a perfect classifier in this task would be 0.445, suggesting an even more serious fairness problem than those in previous tasks.

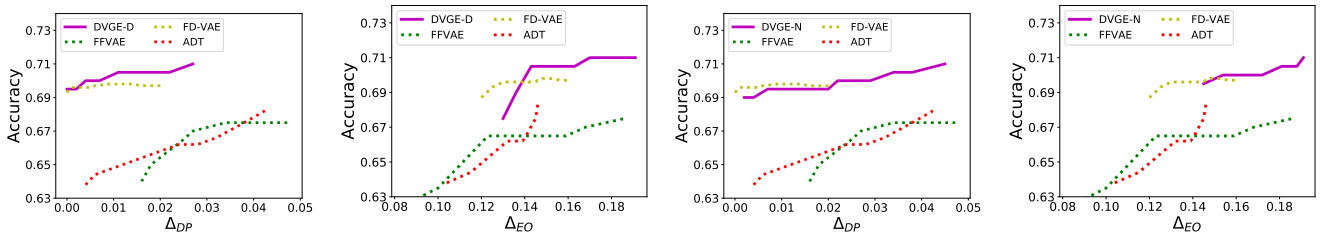
We depict the results for this experiment in Figure 5. As we can observe, our framework overall achieves better fairness-accuracy trade-off than the baselines. For example in Figure 5(b), when achieving the same Δ_{EO}, DVGE-D always hits higher downstream task accuracy than other baselines. Even when Δ_{DP} or Δ_{EO} moves close to 0, and the gaps of the fairness-accuracy trade-off between our framework and the baselines get smaller, our framework still outperforms or is on par with the baselines.

5.3 Experiment Results on South German Credit

On South German Credit, we choose two different combinations of sensitive attributes for the experiments on the structured dataset. DVGE uses the same latent code encoder for the following two different experiments.

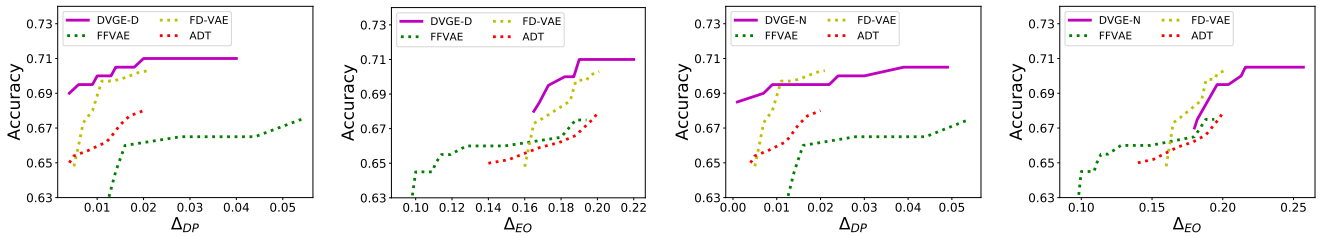
5.3.1 Experiment 4. We select "age" as the sensitive attribute and the downstream task is to predict the label of "credit_risk" in this experiment. Δ_{DP} of a perfect classifier in this task would be 0.188.

[4] ∧ represents logical *and*.



(a) DVGE-D, Δ_{DP} (b) DVGE-D, Δ_{EO} (c) DVGE-N, Δ_{DP} (d) DVGE-N, Δ_{EO}

Figure 6: Fairness-accuracy trade-off comparison results for Experiment 4: South German Credit dataset, sensitive attribute = "age", task label = "credit_risk".



(a) DVGE-D, Δ_{DP} (b) DVGE-D, Δ_{EO} (c) DVGE-N, Δ_{DP} (d) DVGE-N, Δ_{EO}

Figure 7: Fairness-accuracy trade-off comparison results for Experiment 5: South German Credit dataset, sensitive attribute = "age" ∧ "foreign_worker", task label = "credit_risk".

This experiment is designed for testing our framework when dealing with single sensitive attributes.

The experiment results are demonstrated in Figure 6. As we can observe, when the fairness metric is Δ_{DP}, both our framework and the baselines can largely reduce the unfairness of the downstream task model, but our framework achieves much higher accuracy than FFVAE and ADT. When we measure with Δ_{EO}, FFVAE and ADT achieve lower values of Δ_{EO}, but their downstream task accuracy is still lower than our framework. And our framework performs on par with or slightly better than FD-VAE.

5.3.2 Experiment 5. In this experiment, we evaluate our framework when debiasing in the setting of multiple sensitive attributes in structured dataset. We consider the conjunction of "age" and "foreign_worker" as sensitive attributes. The downstream task is still to predict the label of "credit_risk".

As we can observe in Figure 7, the Pareto fronts suggest similar experiment results as those in the setting of a single sensitive attribute in Section 5.3.1. When the extent of fairness is measured by Δ_{DP}, our framework outperforms the baselines by a large margin. When the extent of fairness is measured by Δ_{EO}, the fairness-accuracy trade-off of our framework is still comparable to that of the baselines.

5.4 Ablation

To further evaluate the coverage on sensitive information in our framework, we conduct ablation experiments on CelebA [18]. Specifically, we use the latent code perturbed by our framework to retrain sensitive classifiers. We vary the hyperparameter η_1 (sensitive focus) while setting $\eta_2 = 0$, and observe the highest accuracy that the retrained sensitive classifiers can achieve. Here, we use the highest accuracy of the retrained sensitive classifiers to indicate the coverage on sensitive information. The rationale of this measurement is that better coverage leads to less sensitive information in the perturbed latent code, and further the sensitive classifiers retrained with it are less accurate. **In turn, lower accuracy of the retrained sensitive classifiers indicates better coverage on sensitive information.** For comparison, we retrain sensitive classifiers using the latent code with sensitive dimensions removed [3] and the latent code without removal, respectively. The encoders we use here are a disentangled VAE (FactorVAE [13]) and a non-disentangled VAE (VanillaVAE [14]).

First, we consider a single sensitive attribute "Male". The ablation results are shown in Table 1. As we can observe, when η_1 increases for DVGE, the highest accuracy of the retrained sensitive classifier decreases accordingly. Furthermore, when η_1 increases to only 0.2, DVGE achieves better coverage on sensitive information than the approach based on removing sensitive dimensions. Second, we consider two sensitive attributes, "Male" and "Young". The results are in Table 2. As we can see, when η_1 increases to only 0.3, the highest accuracy of the retrained sensitive classifier with DVGE is lower than that with the approach based on removing sensitive dimensions. The ablation results demonstrate that the sensitive focus in DVGE effectively covers sensitive information.

Table 1: Debiasing performance of DVGE in the setting of single sensitive attribute

Non-disentangled	0.757	0.704	0.736	0.709	0.683	0.664	0.657	0.653	0.653	0.651	0.653	0.649

5.5 Discussions

First, from the experiments above, we can observe that DVGE overall achieves better fairness-accuracy trade-off than the baselines. Second, the ablation study shows that the sensitive focus in our framework effectively covers sensitive information in the latent code. Third, we can also observe that DVGE-D generally performs better than DVGE-N from all the experiments above.

6 CONCLUSION

In this paper, we targeted at the fairness problem in machine learning and followed the idea of using representation learning to tackle it. To overcome the problem of downstream task accuracy degradation and the problem of insufficient coverage on sensitive information, we proposed DVGE that exploits the gradient-based explanation to obtain the model focuses for respectively predicting sensitive attributes and downstream task labels, and perturbs the latent code with the focuses for the purposes of fairness and prevention of downstream task accuracy degradation. We experimentally demonstrated that our framework achieves better fairness-accuracy trade-off and better coverage on sensitive information while not relying on complete disentanglement for debiasing.

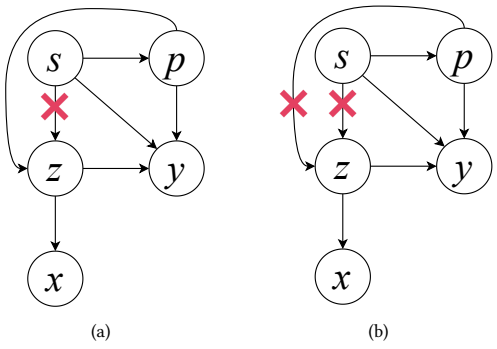

Figure 8: (a) Previous debiasing approaches using disentangled representation learning only break the link between the latent code z and sensitive attributes s in the structural causal model (SCM) when predicting downstream task attributes. (b) DVGE further breaks the link between the latent code z and proxy attributes p.

A PREVIOUS DEBIASING APPROACHES VIA REMOVING SENSITIVE DIMENSIONS USING DISENTANGLED REPRESENTATION LEARNING

Debiasing by exploiting disentangled representation learning was first proposed by Creager et al. in FFVAE [3] and also used by FD-VAE [24]. These approaches begin with training an encoder $f(x)$ and a decoder using disentangled representation learning methods. Then, the encoder is used to produce disentangled latent code $z = f(x)$. Next, the latent code dimensions corresponding to the sensitive attributes z_s (also known as sensitive dimensions) are determined by calculating the correlation between each dimension of z and the sensitive attributes s or pre-designation. At last, these approaches use the latent code without sensitive dimensions $z \backslash z_s$ to train downstream task models $\hat{y} = g(z \backslash z_s)$. During inference, these approaches also need to remove sensitive dimensions from the latent code before feeding the code to downstream task models. In contrast, our framework DVGE does not need to make changes to the latent code during inference.

To further elaborate on these previous approaches, we perform a causal analysis on them by illustrating the structural causality model (SCM) of downstream tasks in Figure 8(a). As we can observe, because of $s \rightarrow z$ and $p \rightarrow z$, when we exploit the latent code z to predict the label y, both sensitive attributes s and proxy attributes p (proxies for s) are considered as confounders that cause biased predictions. Since there is no guarantee of complete disentanglement from current disentangled representation learning on real-world data [22], when previous debiasing approaches remove the dimensions correlated with sensitive attributes, the sensitive information from proxy attributes and some information from sensitive attributes is overlooked. As a result, in Figure 8(a), the link $p \rightarrow z$ is not disconnected, still causing biased predictions. In our framework, we target at breaking both $s \rightarrow z$ and $p \rightarrow z$.

B IMPLEMENTATION DETAILS

The platform for all the experiments in this paper is an Ubuntu 20.04 system equipped with Nvidia V100 GPUs. The implementation is based on PyTorch.

There are basically three steps to implement DVGE. First, we train VAEs to produce the latent code. Then, we train a sensitive classifier with the latent code. Finally, we train the downstream task model with the latent code according to our framework.

B.1 For CelebA

We resize the CelebA [18] images to the size of 64×64. For a fair comparison, we implement the encoder of VAEs (VanillaVAE [14], FactorVAE [13], FFVAE [3], and FD-VAE [24]) and the feature encoder of ADT [8] with the same architecture. In terms of implementing VAEs, we follow Kim et al. [13] and Creager et al. [3] to use a CNN for the encoder, a Deconvolutional Neural Network for the decoder, and an MLP for the discriminator. The detailed structure information is shown in Table 3. To train VAEs, we set the learning rate to 10^{-4} and use Adam optimizer with $\beta_1 = 0.9$ and $\beta_1 = 0.999$. To train the discriminator, we set the learning rate to 10^{-5} and use the Adam optimizer with $\beta_1 = 0.5$ and $\beta_1 = 0.9$. The batch size is 64, and we update them for 10^6 times (about 316 epochs). The input images are encoded into the latent codes with 10 dimensions. In terms of FFVAE, we designate the last one or two dimensions as sensitive dimensions. For FD-VAE, we designate the first three dimensions as downstream-task-related dimensions, the middle four dimensions as mutual-information dimensions, and the last three as sensitive dimensions. As for the hyperparameters of FD-VAE, we set them as in [24], As for the hyperparameters of other VAEs (γ for FactorVAE, α and γ for FFVAE), we sweep their values from 1.0 to 6.4.

Sensitive classifiers, downstream task models, and branches of ADT share the same structure with the discriminator for VAEs as shown in Table 3. To train ADT, sensitive classifiers, and downstream task models, we set the learning rate to 10^{-5} and use Adam optimizer with $\beta_1 = 0.5$ and $\beta_1 = 0.9$. We train sensitive classifiers for 120 epochs, and downstream task models and ADT for 100 epochs. We sweep η_1 and η_2 from 0.1 to 2.0. And we set ϵ_i to $0.1 \times |z_i|$, where i is the index for the latent code dimensions.

B.2 For South German Credit

The values of some attributes in South German Credit [9] are continuous, while others are categorical. To balance the value ranges, we normalize the attributes whose values are continuous with the maximal value, and convert the categorical attributes into $[0, 1]$. In terms of implementing VAEs, we use MLPs for the encoder, the decoder, and the discriminator. The structure of the feature encoder of ADT is the same as that of VAE encoders. The detailed structure information for implementation is shown in Table 4. The training parameters for VAEs and the discriminator, and the latent code configurations are the same as in Appendix B.1.

For South German Credit, sensitive classifiers, downstream task models, and branches of ADT also share the same structure with the discriminator for VAEs as shown in Table 4. Their training parameters are also the same as in Appendix B.1.

B.3 Gradient-based Explanation

For getting gradient-based explanations from sensitive classifiers and downstream task models, we follow Srinivas et al. [30] use predictions on the input to compute the loss for backpropagation, instead of the ground truth labels.

C MORE ON DEBIASING ABLATION

To further specifically evaluate how the sensitive focus influences the coverage on sensitive information in our framework, we design more ablation experiments on CelebA which are different from those in Section 5.4.

In these experiments, we do not retrain sensitive classifiers, but instead directly test the accuracy of the sensitive classifiers which achieve the best accuracy before with the perturbed latent code by our framework. The perturbed latent code is generated with different configurations of the hyperparameter η_1 but without being perturbed by downstream task focus ($\eta_2 = 0$). Then we observe the accuracy that the sensitive classifiers can achieve. Here, we use the accuracy of the sensitive classifiers to indicate the coverage on sensitive information. The lower the accuracy is, the better the coverage on sensitive information is. To compare with our framework, we also test sensitive classifiers with the modified latent code by the existing approach and the latent code without modifications, respectively. The VAEs used in these experiments are a disentangled VAE (FactorVAE) and a non-disentangled VAE (VanillaVAE).

First, we test with the setting of a single sensitive attribute which is set to "Male". The experiment results are demonstrated in Table 5. As we can observe, when we increase η_1 from 0.1 to 1.0, the accuracy of the sensitive classifier decreases from 0.772 to 0.458 for disentangled VAE, and from 0.770 to 0.447 for non-disentangled VAE, which suggests that the sensitive focus in our framework effectively covers the sensitive information with the setting of single sensitive attributes. In addition, when η_1 increases to only 0.2, our

framework achieves comparable coverage on sensitive information with the approach based on removing sensitive dimensions. Second, we test with the setting of two sensitive attributes, which are set to "Male" and "Young". The ablation results are shown in Table 6. As we can see, the results are similar to those in Table 5. With η_1 increasing from 0.1 to 1.0, the accuracy of the sensitive classifier decreases accordingly for both disentangled VAE and non-disentangled VAE. And when η_1 is equal to or greater than 0.3, our framework outperforms the approach based on removing sensitive dimensions on the coverage on sensitive information. These results demonstrate that our framework has a good coverage on sensitive information with the setting of multiple sensitive attributes.

Sampling Individually-Fair Rankings that are *Always* Group Fair

ABSTRACT

Rankings on online platforms help their end-users find the relevant information—people, news, media, and products—quickly. Fair ranking tasks, which ask to rank a set of items to maximize utility subject to satisfying group-fairness constraints, have gained significant interest in the Algorithmic Fairness, Information Retrieval, and Machine Learning literature. Recent works, however, identify uncertainty in the utilities of items as a primary cause of unfairness and propose introducing randomness in the output. This randomness is carefully chosen to guarantee an adequate representation of each item (while accounting for the uncertainty). However, due to this randomness, the output rankings may violate group fairness constraints. We give an efficient algorithm that samples rankings from an individually-fair distribution while ensuring that *every* output ranking is group fair. The expected utility of the output ranking is at least α times the utility of the optimal fair solution. Here, α depends on the utilities, position-discounts, and constraints—it approaches 1 as the range of utilities or the position-discounts shrinks, or when utilities satisfy distributional assumptions. Empirically, we observe that our algorithm achieves individual and group fairness and that Pareto dominates the state-of-the-art baselines.

1 INTRODUCTION

Rankings are ubiquitous on online platforms and have become a quintessential tool for users to find relevant information [7, 23, 42, 43, 50]. The core algorithmic problem in generating a ranking, given m items (denoting individuals, products, or web pages) is to select and order a subset of n items that are "most" relevant to the given query [7, 42, 43]. This is a fundamental problem in Information Retrieval and has been extensively studied in the Machine Learning literature [7, 42, 43].

Without any fairness considerations, rankings on online platforms have been observed to have skewed representations of certain demographic groups resulting in large-scale perpetuation and amplification of fairness-related harms [33, 50]. Skewed rankings can have adverse effects both at the group level–altering the end-users' perception of socially-salient groups [33] and polarizing their opinions [23, 48]–and at an individual level–leading to a denial of economic opportunities to individuals (in later positions) [30]. A reason for this is that the estimated relevance (or utilities) of items may be influenced by societal biases leading to skews affecting socially-salient, and often legally protected, groups such as women and people of color. Another reason for underrepresentation is that the utility estimates used to generate the ranking are bound to have some uncertainty, which leads to over-estimation or underestimation of utilities for different items–at an individual level.

A large body of work designs algorithms to generate rankings that ensure sufficient representation [8, 17, 27, 29, 47, 56, 57, 64–67] (also see the surveys [53, 54, 68, 69]). A significant fraction of these works focus on group-level representation and have considered several types of group fairness constraints [17, 27, 29, 47, 56, 57, 64–67]. Two popular ones are equal representation and proportional representation. In the case of two groups G_1 and G_2, equal representation with a parameter k requires that for every j (roughly) $\frac{k}{2}$ items from each group appear between the $(kj+1)$-th and the $(kj+k)$-th positions [29]. Here, for instance, k could denote the number of items on each "page" of the ranking or the number of items in a user's browser window. Proportional representation requires that, for every j, $k\frac{|G_\ell|}{m}$ items appear between the $(kj+1)$-th and the $(kj+k)$-th positions. Other constraints, that generalize equal representation and proportional representation, and notions of fairness from the perspective of other stakeholders (such as the end-user) have also been considered [53, 54, 68, 69] (also see Section 3). Broadly speaking, all of these works, given group fairness constraints, output a ranking that has the maximum relevance or *utility* subject to satisfying the specified constraints.

Ensuring group-wise representation, via such group fairness constraints, can address underrepresentation across groups of items but may not address harms at an individual level: Across multiple output rankings, specific items (e.g., whose utilities have high

*Both authors contributed equally.

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604671

uncertainty) may be systematically assigned lower positions. In other words, group fairness can mitigate under-representation at the group level but may not mitigate (or could even exacerbate) misrepresentation and denial of opportunities to individual items.

Example 1.1 (**Insufficiency of group-fairness constraints**). *As a concrete example consider an online hiring platform where recruiters search for relevant candidates and are presented with a ranked list of candidates; as is common in existing recruiting platforms [27]. Suppose that this platform ensures proportional representation across individuals with, say, different skin tones. Here, it can be shown that, to maximize the "utility," it is optimal to order individuals inside one group (those with the same skin tone) in decreasing order of their (estimated) utility. Consider two individuals i_1 and i_2 with the same skin tone and estimated utilities ρ and $\rho - \varepsilon$ (for some small constant $\varepsilon > 0$). Due to the difference in their utility, i_2 would always be ranked one or more positions below i_1. Since positions of individuals on recruiting platforms have been observed to affect their chances of being hired, i_2 has a systematically lower chance of being hired – even though there is little difference in their utility [30]. Moreover, this difference may be because of estimation errors that are bound to arise in any real-world setting and especially in the context of online recruiting where the utilities of individuals are inherently uncertain and even change over time.*

Motivated by such examples, recent work on fair ranking has proposed various ways to define and incorporate fairness – from the perspective of individuals – in rankings [8, 56, 58]. Since opportunity, exposure, or attention received by individuals is ultimately linked to positions in the ranked order, a single deterministic ranking cannot avoid denial of opportunity when ranking multiple items with similar relevance, and hence, individually-fair rankings are inevitably stochastic in nature [8, 56, 58]. To gain intuition, observe that in the earlier example, any deterministic ranking must place either i_1 before i_2 or i_2 before i_1, due to which the "exposure" received by the item placed earlier is systematically higher than the other item irrespective of how small the difference in their utilities (i.e., ε) is. While there are many notions of individual fairness with respect to items, their specification often boils down to specifying lower and/or upper bounds on the probability with which an individual or item must appear in a set of positions. For instance, an individual fairness constraint, specified by a matrix C, may require item i to appear between the $(kj+1)$-th and the $(kj+k)$-th position with probability at least C_{ij}. Where, as before, k could encode the number of items in one page of the ranking, in which case, the individual fairness constraint requires item i to appear on page j with at least a specified probability for every i and j. While this stochasticity guarantees that individuals with "similar" utilities (as in the above example) receive similar average exposure, due to their stochastic nature, specific output rankings may violate group fairness requirements (as we empirically verify in Section 5).

Given the importance of both individual and group fairness in ranking, we study a dual-task in fair ranking wherein addition to individual fairness, we want to ensure that every output ranking is group fair. It is important to note that stochastic rankings that incorporate group fairness guarantee *in expectation* may not output rankings that are *always* group fair. This is particularly concerning in high stake contexts (such as online recruiting) where it may be legally required to ensure group fairness for each output ranking. Thus, the following question arises: *Given the individual fairness constraints, the group fairness constraints, and item utilities, is there an algorithm that outputs samples rankings such that (1) individual fairness is satisfied, (2) each output ranking is group fair, and (2) the expected utility of the rankings is maximized?*

1.1 Our Contributions

We present an efficient approximation algorithm (Algorithm 1) for the above problem when the (socially salient) groups of items form a laminar set family (i.e., any two groups are either disjoint or related by containment) (Section 6). This algorithm works for a general family of individual and group fairness constraints, which includes the aforementioned constraints and their generalizations (Definitions 3.1 and 3.2). For any given individual and group fairness constraints from these families along with the utilities of all items, our algorithm outputs rankings sampled from a distribution such that the specified individual fairness are satisfied and each output ranking is group fair (Theorem 4.1). The rankings output by our algorithm have an expected utility that is at least α times the optimal utility, where α is a constant that depends on the utilities, position discounts, and group fairness constraints–it approaches 1 when the ranges of the utilities or of the position-discounts shrink (Equation (13)). In particular, for the aforementioned constraints specified by a parameter k, $\alpha \geq \frac{v_1+v_2+\cdots+v_k}{k \cdot v_1}$, where v_j is a position-discount for each position (Theorem 4.1). With the standard DCG-discounts and equal representation constraints for two groups (for which it suffices to have $k = 2$), this approximation guarantee becomes $\alpha \geq 0.81$ (see Section 4 for other common examples). Further, in addition to these utility-independent bounds, we also derive additional (stronger) bounds on α when the item's utilities are generated via certain generative models (Theorem 4.2).

Empirically, we evaluate our algorithm on synthetic and real-world data against standard group fairness metrics (such as equal representation) and the individual fairness constraints proposed by Singh et al. [58]. We compare the performance of our algorithm to key baselines [17, 56] with both two and multiple protected groups. Unlike baselines, in all simulations, our algorithm outputs rankings that always satisfy the specified individual fairness constraint and group fairness constraint; at a small cost to utility (a maximum of 6% loss compared to the baselines) (Figures 1 and 5 in Section 5 and Appendix D respectively).

To the best of our knowledge, there is no previously known algorithm that takes a stochastic fair ranking satisfying fairness constraints *in expectation* and rounds it to output rankings that are *always* group fair without much loss in the ranking utility. A key technical challenge in doing so is that the Birkhoff-von Neumann rounding of stochastic fair rankings (as used in Singh et al. [58]) can violate group fairness constraints significantly. Overcoming this challenge requires a generalization of the Birkhoff-von Neumann rounding from the polytope of all rankings (that has only integral vertices) to the polytope of group-fair rankings (that can have fractional vertices). Stochastic rankings that satisfy group-wise representation constraints in the top-k positions *in expectation*, typically have a standard deviation of about $\sqrt{k}$ (e.g., Theorem

4.1 by Mehrotra and Vishnoi [46]).[1] As k is small in practice (e.g., $k \approx 10$ on LinkedIn), a deviation of $\sqrt{k}$ in group-wise representation is impractical.

2 RELATED WORK

Relevance estimation for ranking. There is a huge body of work studying relevance estimation for automated information retrieval [19, 41] (also see Manning et al. [43] and the references therein). This body of works develops methods to estimate the relevance (or utility) of items to specific queries in a variety of contexts (from web search [5], personalized feeds [32], to e-commerce [20]) and modalities (from web pages [37], images and videos [7], to products [20]). In the last three decades, the Machine Learning literature has also made significant contributions to this body of works [42] – by supplementing traditional IR methods (by, e.g., auto-tuning hard-to-tune parameters) [60], increasing the efficiency of IR methods (via clustering-based techniques) [2, 59], and proposing novel neural-network-based methods to predict item relevance [7, 10, 11, 63]. That said, despite the numerous methods for relevance estimation, the relevance values output by any method is bound to have some uncertainty and have also been observed to propagate societal biases in their inputs [27, 33].

Fair ranking. Below we summarize previous work on group fair and individually-fair rankings, various approaches to formulate and solve these problems, and their relation to our work. For a comprehensive survey of these topics, we refer the reader to [12, 53, 54, 68, 69].

Group fair ranking. There is a long line of work on group fair rankings that can be divided into two broad categories: (1) those that incorporate group fairness in learning-to-rank (LTR) algorithms [47, 57, 65–67] and (2) (re-)ranking algorithms that modify a given output ranking to satisfy group fairness constraints [8, 17, 27, 29, 56, 64]. Furthermore, there are diverse approaches within each of the above categories. The group fair LTR works can be further subdivided as algorithms that (a) post-process the estimated utilities to ensure group fairness [65], (b) add group fairness penalty in the LTR objective for training [47, 57, 67], and (c) modify feature representation learned by up-stream systems so that the utilities learned from the modified representation satisfy group fairness [66]. The group-fair re-ranking works can be further subdivided based on whether they guarantee that (a) *each* output ranking satisfies group fairness constraints [17, 27, 29, 64] or (b) the group fairness constraints are satisfied *in aggregate* over multiple rankings [8, 56]. As highlighted before, rankings output by these works may lead to adverse effects on individuals due to uncertainties in utilities.

Individually fair ranking. There are a number of notions of individual fairness in ranking. For instance, Biega et al. [8] define "equity of attention" as requiring that the cumulative attention garnered by an item across multiple rankings (corresponding to same or different queries) be proportional to its average relevance (across the corresponding queries). Biega et al. [8] propose an online algorithm to minimize the aggregate unfairness between attention and relevance for all items, amortized over multiple rankings, while maintaining the ranking utility (e.g., NDCG@k) above a given threshold; while they consider a notion of individual fairness, they do not consider group fairness. Other notions include fairness of exposure [56] and "merit-based" fairness–we discuss these below [58].

Ranking under both individual and group fairness constraints. Some of the aforementioned works offer frameworks that can be adapted to incorporate both individual and group fairness constraints [56–58]. Singh and Joachims [56] define fairness of exposure in stochastic rankings, which can be applied at both individual and group levels. They solve a linear programming relaxation over stochastic rankings to maximize the expected ranking utility subject to the fairness of exposure *in expectation* [56]. This approach gets around the exponential search space of deterministic rankings (or permutations), and their final output is the Birkhoff-von Neumann rounding of the above stochastic ranking. Singh et al. [58] define a notion of "merit-based" fairness when the merits (or utilities) are random variables. They take a similar linear-programming approach as Singh and Joachims [56] to formulate the fairness constraints and use the Birkhoff-von Neumann rounding to generate the output rankings. However, unlike this work, these works either do not guarantee that the output rankings satisfy the fairness constraints or they use randomization and only guarantee that the output rankings satisfy group fairness constraints in aggregate (not *always*).

Some recent works step away from the paradigm of utility maximization to incorporate individual fairness and group fairness constraints [25, 26, 29]. García-Soriano and Bonchi [26] propose a polynomial time (re-)ranking algorithm to maximize the utility of the worst-off individual subject to group fairness constraints. They also show that probabilistic rankings give better max-min fairness than deterministic rankings. Gorantla et al. [29] define individual fairness in terms of the worst-case "underranking" of any item compared to its true or deserved rank, and give efficient (re-)ranking algorithms for given group fairness and underranking constraints simultaneously. In the special case of selection, where items only have to be selected and their order is not relevant, [25] select subsets maximizing a specified individual-fairness metric subject to satisfying group-fairness constraints. Unlike these works, we require the output ranking to maximize the utility subject to satisfying the specified (group and individual) fairness constraints. Beyond ranking and selection, there are also works that incorporate fairness constraints in matching problems (where multiple items can be matched to one position) [6, 18, 21]. Among these Benabbou et al. [6] consider block-wise group-fairness constraints that are similar to the block-wise group fairness constraints we consider (Definition 3.1) and design $\frac{1}{2}$-approximation algorithm for the resulting constrained matching task. However, unlike our work, Benabbou et al. [6] do not consider individual fairness constraints and our algorithm provides better than $\frac{1}{2}$-approximation guarantee for common utility models (such as discounted cumulative gain [31]) and block sizes.

Fair decision-making with inaccuracies and uncertainty in inputs. A growing number of works develop fair algorithms for

[1] Concretely, consider a ranking R sampled from some distribution such that R satisfies the equal representation constraints in expectation for two groups. The best guarantee provided by state-of-the-art fair ranking algorithms that sample a ranking [46] is that, with high probability, the output R places at most $\frac{k}{2} + O(\sqrt{k})$ items from each group in the top-k positions–thereby violating the constraint by up to an additive factor of $O(\sqrt{k})$.

decision-making that are robust to uncertainties and inaccuracies in their inputs [4, 13, 16, 21, 24, 39, 44, 46, 49, 52, 61, 62]. Many of these works consider inaccuracies in protected attributes in decision-making tasks including ranking but extending beyond to subset selection, clustering, and classification [4, 13, 16, 24, 39, 44, 46, 49, 62]. A few recent works also consider uncertainty in other parts of the input [21, 52, 61]. Among these, most relevant to our work, Devic et al. [21] and Panda et al. [52] study variants of the matching problem with uncertainty in utilities of items: Devic et al. [21] adapt Singh et al. [58]'s notion of merit-based fairness to the matching task. Panda et al. [52] consider both individual fairness and group fairness constraints, where the individual fairness constraints can capture the merit-based notion of Devic et al. [21]. Panda et al. [52] give an algorithm that samples a matching that satisfies the individual fairness constraints and satisfies the group fairness constraint (always). Interestingly, despite the differences between the ranking and the matching problem, we show a connection between our approach and a technical result in [52] (see Section 6).

3 PRELIMINARIES AND MODEL

Ranking problem. In ranking problems, given m items, the task is to select a subset S of n of these items and output the permutation of S that is most valuable for the user. This permutation is called a *ranking*. We consider a variant of the problem where the values or *utilities* of the items are known. There is a vast literature on estimating item utilities (for specific queries) [5, 20, 32, 42, 43] (see Section 2). Abstracting this, we assume that for each item i there is a utility $\rho_i \geq 0$ and for each position j there is a discount factor $v_j > 0$ such that placing the item i at position j generates value $\rho_i \cdot v_j$. The utility of a ranking is the sum of utilities generated by each item in its assigned position. The position discounts encode the fact that users pay higher attention to items earlier in the ranking. Various values of position discounts have been considered in information retrieval literature. Perhaps the more prevalent one is discounted cumulative gain (DCG), which is specified by $v_j = (\log(1+j))^{-1}$ for each j [31]. Without loss of generality, we assume that item indices are ordered in non-increasing order of utilities, i.e., $\rho_1 \geq \rho_2 \geq \cdots \geq \rho_m$.

We denote a ranking by an assignment matrix $R \in \{0,1\}^{m \times n}$: $R_{ij} = 1$ if item i is placed in position j and $R_{ij} = 0$ otherwise. In this notation, the utility of a ranking R is

$$\rho^\top R v = \sum_{i=1}^{m} \sum_{j=1}^{n} \rho_i v_j R_{ij}.$$

This variant of the vanilla ranking problem asks to solve:

$$\max_{R \in \mathcal{R}} \rho^\top R v,$$

where $\mathcal{R}$ is the set of all assignment matrices denoting a ranking:

$$\mathcal{R} := \left\{ X \in \{0,1\}^{m \times n} : \forall_{i \in [m]},\ \sum_j X_{ij} \leq 1,\ \forall_{j \in [n]},\ \sum_i X_{ij} = 1 \right\} \quad (1)$$

Here, for each i, the constraint $\sum_j X_{ij} \leq 1$ encodes that item i is placed in at most one position. For each j, the constraint $\sum_i X_{ij} = 1$ encodes that there is exactly one item placed at position j.

Fairness constraints. Group fairness constraints are defined with respect to $p \geq 2$ socially-salient groups $G_1, G_2, \ldots, G_p$ (e.g., the group of all women or the groups of all Asian or all black individuals). For simplicity, we state our results when groups $G_1, \ldots, G_p$ are disjoint. In Section 6, we show that the same results hold when $G_1, \ldots, G_p$ belong to a general family of overlapping sets, the laminar set family (see Section 6). There are many forms of group fairness constraints for ranking. We consider a class of fairness constraints that are placed over disjoint blocks of positions $B_1, B_2, \ldots, B_q$. Blocks of positions can correspond to pages of search results or different windows in a scrollable feed. A basic example is where the $q = \frac{n}{k}$ blocks are disjoint sets of $1 \leq k \leq n$ consecutive positions. Note, however, in general blocks can have different sizes.

Definition 3.1 (**Group fairness constraints**; [29]). *Given matrices $L, U \in \mathbb{Z}^{q \times p}$ a ranking R satisfies the (L,U)-group fairness constraints if for each $j \in [q]$ and $\ell \in [p]$*

$$L_{j\ell} \leq \sum_{i \in G_\ell} \sum_{t \in B_j} R_{ij} \leq U_{j\ell}. \quad (2)$$

The above family of constraints can encapsulate a variety of group fairness notions. For instance, the equal representation constraint is captured by $L_{\ell j} = \left\lfloor \frac{|B_j|}{p} \right\rfloor$ and $U_{\ell j} = \left\lceil \frac{|B_j|}{p} \right\rceil$ for each ℓ and j. (For readability, we omit the floor and ceiling operators henceforth.) To capture the Four-Fifths rule, it suffices to choose any constraints such that $L_{\ell j} \geq \frac{4}{5} \cdot U_{tj}$ for each $\ell, t \in [p]$ and $j \in [q]$. Existing works study related families of constraints [54, 68, 69]. We specifically consider Definition 3.1 as its block structure enables us to design efficient algorithms. In Appendix C, we show that Definition 3.1 can ensure fairness with respect to the families of constraints from existing works [54, 68, 69], hence, it also captures the corresponding notions of group fairness.

That said, Definition 3.1 does not capture the adverse effects on specific items or individuals (henceforth, just items): highly-relevant items may get low visibility even though each protected group is sufficiently represented in every block (Example 1.1). To capture such underrepresentation, we consider the following family of individual fairness constraints.

Definition 3.2 (**Individual fairness constraints**). *Given $A, C \in [0,1]^{m \times q}$, a distribution $\mathcal{D}$ over the set $\mathcal{R}$ of all rankings satisfies (C,A)-individual fairness constraints if for each $i \in [m]$ and $j \in [q]$*

$$C_{ij} \leq \Pr_{R \sim \mathcal{D}} \left[R_{it} = 1 \text{ for some } t \in B_j \right] \leq A_{ij}. \quad (3)$$

By choosing C_{ij}, A_{ij}, one can lower and upper bound the probability that item i appears in the block B_j by a desired value. When item utilities are only probabilistically known, then a natural choice for the lower bounds is

$$C_{ij} = Z \cdot \Pr_{\mathcal{U}}[\exists t \in B_j,\ \rho_i \text{ is the } t\text{-th largest value in } \{\rho_1, \ldots, \rho_m\}]. \quad (4)$$

where $\mathcal{U}$ is the joint distribution of utilities (see the discussion in [58]) and Z is a normalization constant that ensures that $\sum_{j=1}^{m} C_{ij} = 1$ for all $1 \leq i \leq m$. Existing works have considered closely related families of individual fairness constraints and shown that those families capture many common notions of individual fairness [38, 58]. Like group fairness constraints in Definition 3.1, we consider the specific family in Definition 3.2 as it enables efficient algorithms. In Appendix C, we show that Definition 3.2 can ensure fairness with respect to the constraints studied in [38, 58], hence, can also capture most common notions of individual fairness.

In the special case where $\mathcal{D}$ is supported at just one ranking R, Definition 3.2 specializes to the following: A ranking R is (C,A)-individually fair if and only if the distribution supported on just R

is (C, A)-individually fair. Apart from very specific choices of the matrices C and A, no ranking R can be (C, A)-individually fair. For instance, this is true, whenever there is at least one j such that C_{ij} is positive for more than $|B_j|$ choices of $i \in [n]$. Thus, in general, some of the output rankings must violate the individual fairness constraint. This has been recognized in the fair ranking literature [8, 51, 54, 68, 69], and is one of the main reasons to consider randomized algorithms for ranking. In contrast, as mentioned in Section 1, it may be necessary (legally or otherwise) to ensure that each output ranking satisfies the group fairness constraints. Motivated by this, our goal is to solve the following problem.

Problem 3.3 (**Ranking problem with individual and group fairness constraints**). *Given matrices L, U, A, C and vectors ρ, v, find a distribution $\mathcal{D}^\star$ over rankings maximizing the expected utility $\Pr_{R\sim\mathcal{D}^\star}[\rho^\top Rv]$ subject to satisfying (i) (C, A)-individual fairness constraints and (ii) that each R in the support of $\mathcal{D}^\star$ satisfies (L, U)-group fairness constraints.*

A naive representation of $\mathcal{D}^\star$ is to specify $\Pr_{S\sim\mathcal{D}^\star}[S = R]$ for each ranking R. However, since the number of rankings is exponential in n and m (at least $n!$), even writing down this representation is intractable. Instead, like prior works [56, 58], we encode $\mathcal{D}^\star$ by the following nm marginal probabilities. Given a distribution $\mathcal{D}$, let $D \in [0,1]^{m\times n}$ encode the following marginals of $\mathcal{D}$:

$$D_{ij} := \Pr_{R\sim\mathcal{D}}[R_{ij} = 1].$$

In other words, in a ranking sampled from $\mathcal{D}$, item i appears in position j with probability D_{ij}.

3.1 Challenges in Solving Problem 3.3

We first discuss the approach of a prior work Singh and Joachims [56], Singh et al. [58] and then discuss why it is challenging to use a similar approach to solve Problem 3.3.

The approach of prior work. Singh et al. [58] study a version of Problem 3.3 where the blocks overlap and there are no group fairness constraints. Let $\widehat{\mathcal{D}}$ and $\widehat{D}$ be an optimal solution of their problem and its marginal respectively. Their algorithm has two parts: (1) solve Program (5) to compute $\widehat{D}$, (2) use the Birkhoff-von-Neumann (BvN) algorithm [9] to recover $\widehat{\mathcal{D}}$ from $\widehat{D}$.

$$\text{argmax}_{D\in[0,1]^{m\times n}} \quad \rho^\top Dv, \tag{5}$$

$$\text{s.t.,} \quad \forall i, \qquad C_{ij} \le \textstyle\sum_{t\in B_j} D_{it} \le A_{ij}, \tag{6}$$

$$\forall j, \qquad \textstyle\sum_i D_{ij} = 1 \quad \text{and} \quad \forall i,\ \sum_j D_{ij} \le 1. \tag{7}$$

Consider any distribution $\mathcal{D}$ and its marginal D, it can be shown that the objective $\rho^\top Dv$ is equal to expected utility of $\mathcal{D}$, i.e., $\rho^\top Dv = \Pr_{R\sim\mathcal{D}}[\rho^\top Rv]$, and that D is feasible for Program (5) if and only if $\mathcal{D}$ is (C, A)-individually fair. Using these, one can show that $\widehat{D}$ is an optimal solution of Program (5).

Since Program (5) is a linear program with $\text{poly}(n, m)$ variables and constraints, it can be solved in polynomial time to get $\widehat{D}$. $\widehat{\mathcal{D}}$ can be recovered from $\widehat{D}$ using the BvN algorithm: Given $\widehat{D}$, the BvN algorithm outputs at most nm rankings $R_1, \ldots, R_{nm}$ and corresponding coefficients $\alpha_1, \ldots, \alpha_{nm}$ such that $\widehat{\mathcal{D}}$ is the distribution that samples ranking R_i with probability α_i for each $1 \le i \le nm$.

Challenges in solving Problem 3.3. Let $\mathcal{R}_{\text{GF}}$ be the set of all rankings that satisfy the (L, U)-group fairness constraints. Unlike Singh et al. [58], we require the output distribution $\mathcal{D}$ to be supported over $\mathcal{R}_{\text{GF}}$. In other words, each R sampled from $\mathcal{D}$ should satisfy the (L, U)-group fairness constraints. An obvious approach to solve Problem 3.3 is to add "group fairness constraints" to Program (5) (to get Program (8)) and generalize [58]'s algorithm as follows:

(1) Find a solution $\widetilde{D} \in [0,1]^{m\times n}$ of Program (8)
(2) Given $\widetilde{D}$, output a distribution $\widetilde{\mathcal{D}}$ such that $\widetilde{D}$ is $\widetilde{\mathcal{D}}$'s marginal and each R sampled from $\widetilde{\mathcal{D}}$ is in $\mathcal{R}_{\text{GF}}$, i.e., $\Pr_{R\sim\widetilde{\mathcal{D}}}[R\in\mathcal{R}_{\text{GF}}]=1$

$$\text{argmax}_{D\in[0,1]^{m\times n}} \quad \rho^\top Dv, \tag{8}$$

$$\text{s.t.,} \qquad D \text{ satisfies Equations}(6)\textit{and}(7), \tag{9}$$

$$\forall j \in [q],\ \forall \ell \in [p],\ \ L_{j\ell} \le \textstyle\sum_{i\in G_\ell} \sum_{t\in B_j} D_{ij} \le U_{j\ell}. \tag{10}$$

Unfortunately, in general, the marginal of $\mathcal{D}^\star$, say $D^\star$, is not a solution of Program (8), hence, in general, the output distribution $\widetilde{\mathcal{D}}$ is different from the solution $\mathcal{D}^\star$. In fact, it is possible that there is no distribution $\widetilde{\mathcal{D}}$ supported over $\mathcal{R}_{\text{GF}}$ such that $\widetilde{D}$ is the marginal of $\widetilde{\mathcal{D}}$–making it impossible to implement Step 2. One can explore different relaxations of Step 2. A relaxation is to output $\widetilde{\mathcal{D}}$ that maximizes $\Pr_{R\sim\widetilde{\mathcal{D}}}[R \in \mathcal{R}_{\text{GF}}] = 1$ subject to ensuring that $\widetilde{D}$ is the marginal of $\widetilde{\mathcal{D}}$. This, however, turns out to be **NP**-hard (Theorem A.15).

Let $\mathcal{S}$ be the set of all matrices D that are a marginal of some distribution $\mathcal{D}$ that: (1) is C-individually fair and (2) is supported over rankings in $\mathcal{R}_{\text{GF}}$. The key reason for these difficulties is that there are feasible solutions of Program (8) that are not in $\mathcal{S}$. Using the definition of the marginal and $\mathcal{S}$, one can show that $D^\star$ is an optimal solution to $\text{argmax}_{D\in\mathcal{S}}\, \rho^\top Dv$. However, it is unclear how to solve this program as it is not obvious how to even check if a matrix is in $\mathcal{S}$. Thus, solving Problem 3.3 requires new ideas.

4 THEORETICAL RESULTS

In this section, we give our main algorithmic and hardness results.

4.1 Main Algorithmic Result

Our approach. The key idea is to consider a family of "coarse rankings" or *matchings*: Each matching places $|B_j|$ items in block B_j (for each $1 \le j \le m$), but it does not specify which items are placed at which positions inside B_j. We define natural analogs of the group fairness and the individual fairness constraints for matchings–leading to an analog of Problem 3.3 for matchings. At a high level, our algorithm (Algorithm 1) first solves this analogue of Problem 3.3 to get a distribution $\mathcal{D}^{(\mathcal{M})}$ over matchings and then maps $\mathcal{D}^{(\mathcal{M})}$ to a distribution $\mathcal{D} = f(\mathcal{D}^{(\mathcal{M})})$ over rankings; for an appropriate function f.

The fairness guarantee follows because of the facts that: (1) a matching M is (L, U)-group-fair if and only if the corresponding ranking $R = f(M)$ is (L, U)-group-fair and (2) a distribution $\mathcal{D}^{(\mathcal{M})}$ over matchings is (C, A)-individually-fair if and only if the corresponding distribution $\mathcal{D} = f(\mathcal{D}^{(\mathcal{M})})$ over rankings is (C, A)-individually-fair. This is where we use the fact that the blocks are disjoint. The utility guarantee follows because if $R = f(M)$ then the utility of R is at least α-times the utility of M (see Section 4.3 for a definition of f).

Crucially, we are able to efficiently solve the analog of Problem 3.3 for matchings because the linear inequalities capturing the group fairness constraints for matchings form a polytope such that all of its vertices are integral. The analogous statement is not true for rankings (see Appendix B); this is why all optimal solutions of Program (8) can be different from $D^\star$.

Main algorithmic result. Next, we state our main algorithmic result, whose proof appears in Appendix A.1. This result holds for blocks of different sizes and any position discounts, but we also give a simpler expression for the utility when each block has size k and the position discounts v satisfy the following condition:

$$\forall r \geq 0,\ \frac{v_{t+r}}{v_t} \text{ is a non-decreasing in } 1 \leq t \leq n-r. \tag{11}$$

Standard position discounts such as those in DCG [31] satisfy this assumption.

Theorem 4.1 (**Main algorithmic result**). *There is a polynomial time randomized algorithm (Algorithm 1) that given matrices $L, U \in \mathbb{Z}^{q\times p}$, and $A, C \in \mathbb{R}^{m\times q}$, and vectors $\rho \in \mathbb{R}^m$ and $v \in \mathbb{R}^n$, outputs a ranking R sampled from a distribution $\mathcal{D}$ such that:*

- *$\mathcal{D}$ satisfies (C, A)-individual fairness constraint, and*
- *R satisfies (L, U)-group fairness constraint.*

The expected utility of R is at least α times the expected utility of a ranking sampled from $\mathcal{D}^\star$. If all blocks have size k and Equation (11) *holds, then*

$$\alpha \geq \frac{v_1+v_2+\cdots+v_k}{k\cdot v_1}. \tag{12}$$

Furthermore, regardless of block-sizes and Equation (11)*, it holds that $\alpha \geq \min_{1\leq j\leq q} \frac{\sum_{s\in B_j} v_s}{|B_j|\cdot v_{s(j)}}$, where $s(j)$ is the first position in B_j.*

Thus, Algorithm 1 is an α-approximation algorithm for Problem 3.3. Here, α is a value that approaches 1 as the range of position discounts shrinks. In the worst case, when $v_2 = v_3 = \cdots = v_k = 0$, the RHS in Equation 12 is $\frac{1}{k}$. For common position discounts the RHS of Equation (12) is closer to 1: for instance, for DCG [31] with $k = 2, 3, 4$ it is at least $0.81, 0.71, 0.64$ respectively. These lower bounds are tight in some examples where a few items have a very large utility. If, however, items' utilities lie in a bounded interval, then this lower bound can be improved. To see concrete bounds, suppose $\frac{\max_i \rho_i}{\min_i \rho_i} \leq 1+\Delta$. One can show that

$$\alpha \geq (1+\Delta)\left(1+(kv_1\Delta)/(v_1+v_2+\cdots+v_k)\right)^{-1}. \tag{13}$$

Thus, α approaches 1 as Δ approaches 0, i.e., as the range of item utilities shrinks. One can show that, for any $\Delta \geq 0$, the above bound is at least as large than the RHS in Equation (12) (Appendix A.1.6). The proof of Equation (13) appears in Appendix A.1.6. We present further utility-dependent approximation guarantees in Appendix A.1.5. As for the running time, Algorithm 1 solves a linear program in $O(nm)$ variables with $O(np+m)$ constraints and performs $O(n^2m(p+m))$ additional arithmetic operations (Appendix A.1.4). Theorem 4.1 also holds, without change, for any set of protected groups that form a laminar family, i.e., for any set of groups such that either $G_\ell \subseteq G_k$ or $G_k \subseteq G_\ell$ for each $1 \leq \ell, k \leq p$ (Section 6). Laminar groups can be relevant in contexts where (some notion of) group fairness for intersectional groups is desired: as a concrete example, if one defines (1) G_1 to be the group of all non-women, (2) G_2 to be the group of all women, and (3) G_3 to be the intersectional group of all Black women (within the group of all women), then Algorithm 1 ensures that (the specified notion of) group fairness is also satisfied for the intersectional group of all Black women. Finally, one can verify that the more general bound in Theorem 4.1 (i.e., $\alpha \geq \min_{1\leq j\leq q} \frac{\sum_{s\in B_j} v_s}{|B_j|\cdot v_{s(j)}}$) reduces to the one in Equation (12) when all blocs have size k and Equation 11 holds (see Equation (24)).

4.2 Better Approximation Guarantees With Distributional Assumptions

Next, we present utility-dependent approximation guarantees of Algorithm 1 under generative models where each item i's utility ρ_i has uncertainty and is only "probabilistically known." For the sake of concreteness, we begin with the generative model where, the "true" utility, ρ_i, of each item $1 \leq i \leq m$ is drawn from the normal distribution $\mathcal{N}(\mu_i, \sigma_i^2)$ independent of all other items where $\mu_i \in \mathbb{R}$ and $\sigma_i \geq 0$ are parameters that are known to the algorithm.

Here, we choose the normal distribution for the sake of simplicity: more generally, ρ_i can be drawn from any (possibly nonsymmetric) sub-gaussian distribution with mean μ_i and variance σ_i^2. In particular, the specific sub-gaussian distribution can be different for different items. If we choose the normal distribution for each item, then the resulting utility model is identical to the implicit variance model of Emelianov et al. [22], who claim that such uncertainties in the utilities can arise in the real world.

Uncertainties in utilities arise from various sources (from measurement errors, uncertainties in prediction, to errors in data) in practice and are one of the motivations to consider individual fairness constraints [58]. When utilities are only probabilistically known, a natural family of individual fairness constraints (which is also proposed by Singh et al. [58]) is in Equation (4). Under these individual fairness constraints, when the parameters $\mu_1, \mu_2, \ldots, \mu_m$ are i.i.d. from the uniform distribution on $[0, S]$ (for some constant $S > 0$), we have the following approximation guarantee whose proof appears in Appendix A.2.

Theorem 4.2. *Suppose $\mu_1, \mu_2, \ldots, \mu_m$ are i.i.d. from the uniform distribution on $[0, S]$, ρ_i follow the above generative model, $C \in \mathbb{R}^{m\times q}$ is as specified in Equation* (4)*, $A = [1]_{m\times q}$, and nm^{-1} is bounded away from 1. Algorithm 1, given means of the utilities $\mu \in \mathbb{R}^m$ and other parameters (L, U, A, C, v), outputs a ranking R sampled from a distribution $\mathcal{D}$ that satisfies the fairness constraints in Theorem 4.1 and has an expected utility at least α times the expected utility of a ranking sampled from $\mathcal{D}^\star$, where*

$$\alpha \geq 1 - \widetilde{O}\left(\left(\sigma_{\max}\sqrt{\log m}\right)/S\right) - O\left(m^{-\frac{1}{4}}\right) \text{ and } \sigma_{\max} := \max_{i\in[m]} \sigma_i.$$

Hence, Theorem 4.2 shows that if the variance of the uncertainty in items' utilities ($\sigma_{\max}^2$) is "small" compared to the range of their utilities (S), then with high probability Algorithm 1 has a near-optimal approximation guarantee. As for the assumption about the distribution of the means $\mu_1, \mu_2, \ldots, \mu_m$, note that if the utilities denote the percentiles of items, then one expects $\mu_1, \mu_2, \ldots, \mu_m$ to be uniformly distributed in $[0, 100]$ [35]. In this case, $S = 100$ and the approximation guarantee is of the order of $1 - \sqrt{\log m}/S \geq 0.95$, for any $m \leq 10^{10}$.

The proof of the above result only uses the concentration property of the Gaussian distribution. This is why the result extends to (possibly non-symmetric) sub-Gaussian distribution (which can be

different for different items). Note that since ρ_i is drawn from the normal distribution $\mathcal{N}(\mu_i, \sigma_i^2)$, it can take negative values. To avoid this, one can consider an appropriately truncated version of the normal distribution. Since any truncation of the normal distribution is sub-gaussian, a bound of the same form (with an appropriate constant) continues to hold for α.

Moreover, if $\mu_1, \mu_2, \ldots, \mu_m$ are arbitrary deterministic values, then the following approximation guarantee for Algorithm 1 is implicit in the proof of Theorem 4.2 (see Equation (14))

$$\alpha \geq 1 - \widetilde{O}\left(\left(\sigma_{\max}\sqrt{\log m}\right)/\mu_n\right) - O\left(m^{-\frac{1}{4}}\right), \tag{14}$$

where $\mu_{(n)}$ is the n-th largest value in $\mu_1, \mu_2, \ldots, \mu_m$.

4.3 Overview of the Algorithm

Algorithm 1 encodes a matching by an $m \times q$ matrix $M \in \{0,1\}^{m\times q}$ where $M_{ij} = 1$ if item i is in the block B_j and $M_{ij} = 0$ otherwise. Let $\mathcal{M}$ be the set of matrices encoding a matching. Algorithm 1 uses two functions f and g. For any ranking $R \in [0,1]^{m\times n}$, $g(R) \in [0,1]^{m\times q}$ is the matching such that $g(R)_{ij} \coloneqq \sum_{t\in B_j} R_{it}$, for each $i \in [m]$ and $j \in [q]$. Intuitively, for a ranking R, $g(R)$ is the unique matching that matches item i to block B_j if and only if item i appears in B_j in R. For any matching M, $f(M)$ is the unique ranking that satisfies: (1) $g(f(M)) = M$ and (2) for each j, items in block B_j appear in non-increasing order of their utility in $f(M)$. Concretely, our algorithm is as follows.

Algorithm 1 Pseudo-code for the algorithm in Theorem 4.1

Input: Matrices $L, U \in \mathbb{R}^{q\times p}$ and $A, C \in \mathbb{R}^{m\times q}$, and vectors $\rho \in \mathbb{R}^m$ and $v \in \mathbb{R}^n$, and sets $B_1, B_2, \ldots, B_q \subseteq [n]$

Output: A ranking $R \in \mathcal{R}$

1: *(Solve)* Compute an optimal solution $\widehat{D}$ of Program (8)
▷ poly(n,m)-time as (8) has poly(n,m) variables/constraints
2: *(Project)* Compute the projection $\widehat{M} \coloneqq g(\widehat{D})$ ▷ $O(mn)$ time
3: *(Decompose)* Compute $M_1, M_2, \ldots, M_T$ and $\alpha_1, \alpha_2, \ldots, \alpha_T$ s.t.

$$\widehat{M} = \textstyle\sum_{t\in[T]} \alpha_t M_t,$$

where $T = O(n^2m^2)$
▷ $(M_t, \alpha_t)_{t=1}^T$ can be computed in $O(n^2m^2)$ time, see Lemma A.7
4: *(Refine)* **For each** $t \in [T]$ **do:** Set $R_t \coloneqq f(M_t)$ ▷ $\widetilde{O}(Tmn)$ time
5: **return** R_t with probability $\propto \alpha_t$ for each $t \in [T]$

5 EMPIRICAL RESULTS

In this section, we show the performance of our algorithm on synthetic and real-world datasets. We explore two research questions: (*i*) *How likely is it for a fair ranking baseline to sample a ranking that violates group fairness constraints?* (*ii*) *Does Algorithm 1 achieve a similar utility as baselines?* We start by describing our experimental setup before diving into the results of our experiments.

5.1 Setup, Baselines, and Metrics

Recall the ranking problem we consider – given m items, the output should be an ordered list or ranking of n items that maximize the utility. The utility generated by item i in position j is $\rho_i \cdot v_j$, where ρ_i is an item-specific utility and v_j is the position discount. The choices of n, m, k, and ρ are data and application dependent; we specify our choices of these parameters in table 1 and discuss the choice of all of n, m, k and ρ further with each dataset. Across all datasets, we set $v_j \coloneqq \frac{1}{\log(j+1)}$ for each $1 \leq j \leq n$, corresponding to the popular discounted cumulative gain (DCG) measure [31].

Fairness constraints. The choice of the right fairness constraints is context-dependent. For illustration, we choose generalizations of the equal representation constraint (which is, perhaps, the most common group fairness constraint considered in the literature [68, 69]). These generalizations are parameterized by $1 \leq \phi \leq p$ are specified by blocks $B_1, B_2, \ldots, B_q$ of equal size $k \coloneqq \frac{n}{2}$. Given a value of ϕ, the constraint is specified by the upper bounds $U_{j\ell} \coloneqq \left\lceil \frac{\phi k}{p} \right\rceil$ for block B_j and the protected group G_ℓ (for each j and ℓ); the lower bounds of the group fairness constraints are set to be vacuous, i.e., $L_{j\ell} = 0$ for all j and ℓ. To gain some intuition about the relevant values of ϕ, note that when $\phi = p$ the upper bounds are vacuous and when $\phi = 1$ the upper bounds require the ranking to contain exactly $\frac{k}{p}$ items in each block. As for the individual fairness constraints, we consider a family of individual fairness constraints proposed by Singh et al. [58] which, in turn, are motivated by the uncertainties in the item utilities, as are bound to arise in the real world. Following the construction in [58], we assume that the true utility of item i is $\rho_i = \widetilde{\rho}_i + X_i$, where $\widetilde{\rho}_i$ is an estimated utility and X_i is a Gaussian random variable with mean 0 and a data-dependent standard deviation σ computed to be the smallest value such that there are at least $\frac{k}{2}$ items with estimated utility within $\widetilde{\rho}_i \pm \sigma$, on an average. Given these, the matrix C specifying the individual fairness constraints is specified as $C_{ij} = \gamma \cdot \Pr[\exists t \in B_j, \rho_i \text{ is the } t\text{-th largest value in } \{\rho_1, \ldots, \rho_m\}]$ where $0 \leq \gamma \leq 1$ is a relaxation factor. We set the upper bounds of the individual fairness constraints to be vacuous,i.e., $A_{ij} = 1$ for all i and j. Note that when $\gamma = 1$, C_{ij} is equal to the probability that item i appears in the j-th block when items are ordered in decreasing order of true utility. Note that the "strength" of our group fairness constraint is specified by the parameter $1 \leq \phi \leq p$ (where the closer ϕ is to 1 the closer the constraint is to equal representation) and the strength of our individual fairness constraint is specified by $0 \leq \gamma \leq 1$ (where the closer $\gamma = 1$ the "stronger" the individual fairness requirement is).

Baselines. We compare our algorithm to both baselines that output a deterministic ranking and those that sample a ranking from a distribution.The following baselines output a deterministic ranking:

(1) **Unconstrained**, which is a baseline that outputs a ranking that maximizes the utility (without consideration for fairness constraints); and
(2) **CSV18 (Greedy)** [17], which is an algorithm that greedily ranks the item and is guaranteed to satisfy the specified group fairness constraints, but does not consider individual fairness constraints.

We also consider baselines that are closer to Algorithm 1, in the sense that, they sample a ranking from an underlying distribution such that the output is guaranteed to satisfy the specified individual fairness constraints:

(1) **SJK21 (IF)**, which is the algorithm of Singh et al. [58] specialized to the individual fairness constraints considered in our simulations; (This algorithm first solves Program (5) to compute a marginal D, decomposes it as $D = \sum_t \alpha_t R_t$ (using Birkhoff

Dataset	m	n	k	p
Synthetic [44]	100	40	20	2
Real-world Images [46]	100	20	10	2
Real-world Names [15]	400	16	8	4

Table 1: Parameter choices for each dataset. Experiments with additional parameter choices are presented in Figure 6 in Appendix D.

von Neumann decomposition), and outputs R_t with probability $\propto \alpha_t$.)

(2) **SJK21 (GF and IF)**, which is the algorithm of Singh et al. [58] specialized to satisfy both the individual fairness constraints and (in aggregate) the group fairness constraints considered in our simulations. (This algorithm first solve Equation (8) to compute a marginal D, decomposes it as $D = \sum_t \alpha_t R_t$ (using Birkhoff von Neumann decomposition), and outputs R_t with probability $\propto \alpha_t$.)

Metrics. We evaluate the rankings output by each algorithm using three metrics: the probability with which the output ranking violates the group fairness constraints $\mathscr{G}_{\text{violation}}$, a measure of the amount of violation of the individual fairness constraints $\mathscr{I}_{\text{violation}}$ (see below), and the output ranking R's normalized output utility

$$\mathscr{U} = \mathbb{E}[\rho^\top R v]/\mathscr{U}_{\max}$$

(where the expectation is over any randomness in R and $\mathscr{U}_{\max}$ is a normalization constraint that ensures that $\mathscr{U}$ has range from 0 to 1). It remains to define $\mathscr{I}_{\text{violation}}$: let P_{ij} be the probability with which item i appears in block B_j in the output ranking R, the individual fairness violation of the corresponding algorithm is defined as

$$\mathscr{I}_{\text{violation}} := \frac{1}{m}\sum_{i\in[m]}\frac{1}{q}\sum_{j\in[q]}\max\left\{1-\left(P_{ij}/C_{ij}\right),0\right\}.$$

Note here that both $\mathscr{G}_{\text{violation}}$ and $\mathscr{I}_{\text{violation}}$ have a range from 0 to 1, where a smaller value implies a smaller violation.

5.2 Datasets

We perform simulations with three datasets.

Synthetic dataset. We use the synthetic dataset generated by the code provided by recent work on fair ranking [46]: this dataset consists of two protected groups G_1 and G_2, where G_1 comprises 60% of the total items, and the utilities of items in the minority group are systematically lower (with mean 0.35) compared to the utilities of items in the majority group (with mean 0.7).

Real-world image dataset. This dataset, also known as the Occupations dataset, consists of the top 100 Google Image results for 96 queries [15]. For each image, the dataset provides the rank of the image in the search result and the (apparent) gender of the person in the picture (encoded as binary labels collected via MTurk) [15]. We use the same preprocessing as Mehrotra and Vishnoi [46]: let an occupation be stereotypical if more than 80% of the images in the corresponding search result are labeled to be of a specific gender. This results in 41/96 stereotypical occupations, with 4,100 images. Each of the 4,100 images, is labeled as stereotypical if the image's gender label corresponds to the majority gender label in the corresponding occupation and is otherwise labeled as unstereotypical. We consider the set of stereotypical and unstereotypical images as protected groups and fix $\rho_i = \frac{1}{\log(1+r_i)}$, for all $i \in [m]$ (as in [46]).

Real-world names dataset. This dataset, known as the chess ranking data, consists of the which consists of the FIDE rating of 3,251 chess players across the world [28]. For each player, the dataset consists of the players' self-identified gender (encoded as binary: male or female) and their self-identified race (encoded as Asian, Black, Hispanic, or White). For the simulation with this dataset, we consider the following four intersectional groups: White Male, White Female, Non-White Male, and Non-White Female.

Data-specific parameters and setup. Table 1 lists the parameters n, m, k, and p for each dataset. For the specified values of n and m, in each simulation, we sample a subset of each dataset to select m items from the data uniformly without replacement – where m is chosen to be the smallest value (up to a multiple of 100) so that in each draw there are at least n/p items from each group (to ensure that the equal representation constraints are satisfiable).

5.3 Observations and Discussion

We now summarize our experimental observations and answer the research questions raised at the beginning of this section.

Pareto-optimality for individual and group fairness. Figure 1 presents the results that compare the individual and group fairness violations achieved by all the algorithms. In Figure 1, each row corresponds to results over the three respective datasets. The sub-figures in the first column show group fairness violation against individual fairness violation by the algorithms. Obviously, when no individual fairness constraints are enforced, i.e., $\gamma = 0$, all the algorithms achieve 0 individual fairness violation.

We observe that our algorithm achieves Pareto-optimality with respect to individual $\mathscr{I}_{\text{violation}}$ and group-fairness $\mathscr{G}_{\text{violation}}$. When the value of γ is increased (sub-figures on the second and third columns), we see that the baseline **SJK21 (GF and IF)** violates group fairness constraints for smaller values of ϕ ($\phi \in \{1, 1.5\}$ for the synthetic and image dataset and $\phi \in \{1, 2.5\}$ for the Name dataset). This is caused because there are non-group fair rankings in the support of the distribution output by this algorithm. **SJK21 (IF)** has high group fairness violation ($\mathscr{G}_{\text{violation}} \approx 1$ for almost all non-trivial values of ϕ and γ) and no individual fairness violation as expected. Since **CSV18 (Greedy)** outputs a deterministic ranking, it has high individual fairness violation ($\mathscr{I}_{\text{violation}} \geq 0.8$ for all values of ϕ and γ) but has no group fairness violation. We note here that any deterministic ranking can have either 0 or 1 group fairness violation. Finally, **Unconstrained** does the worst of all the algorithms with $\mathscr{G}_{\text{violation}} = 1$ and $\mathscr{I}_{\text{violation}} \geq 0.8$ on all the datasets. In contrast, our algorithm does the best by achieving 0 individual fairness violation and 0 group fairness violation, thus indicating Pareto dominance over all other baselines.

Utility vs. Fairness Figure 5 in Appendix D shows the utility vs. group fairness violation plot for values of ϕ ranging from 1 to p. Our algorithm achieves a very small decrease in the utility; that is, across all the datasets, our algorithm suffers only a maximum of 6% loss in utility compared to other algorithms when all the algorithms are subject to the same fairness constraints. We also observe similar trends as Figure 1 on the synthetic dataset for other values of the parameters m and n (see Figure 6 in Appendix D).

6 THEORETICAL OVERVIEW

In this section, we explain the key ideas in the proof of our main theoretical result, Theorem 4.1. Recall that Theorem 4.1 proves that there is an algorithm, namely Algorithm 1, that given matrices

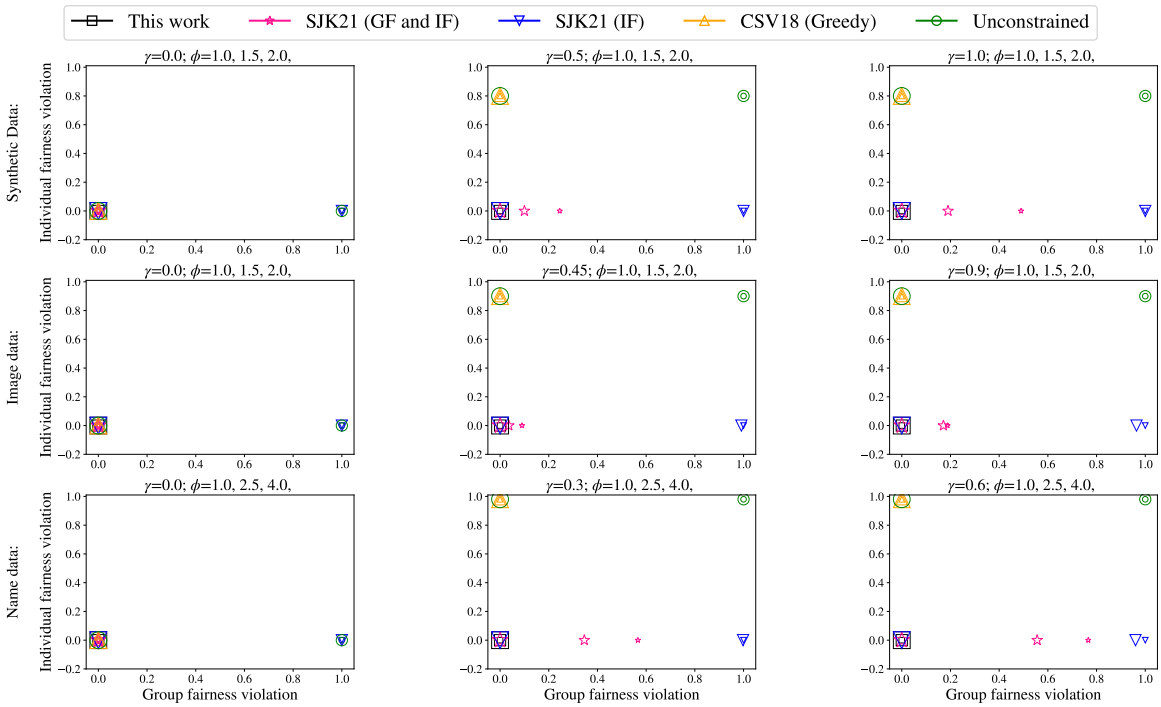

Figure 1: Individual fairness violation vs. Group fairness violation: In the plots, the parameter γ controls individual fairness constraints and the parameter ϕ defines block-wise representation constraints. The size of the marker for each algorithm in each plot is proportional to the value of ϕ. Lower the value of ϕ, the stronger the group fairness constraints. In contrast, the lower the value of γ, the weaker the individual fairness constraints.

L, U specifying the group-fairness constraints and matrices A, C specifying the individual fairness constraints along with vector ρ specifying item utilities, outputs a ranking R sampled from distribution $\mathcal{D}$ such that: (1) R *always* satisfies the group fairness constraints and (2) $\mathcal{D}$ satisfies the individual fairness constraints. Moreover, the expected utility of R is at least α times the optimal– where α satisfies the lower bound in Equation 12 (see Section 4 for tighter bounds on α under additional assumptions).

The algorithms in prior work [56, 58] roughly have the following structure: they first solve a linear program (e.g., Equation (5)) to compute a marginal $\widehat{D} \in [0,1]^{n\times m}$ of distribution $\widehat{\mathcal{D}}$ from which they want to sample the ranking, and then they decompose $\widehat{D}$ into a convex combination of at most poly(n, m) rankings: $\widehat{D} = \sum_t \alpha_t R_t$. Let's represent this pictorially by the following two-step process:

$$LP \xrightarrow{\text{Solve}} \widehat{D} \xrightarrow{\text{Decompose}} \sum \alpha_t R_t$$

In general, there exist infinitely many decompositions of any matrix $\widehat{D}$ and any valid decomposition is suitable for prior work [56, 58]: this is because, for any valid decomposition $\sum_t \alpha_t R_t$, sampling ranking R_t with probability $\propto \alpha_t$ (for all t) results in optimal utility and satisfies the fairness constraints (both individual and group) in expectation. We, however, require a decomposition where *each* ranking R_t in the decomposition satisfies the group fairness constraints. Computing such a decomposition is the key technical difficulty in proving Theorem 4.1.

In fact, such a decomposition may not even exist (see Fact B.1 for an example). Moreover, instances, where the decomposition does not exist, are also not "isolated" or avoidable instances. Rather, they arise due to a fundamental property of group fairness constraints: that the set of matrices R which satisfy the group fairness constraint and the constraint Equation (7) form a polytope that has fractional vertices, which are vertices that (in matrix representation) have fractional entries. This is also related to the computational complexity of the problem: the Birkhoff von Neumann algorithm is able to efficiently compute a decomposition (when output all rankings are not required to satisfy group fairness constraints) precisely because such fractional vertices do not arise. Indeed, a deep result in Combinatorial Optimization is that the set of doubly-stochastic matrices – which is the set of matrices that satisfy Equation (7) (but do not necessarily satisfy the group fairness constraints) – form a polytope that does not have fractional vertices [55]. Such polytopes are said to be *integral*; see [55]. If such an integrality result was true in our setting, then we could have used a straightforward analog of the Birkhoff von Neumann algorithm. However, this is not the case as shown in Appendix B.

Our idea is to first compute a "coarse" version of the decomposition and then "refine" it. Pictorially, our algorithm follows the following four-step process.

$$\text{Prog. (8)} \xrightarrow{\text{Solve}} \widehat{D} \xrightarrow[\widehat{M} := g(\widehat{D})]{\text{Project}} \widehat{M} \xrightarrow{\text{Decompose}} \sum \alpha_t M_t \xrightarrow[R_t := f(M_t)]{\text{Refine}} \sum \alpha_t R_t$$

Intuitively, a "coarse ranking" or a matching is an assignment of m items to q blocks $B_1, B_2, \ldots, B_q$. Each item is matched to exactly 1 block and the j the block has exactly $|B_j|$ items. We encode a matching by an $m \times q$ matrix $M \in \{0,1\}^{m\times q}$ where $M_{ij} = 1$ item i is in the block B_j and $M_{ij} = 0$ otherwise.

Before discussing how to efficiently compute the decomposition $\sum_t \alpha_t M_t$ where each matching M_t satisfies "group fairness constraints," we need to define notions of fairness for matchings.

Definition 6.1. *Given matrices $L, U \in \mathbb{Z}^{q\times p}$ and $A, C \in [0,1]^{m\times q}$, define the following definitions of fairness:*

(1) *A distribution $\mathcal{D}^{(\mathcal{M})}$ over the set $\mathcal{M}$ of all matchings satisfies (C, A)-individual fairness constraints if for each i and j, $C_{ij} \le \Pr_{M\sim\mathcal{D}^{(\mathcal{M})}}\left[M_{ij} = 1\right] \le A_{ij}$.*
(2) *A matching M satisfies the (L, U)-group fairness constraints if for each j and ℓ, $L_{j\ell} \le \sum_{i\in G_\ell} M_{ij} \le U_{j\ell}$.*

The fairness guarantee of Algorithm 1 follows because of the following invariance.

Lemma 6.2. *Let $f(D) \in [0,1]^{m\times q}$ be the projection of a matrix $D \in [0,1]^{m\times n}$ to the space of matchings. For any matrices $L, U \in \mathbb{Z}^{q\times p}$ and $A, C \in [0,1]^{m\times q}$, the following holds*

(1) *A matrix D satisfies (C, A)-individual fairness constraints if and only if $f(D)$ satisfies (C, A)-individual fairness constraints; and*
(2) *A matrix D satisfies (L, U)-group fairness constraints if and only if $f(D)$ satisfies (L, U)-group fairness constraints.*

Let the "refinement" of a matching M be $g(M)$. One can show that the projection of the refinement of M, i.e., $g(f(M))$ is M itself. This and Lemma 6.2 imply that the refinement $f(M)$ of a matching M satisfies the (L, U)-group fairness constraints if and only if M satisfies (L, U)-group fairness constraints. Since the marginal $\widehat{D}$ computed by our algorithm satisfies group fairness and individual fairness constraints, chaining the above invariance results over the four steps presented above implies that each ranking R_t output by our algorithm also satisfies individual fairness and group fairness constraints.

It remains to show that Algorithm 1 is efficient and to establish its utility guarantee. A lower bound on the utility follows straightforwardly due to the following: First, one can show that both $\widehat{D}$ (which has the optimal utility) and $\sum_t \alpha_t R_t$ project to the same point in the matching space $\widehat{M}$. Second, one can lower bound the ratio of the utility of any two points $D_1, D_2 \in [0,1]^{m\times n}$, in the ranking space, that have the same projection in the matching space (Lemma A.6).

As for the efficiency of Algorithm 1, it follows because the set of matchings satisfies the "integrality" property we discussed above. This is why we introduce matching into our algorithm. Consider the set of points in the matching space that satisfy the group fairness constraint and the following analog of Equation 7:

$$\forall 1 \le j \le q,\ \ \textstyle\sum_i D_{ij} = \left|B_j\right| \quad \text{and} \quad \forall 1 \le i \le m,\ \ \sum_j D_{ij} \le 1.$$

Formally, this set of points forms a polytope $\mathscr{M}$ that is integral. Somewhat surprisingly, this connects our work to a recent work on fair matchings that also makes this observation [52]. The polytope $\mathscr{M}$ is a part of the problem statement of Panda et al. [52]. Our key insight is to make the connection between rankings and matchings discussed in this section, which may be of independent interest to works designing fair ranking algorithms.

Extension to laminar families of protected groups. The fact that $\mathscr{M}$ is integral is the only part of the proof where we use the fact that the protected groups $G_1, \ldots, G_p$ are disjoint. All the remaining steps in the proof hold for arbitrary group structures. Panda et al. [52] observe that this property continues to hold when the groups $G_1, \ldots, G_p$ form a laminar family, i.e., for any set of groups such that either $G_\ell \subseteq G_k$ or $G_k \subseteq G_\ell$ for all $1 \le \ell, k \le p$. Hence, our proof extends to laminar families of protected groups. This provides another example where efficient algorithms continue to exist when the underlying set structure is related from disjoint to laminar; as has also been observed by earlier works in algorithmic fairness [14] and, more broadly, in the Combinatorial Optimization literature [40]. This allows our algorithm to incorporate constraints on certain intersectional groups, as has been argued by seminal works on intersectionality [34] and, more recently, by works analyzing mathematical models of intersectional bias [45]. A concrete example is as follows: since the collection of the sets of all women, all Hispanic women, and all Black (non-Hispanic) women is laminar, one can ensure sufficient representation of women in the output ranking and, within women, also ensure the representation of Hispanic and Black women.

7 LIMITATIONS AND CONCLUSION

We present an algorithm (Algorithm 1) that works with a general class of group fairness constraints and individual fairness constraints, it outputs rankings sampled from a distribution that satisfies the specified individual fairness constraints and, moreover, each output ranking satisfies the specified group fairness constraints (Theorem 4.1). Further, the algorithm guarantees a constant fraction approximation of the optimal (expected) utility subject to satisfying these constraints (Theorem 4.1 and 4.2). This algorithm works with families of disjoint protected groups as well as certain families of overlapping protected groups (namely, collections of laminar sets) (Section 6). Empirically, we observe that our algorithm is able to satisfy the specified fairness criteria while losing at most 6% loss of the utility compared to the unconstrained baseline (Section 5).

Our work raises several questions. We consider the setting where the utility of a ranking of multiple items is a linear function of the utilities of individual items. While this captures a broad spectrum of applications [54, 68, 69], in some applications, the utility of a ranking may be a non-linear function of the items present in the ranking; this is particularly, the case where the diversity of the items in a ranking has an effect on its utility [1, 3, 36]. Extending our approach to this (more complicated) setting is an interesting direction for future work. Moreover, while our algorithm works for certain families of overlapping protected groups, extending it to arbitrary families of overlapping protected groups is an important question. Further, Theorem A.15 demonstrates that solving a certain relaxation of our problem is **NP**-hard, exploring other potential relaxations may be fruitful to further improve the utility guarantee of our algorithm.

ABSTRACT

Machine learning models trained with passive sensor data from mobile devices can be used to perform various inferences pertaining to activity recognition, context awareness, and health and well-being. Prior work has improved inference performance through the use of multimodal sensors (inertial, GPS, proximity, app usage, etc.) or improved machine learning. In this context, a few studies shed light on critical issues relating to the poor cross-country generalization of models due to distributional shifts across countries. However, these studies have largely relied on inference performance as a means of studying generalization issues, failing to investigate whether the root cause of the problem is linked to specific sensor modalities (independent variables) or the target attribute (dependent variable). In this paper, we study this issue in complex activities of daily living (ADL) inference task, involving 12 classes, by using a multimodal, multi-country dataset collected from 689 participants across eight countries. We first show that the 'country of origin' of data is captured by sensors and can be inferred from each modality separately, with an average accuracy of 65%. We then propose two *diversity scores (DS)* that measure how a country differentiates from others w.r.t. sensor modalities or activities. Using these diversity scores, we observed that both individual sensor modalities and activities have the ability to differentiate countries. However, while many activities capture country differences, only the 'App usage' and 'Location' sensors can do so. By dissecting country-level diversity across dependent and independent variables, we provide a framework to better understand model generalization issues across countries and country-level diversity of sensing modalities.

1 INTRODUCTION

Current literature on mobile sensing has demonstrated the utility of multimodal passive sensor data in performing various inference tasks associated with activity recognition, context awareness, and health and well-being [24]. Examples include eating and drinking behavior [22, 25–28], activities of daily living [5, 6], energy expenditure estimation [3], mood [19, 23, 35], stress [20, 33], and depression [7, 10], all of which exhibit reasonable performance when inferred from multimodal sensing data. Even though cross-country generalization is needed for models to be deployed across diverse world regions [31, 34], most prior work has focused on homogeneous populations in one or two countries, hence limiting the understanding of model generalization to other countries [38].

Recent work has emphasized the importance of training models that generalize across multiple countries and thus higher real-world utility[5, 23]. These studies demonstrated that poor generalization across countries could be attributed to distributional shifts in data across countries. However, work on cross-country generalization has largely relied on techniques for downstream inferences, such as mood inference, social context inference, and activity recognition, and compare their performance across countries to understand distributional shifts [5, 16, 23, 38]. For example, for a two-country setting, when a model trained in Country 1 performs poorly in Country 2, studies directly attribute this finding to distributional shifts in data across the two countries. Although this approach is effective, it requires building multiple models to systematically test generalization performance across countries, which can be time-consuming and resource-intensive as the number of experiments grows. Furthermore, comparing models is not always straightforward due to differences in performance, attributable to choice of training algorithms, non-optimal parameter tuning, and training set characteristics, such as different numbers of training samples per country. However, even though discussed in general terms (e.g., data distribution-based shift detection and classifier performance-based shift detection [37]), prior work does not examine techniques

that allow an understanding of cross-country differences in sensing modalities without relying on classifier performance.

Further, evaluations of model generalization must consider the potential for diversity at the sensor level (independent variables) and target attribute level (dependent variables). For instance, in a three-country setting, accelerometer readings may exhibit similarity between Country 1 and Country 2 but dissimilarity between Country 1 and Country 3, whereas location readings may display similarity between Country 1 and Country 3 but dissimilarity between Country 1 and Country 2. Current inference performance-based techniques do not explicitly address the sensor-level diversity and target attribute diversity across countries (also known as covariate shift and label shift, respectively [37]), which may obscure the understanding of whether shifts affecting poor generalization occur in the sensors or the targets. Moreover, if such shifts occur in the sensors, investigations into which sensor modalities are more likely to be impacted by distributional shifts have yet to be investigated. In this work, we use the terms sensors and sensor modalities, interchangeably.

Studying topics around mobile sensing and generalization is important because poor cross-country generalization of machine learning models could potentially perpetuate societal biases and result in unfair or ineffective systems. For instance, models developed in economically privileged countries might not function as well in less wealthy ones due to different data distributions, which could exacerbate existing global disparities in technology benefits. In this context, despite extensive discussion of these issues in fields such as computer vision, speech, and natural language processing, the challenges of understanding dataset shifts and generalization are relatively unexplored in the domain of mobile sensing [5, 23, 38]. Therefore, this study introduces a low-cost framework to analyze country-level diversity across sensor modalities and target attributes with a large, multi-modal, multi-country dataset from 689 participants across eight countries. We investigate whether sensor modalities can reveal the data's *country of origin* and then distinguish country differences in sensor modalities and the target variable. We suggest two *diversity scores* to measure country differences and analyze country pairs to identify generalization impacting factors. We then apply these scores to study how cross-country data diversity influences inferences of complex activities of daily living (ADL). In line with prior work [5], ADL are activities that punctuate daily routines, are complex in nature, occur over a non-instantaneous time window, and have a semantic meaning around which context-aware applications could be built. In this context, we pose the following research questions:

RQ1: Can the country of origin of data be inferred from each sensing modality independently and in conjunction, to ascertain whether each sensing modality captures country-level information?
RQ2: Can country-level diversity be methodically measured in terms of the capacity to distinguish between countries, using various sensing modalities, to gain a comprehensive understanding of the sensors that influence variations across countries?
RQ3: By considering the inference of ADL as a case study, how can we consider both sensor data (independent variables) and the target attribute (ADL—dependent variable) together to understand country-level diversity across target as shown by sensor data?

By addressing the above research questions, this paper provides the following contributions:

Contribution 1: We utilized a dataset comprising sensor data collected from 689 college students over a period of four weeks across eight countries, namely, China, Denmark, India, Italy, Mexico, Mongolia, Paraguay, and UK. Our analysis found that each sensing modality can reasonably infer the country of origin of the user, with an accuracy ranging between 0.57 and 0.71 for different sensors and an average accuracy of 0.65. This observation underscores the crucial role of sensor modalities in comprehending cross-country dataset generalization. Furthermore, the collective performance of all sensors in distinguishing countries had an average accuracy of 0.73, with a minimum of 0.59 and a maximum of 0.84, across countries. This finding is intriguing as it suggests that different sensor modalities may capture various aspects of the 'country of origin' and highlights the necessity for further investigation at the sensor modality level to better understand dataset shifts and model generalization issues.
Contribution 2: We present a novel approach to assess country-level diversity by introducing a country-level diversity score (DS1) that incorporates differences in sensor modalities and countries. While this is a simple measure, it provides insight into the distributional disparities of multimodal sensor data across countries. Based on our scoring methodology, we discovered notable variations in countries for certain sensor modalities, with high diversity scores for Italy, Mongolia, and Mexico and low scores for Denmark and Paraguay. These country-level diversity discrepancies are intriguing as they could help to understand generalization, even before training any machine learning models. Specifically, do countries with high country-level diversity across sensor modalities provide better training data in terms of generalization? Are they more challenging as test countries? By examining country pairwise differences (e.g., testing if data captured by the App modality differs significantly for Italy and the UK users), we found that 'App usage' and 'Location' are the two modalities with the highest discriminatory ability between countries. These outcomes suggest that certain sensor modalities might have a more pronounced effect on generalization than others.
Contribution 3: We propose a second country-level diversity score (DS2) that takes into account the country, sensors, and the target attribute (ADL). Under this scoring scheme, we found considerable country differences across activities. When comparing the order of countries in DS1 and DS2, we observed noteworthy differences. For instance, Italy ranks highest in DS1 but falls to fifth in DS2 scoring. Only Paraguay and Denmark maintain the same rank in both orderings. This suggests that a country's distribution of target attributes may differ from others yet remain similar in terms of sensor modalities. When analyzing pairwise country differences across activities (e.g., examining whether the sensor data of Italy and India's users differ for a given activity), we found that no single activity stands out as a definitive differentiator between pairs of countries, but many activities can serve this purpose. These results imply that a person's 'country of origin' could influence the manner in which activities are practiced (dependent variable), as demonstrated by sensor data (independent variables).

2 BACKGROUND AND RELATED WORK

There is a plethora of research on mobile sensing related to health and well-being. These studies have utilized passive sensing data to infer behavioral, contextual, and psychological aspects of smartphone users. Recent studies have highlighted the challenges of generalization, and several issues remain unresolved. To address this, Adler et al. [2] employed two longitudinal study datasets to infer mental health symptoms and investigate their generalization across publicly available data using inference performance as a measure of generalization. They found that models trained on combined data achieved better inference than models trained on single-study data.

Muller et al. [29] investigated whether patterns in people's mobility behaviors could passively measure depression. They used a U.S.-wide sample that was socio-demographic heterogeneous as well as in mobility patterns, and found that depression inference from GPS-based mobility did not generalize well to large, demographically heterogeneous samples. Meegahapola et al. [23] studied mood inference and found that country-specific approaches performed reasonably well for two or three classes of mood inferences, but country-agnostic models did not generalize well to unseen countries. Assi et al. [5] demonstrated that country-specific models outperformed multi-country models in Human Activity Recognition (HAR) task settings, even when trained on smaller data samples. Khal et al. [16] showed that it is possible to achieve state-of-the-art accuracy in a new country when building personality models (Big 5), and investigated cross-cultural differences in features by constructing multiple country-specific models and comparing the most influential features per country.

Although these studies have highlighted the challenges of generalization in diverse datasets for a given target task, they all consider inference performance as a metric for generalization. Further, most of these studies advocate finding better techniques for model generalization (in case data and labels from target domains are unavailable) and domain adaptation (when target domain labels are available). However, they also acknowledge the challenge of adapting currently available techniques from other domains to multimodal sensing data. Prior work has seldom examined domain adaptation strategies or techniques to understand distributional shifts in mobile sensing data for in multimodal settings [8, 23]. In this work, we analyze country-level diversity directly from sensor data to provide insights into how country differences are distributed between sensor modalities and the target attribute (ADL). Our goal is to contribute to a better understanding of what factors could influence cross-country generalization in multimodal sensor datasets. The findings would allow researchers working on mobile sensing to have a better understanding of distributional shifts when developing future domain adaptation or generalization techniques in multimodal settings.

3 DATASET

We used a dataset originally collected as part of the European WeNet project and described in [13, 23]. The data was gathered from both undergraduate and graduate students in eight countries, namely China, Denmark, India, Italy, Mexico, Mongolia, Paraguay, and the UK, to capture diversity in behaviors across countries. This

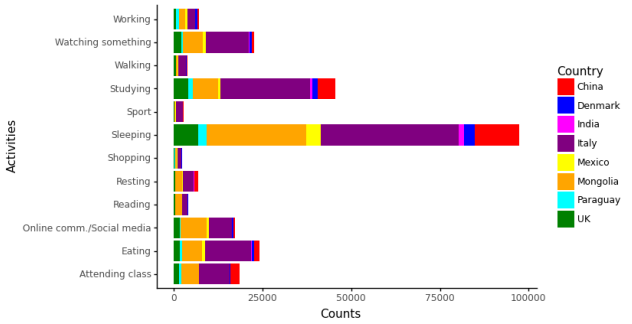

Figure 1: Distribution of countries per activity. The x-axis is the count of practiced activities.

diversity is decomposed into two dimensions: inherent attributes (observable characteristics such as country of origin, gender, and age) and acquired characteristics[1]. Both of these dimensions of diversity were captured during four weeks in November 2020, via an online questionnaire and a smartphone application called iLog. The app was designed to record software and hardware sensors, as well as some metadata, along with hourly questionnaires assessing the participant's activity and context. Information such as what the students were doing, where they were, with whom, and how they were feeling was collected in time diaries.

The original list of activities included 34 items selected using prior work in human behavior modeling and social practice [12, 39]. As the data collection took place during the Covid-19 pandemic, it significantly influenced the students' way of life. Consequently, some activities, such as traveling and walking, were underrepresented. To address this issue, activities with similar broad semantic meanings were merged, such as 'eating' and 'cooking' and 'social media' and 'internet chatting'. Activities with very disparate semantic meanings, such as 'hobbies', which include dissimilar activities such as 'painting' or 'playing the piano', were filtered out. The resulting dataset consisted of twelve activities of daily living, that modeled the life of a student (Attending class, Eating, Online comm./Social media, Reading, Resting, Shopping, Sleeping, Sport, Studying, Walking, Watching something and Working). In total, the dataset contains 252,393 ADL reports and covers eight countries. More information about the dataset, including the process of narrowing down the ADL to 12, and data collection can be found in [5, 23]. Figure 1 displays the selected activities with their country distribution.

4 FEATURE EXTRACTION PIPELINE

In this section, we explain how we extract features from a sequence of data captured from sensors.

4.1 Obtaining Raw Features

The raw data collected from the mobile app contains a sequence of data captured from hardware and software sensors and time diary metadata. In our study, we decided to keep a traditional feature

[1]We point out that inherent and acquired characteristics are the terms used by ACM as part of its "Commitment to Diversity, Equity, and Inclusion in Computing": https://www.acm.org/diversity-inclusion/about.

Table 1: Summary of features extracted from raw sensor data, aggregated around self-reports using ten-minute windows before and after a time diary entry.

Sensor modality	Count	Corresponding features
Activity	8	time spent doing following activities: still, in_vehicle, on_bicycle, on_foot, running, tilting, walking and unknown (Google Activity Recognition API)
App usage	5	time spent on apps of each category: personalization, social, communication, tools and app not found
Cellular [lte]	4	mean/std/min/max signal strength
Location	3	radius of gyration, sum of distance, altitude mean/min/max, speed mean/min/max
Notifications	4	notifications posted, notifications removed (with and without duplicates)
Proximity	4	mean/std/min/max
Screen events	6	touch events, user presence time, number of episodes, time per episode, min/max/std episode time, total time
Steps	2	steps counter (since turned on), steps detected
WiFi	5	connected indicator, number of devices, mean/std/min/max rssi

extraction approach by extracting features by means of functionals applied to a window of features [18, 28]. This approach has the advantage of yielding features that are interpretable.

Practically, feature extraction for the current activity is done as follows: first, we pool software and hardware sensor data in a window of 10 minutes centered around the current ADL report, in order to capture the characteristics of the activity; then the window data is discretized by applying various functionals to the continuous stream. Some functionals are specific to the sensor modalities (i.e. radius of gyration), while others are statistical functions like the mean, standard deviation, minimum, and maximum. We also decided to include some high-level features that represent the participant movement, by using the Google Activity Recognition API. This leaves us with nine modalities of sensors describing the ADL report. Table 1 shows a full description of the sensor modalities with their respective features. For more infomation about the feature processing pipeline, please refer to [5, 23]. Note that the 'Location' sensor modality here captures physical location (GPS), and we derive various features from by considering a time window and location traces that quantify the mobility.

4.2 Embedding-Based Representation

The raw extracted features, grouped by sensor modalities, differ in terms of the range of values and are sparse, i.e., they contain many zeros. Motivated by these two observations, we converted each sensor modality raw data into a continuous and dense representation using the fast.ai toolkit [14] tabular data recipe for auto-encoders[2], without the categorical input part. The number of layers for the auto-encoders is chosen empirically to maximize the evaluation set performance.

Regarding the embedding size, it is usally chosen in order to perform well on a downstream task, but in our case, we would like the embeddings to be as generic as possible, i.e., not depending on a specific task. We selected the optimal embedding size empirically, for each sensor modality, by using the elbow method [36] on the evaluation set reconstruction scores (R2 scores [1]). Optimal embedding R2 scores are close to one for all sensor modalities except for the 'Location' sensor modality, which has a score of 0.56. Then, we decided to choose the largest optimal embedding size across sensor modalities as the common embedding size for all sensor modalities (size of 22) to avoid dimensional bias in the statistical and visual analyses and to facilitate their combination. Doing so is appropriate, as R2 scores empirically increase with higher embedding dimensions.

To analyze diversity at the smartphone level, we added the 9 sensor modalities. The resulting embedding is a representation of sensor data. We will use this term in the rest of the paper to refer to this combined representation. An alternative way would have been to concatenate them, but this would have yielded a high-dimensional vector of size 198. We believe that keeping the dimension smaller is beneficial in terms of dimensionality reduction and statistical analysis. The resulting embedding can be thought of as an approximation of embedding modeling all sensor modalities. This technique is widely used in Graph Neural Network message passing [11] and has also been used in past ubicomp literature [17].

5 METHODS

In our experimental setting, for all cases where an inference is performed, the dataset was partitioned in a way that ensures similar country distributions and no overlap of users across the training, validation, and testing sets, similar to prior work that used leave-k-participants-out strategy [5, 23]. Specifically, a test user is unseen during the training phase. The use of this splitting strategy allows for the exploration of country diversity in the testing set with no bias toward particular users. To assess the generalization of the approach, we utilized a 10-fold cross-validation [32]. In pairwise country diversity analysis, all test embeddings from the ten folds are employed. To implement the aforementioned splitting strategy, we make ten train/validation/testing sets with respective proportions of 80%, 10%, and 10%. First, we perform a 'group stratified split' utilizing the 'StratifiedGroupKFold' class, from the scikit-learn toolkit [30], with K=10. This gives us the ten sets. Then, for each training set, we split it into training and validation using the 'GroupShuffleSplit' class. In both 'group stratified splits', the user ids are serving as the grouping variable.

5.1 Inferring Country of Origin of Sensor Data (RQ1)

The objective of this research question is to determine if the various sensing modalities, individually or collectively, contain country-level information, thereby enabling inference of *country of origin* from data. To achieve this, a one-versus-all binary classification task was set up for each country, and the performance of each sensor modality, separately and combined, was evaluated. The approach involved selecting one country for testing, and replacing labels for all other countries with an 'all' label, resulting in two labels: the country label and the 'all' label (e.g., Italy vs. All, Mongolia vs. All, etc.). To mitigate class imbalance, an equivalent number of samples as the number of samples for the selected country were randomly sampled from the 'all' sample. A binary classifier was trained using a random forest model on the sampled data, and the resulting accuracies averaged across the 10 folds. We used different models, such as multi-layer perceptron neural networks, XGboost, and Support vector machines, for the evaluation. However, we only report results for random forest models for brevity because they performed the best. Mean accuracy per sensor modality was determined by averaging all country accuracies.

5.2 Diversity Score (DS1) Considering Sensor Modalities (RQ2)

This research question aims to quantify country-level diversity based on various sensing modalities. We propose to assess a country's diversity through a country-level diversity score (DS1) that summarizes country differences across sensor modalities. To assess the significance of these differences, we rely on statistical tests. Each country pair for each modality and sensor data is tested. The experiment consisted of a two-group assessment, evaluating the country pairwise difference between the averages of the user embeddings across all activities. To accomplish this, each country pair was tested using a PERMANOVA test in conjunction with a PERMDISP test [4]. The PERMDISP test was necessary to ensure that a significant difference was not due to dispersion. It is important to note that the PERMANOVA tests the null hypothesis that "the centroids and dispersion of the groups as defined by measure space are equivalent for all groups." Failure to do so could result in type I errors, i.e., finding a difference in countries where there are none. This is especially true since our design is unbalanced (i.e., the number of users in each country differs). The scikit-bio framework[3] was utilized to conduct the tests, with 5000 permutations for the PERMANOVA test and 1000 permutations for the PERMDISP test, which tested the 'centroid'. These numbers were chosen empirically, to obtain results with high accuracy, while keeping performance considerations acceptable. A significant threshold of 5% was set for both tests, requiring the PERMANOVA p-value to be <= 0.05 and the PERMDISP test >= 0.05 for a test to be significant. Since both PERMANOVA and PERMDISP tests are permutation tests and have an element of randomness that can impact the results between different runs, especially for p-values close to 0.05, our strategy for almost reproducible results was to perform a series of combined tests (PERMANOVA and PERMDISP) incrementally. Each incremental test in the series contributed to the previous test by adding missing significant values (or nothing), with the testing procedure stopping when ten combined tests did not add new significant values.

Next, we introduce the country-level diversity score (DS1) across sensor modalities. This score is calculated for a given country by considering both country and sensor modality differences. The country count denotes the number of instances in which the given country differs from another country across all modalities, while the sensor modality count indicates the number of unique sensor modalities involved in these differences. By adding both counts we consider diversity originated from country and modality differences and obtain the country-level diversity score (DS1). For instance, according to Table 2, Denmark differs from Mexico only in terms of the 'App usage' and 'Location' sensors, resulting in a diversity score of 3 = 1 (country count) + 2 (modality count). Although this measure is simple, it allows us to gain an understanding of where distributional differences exist in multimodal sensor data across countries. Depending on the research objective, it may be worth considering a different approach to combining both counts that places greater emphasis on one aspect over the other.

5.3 Diversity Score (DS2) Considering Sensor Data and ADL (RQ3)

To assess the diversity of countries across the independent variable, we propose a country-level diversity score (DS2), which summarizes the differences between countries with respect to ADLs.

We employ pairwise statistical tests on sensor data (all modalities) for a specific activity and two countries to identify how countries differ with respect to the target variable. The test provides insights into how countries differ in terms of the target variable, and a deeper analysis at the sensor modality level is left for future work. To obtain reproducible results, we follow the same incremental procedure as in RQ2, and the same number of permutations is used for both tests. The country-level diversity score (DS2) across the target attribute is defined similarly to DS1, but this time across activities. For instance, when examining Denmark, we found that it differs from the UK and India in four unique activities, including Online comm./Social media, Shopping, Studying, and Walking (Table 4). Therefore, Denmark's diversity score is 6 = 2 (country count) + 4 (activity count).

6 RESULTS

6.1 Inferring Country of Origin of Sensor Data (RQ1)

In this section, we aim to examine whether each sensing modality contains country-level information, and to determine the degree of accuracy gained by combining all sensor modalities.

The results of the analysis are presented in Figure 2, which provides a breakdown of the accuracy levels achieved by each sensor modality. The average accuracy attained in inferring the *country of origin* from a single sensor modality is 64.5%, with two modalities performing well above the average. However, the 'Steps' sensor modality falls short of this mark. The 'Location' modality, on the other hand, exhibits the best performance with an average accuracy

[3] http://scikit-bio.org

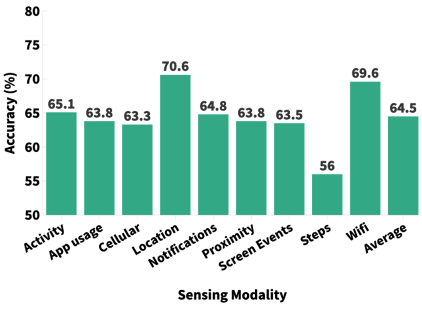

Figure 2: A comparison of the average of the 8 one-country-vs.-all binary classification accuracies, by individual sensor modalities. Random accuracy is 50%.

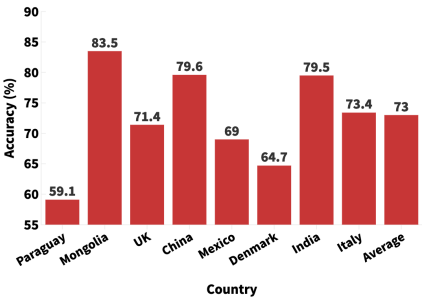

Figure 3: A comparison of the eight one-country-vs.-all binary classification accuracies with sensor data (all sensor modalities). Random accuracy is 50%.

of 70.6%. It is worth noting that the standard deviation values are moderate (less than 10% across all sensing modalities), indicating a diversity of smartphone usage patterns across countries. These findings underscore the importance of analyzing each sensor modality separately to account for inference biases. Figure 3 presents the results obtained from combining all sensor modalities. On average, it is possible to infer a country from smartphone sensor data with an accuracy of 73.0%. The country with the highest inferred accuracy is Mongolia, with an accuracy rate of 83.5%, while Paraguay has the lowest inferred accuracy rate of 59.1%. The results suggest that sensor modalities capture complementary country-level information, thereby boosting the overall accuracy of smartphone sensor data in identifying the *country of origin*.

Hence, in summary, regarding the first research question (RQ1), our analysis has revealed that, on average, sensor modalities allow for the inference of the *country of origin* of sensor data with an accuracy of 64.5%. Furthermore, we have observed that when combining sensor modalities, there is a relative gain in performance of 13.2% compared to the average accuracy of individual modalities. Our results show that on average, a country can be inferred from smartphone sensor data with an accuracy of 73.0%. Hence, these results show that sensor data contains country-level information. This again provides us a motivation into disentangling country-level distributional shifts across different sensing modalities, rather than just relying on inference performance of a target variable.

6.2 Diversity Score (DS1) Considering Sensor Modalities (RQ2)

In this section, our objective is to quantify the diversity across countries at the sensor modality level, with the aim of gaining insights into the sensors that contribute to country differences. Specifically, our analysis seeks to achieve two goals: 1) to identify statistically significant pairwise differences between countries for each sensor modality; 2) to rank countries based on a country-level diversity score (Diversity Score 1—DS1) that combines both country and sensor modality differences. It is important to note that no distinction is made between activities in this analysis, as we will explore the influence of activities in the next research question.

Table 2 displays the significant pairwise differences between countries based on sensor modalities as part of our first goal. Please note that as a result of this choice, not all country pairs appear in the Table. The PERMANOVA F statistic is shown as an effect size indicator if the PERMANOVA p-value < 0.05 (statistically significant) and left empty if the PERMDISP p-value > 0.05 (not statistically significant). We have omitted the 'Activity' and 'Screen events' sensor modalities as no significant differences were found among countries regarding these sensors. Out of the 56 possible country pairwise comparisons (e.g., Italy vs. India, Italy vs. Mongolia, etc.), 17 showed significant differences (as shown in the first column of Table 2). Our analysis revealed that sensor modalities do not capture an equal number of country differences. Specifically, 'App usage' exhibited the highest number of differences (13), followed by 'Location' (6). On the other hand, the 'Cellular' sensor modality only captured one country difference, and 'Activity' (here we do not refer to the ADL, our dependent variable, but to the simple activity captured using the Google activity recognition API, which is an independent variable used to infer ADL) and 'Screen events' did not capture any, hence not shown on the table. We further observed that country differences can be attributed to sensor modality differences. For instance, Mongolia and Paraguay differ in their readings from the 'App usage', 'Proximity', and 'Wifi' sensors. Generally, pairwise country differences are explained by 1-3 sensor modalities (out of 9 possible), but the sensor modalities that contribute to such differences vary for specific country pairs. Therefore, we can conclude that while differences between the two countries are limited, there is a large diversity of country differences when considering all countries. We also noted that most of the differences involved countries from different continents, except for 'Italy-UK', which exhibited differences in 'Location' and 'App usage'. This finding is in agreement with the previous work of Meegahapola et al. [23], which reported that on other inference tasks using the same dataset, European countries performed better for other European countries than for non-European ones.

Table 3 presents the country ordering based on the DS1. Italy holds the highest score, followed by Mongolia and Mexico. Although Italy and Mexico have almost the same DS1, Italy is distinct in terms of its sensor modalities (i.e., sensor modality count: 6) rather than its country differences (i.e., country count: 5). This

Table 2: Statistically significant differences in smartphone usage by users of different countries per sensor modality. Tests are performed on individual sensor modality embeddings. The PERMANOVA F statistic is shown if PERMANOVA p-value < 0.05 (statistically significant) and left empty if PERMDISP p-value > 0.05 (not statistically significant).

	App usage	Cellular	Location	Notifications	Proximity	Wifi	Steps
China-Mexico	3.2						
Denmark-Mexico	2.7		2.1				
Italy-China				2.5			
Italy-India		2.9					2.9
Italy-Mexico	3.4		1.9				
Italy-Mongolia	2.4					4.0	
Italy-UK	1.8		2.9				
Mexico-India	2.3						2.2
Mongolia-China	1.9						
Mongolia-India				2.0		2.7	
Mongolia-Mexico	3.5						
Mongolia-Paraguay	1.9				2.4	2.0	
Mongolia-UK					1.9		
Paraguay-Mexico	2.8		2.1				
Paraguay-UK	2.2						
UK-China	2.2		3.2				
UK-Mexico	2.4		4.4				

Table 3: Country-level diversity across sensor modalities. Country count corresponds to the number of pairwise differences for the given country. The sensor modality count is the number of unique sensor modalities involved in these pairwise differences.

Country	Diversity Score (DS1)	Country count	Sensor modality count	Involved sensor modalities
Italy	11	5	6	App usage, Cellular, Location, Notifications, Steps, Wifi
Mongolia	10	6	4	App usage, Notifications, Proximity, Wifi
Mexico	10	7	3	App usage, Human Location, Steps
India	8	3	5	App usage, Cellular, Notifications, Steps, Wifi
UK	8	5	3	App usage, Location, Proximity
China	7	4	3	App usage, Location, Notifications
Paraguay	7	3	4	App usage, Location, Proximity, Wifi
Denmark	3	1	2	App usage, Location

observation is interesting because it implies that country-level diversity of Mexico may be caused by only a few sensor modalities (i.e., sensor modality count: 3). On the other hand, Denmark has the lowest score with 1 country and 2 sensor modalities differences. It is noteworthy that while differences often emerge between two continents, this does not hold true for country-level diversity across sensor modalities.

In summary, this research question provides insights into RQ2 by proposing a country-level diversity score that considers both country and sensor modality differences. Our findings show that country-level diversity across sensor modalities significantly varies across different countries. Moreover, we observe that the 'App usage' captures the highest country diversity, followed by the 'Location' sensor. Additionally, we note that pairwise country differences can be explained by a maximum of 1-3 sensor modalities. For example, as mentioned in Table 2, Italy-China have statistically significant differences in terms of Notifications (1 modality); Mongolia-Paraguay have statistically significant differences in terms of App usage, Proximity, and Wifi (3 modalities), etc. Therefore, our results indicate that a few specific sensor modalities play a crucial role in capturing country differences.

6.3 Diversity Score (DS2) Considering Sensor Data and ADL (RQ3)

In this section, we undertake an analysis that takes into account both sensor data and the target attribute to gain a better understanding of country-level diversity across the classes of the target variable as represented by the sensor data. For this, we specifically used ADL Recognition, where target attributes contain 12 activity classes (see Section 3 for the list of activities). Our analysis has two goals: 1) to analyze country pairwise differences across ADL statistically and 2) to rank countries using a country-level diversity score (Diversity Score 2—DS2) that considers both country and activity differences.

First, we perform an analysis to investigate the extent to which sensor modalities can be used to infer each activity. We follow the same procedure as in RQ1, but this time, we focus on activities instead of countries. Figure 4 shows that the practiced activity can be inferred from each sensing modality separately with an average activity accuracy of 52.4%. Furthermore, Figure 5 demonstrates that combining sensor modalities is beneficial when inferring ADL, indicating that sensor modalities are complementary. The average activity accuracy improves to 55.3% when all sensor modalities are combined. These results reveal that differentiating a practiced

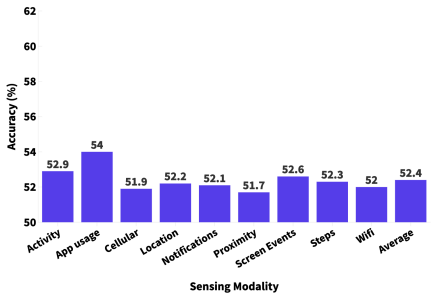

Figure 4: A comparison of the average of the 12 one-activity-vs.-all binary classification accuracies, by individual sensor modalities.

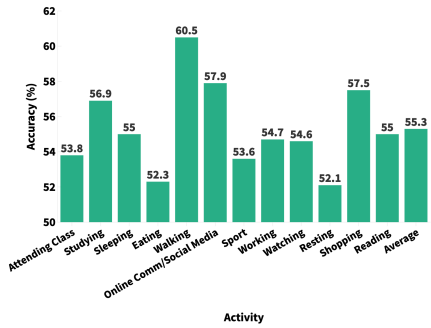

Figure 5: A comparison of one-activity-vs.-all binary classification accuracies with sensor data (all sensor modalities). Random accuracy is 50%.

activity from the other 11 ADLs using sensor data is a challenging task, as compared to a random accuracy of 50%. Prior studies have also shown that this is a challenging task, and personalization is required to attain better performance [5].

Similar to RQ2, we conducted a test to determine significant differences across countries, this time in relation to different ADL (goal 1). The results are presented in Table 4. The 'Sport' and 'Working' activities were excluded from the tables as no significant pairwise differences were found between countries. We also discarded 4 significant differences involving one country with a sample size (number of unique students) less than 15, assuming that this case might not contain enough variability in the data that describes the activity. Out of 56 possible pairwise comparisons, 18 showed significant differences (as shown in the first column of Table 4). Similar to the findings from the analysis of sensor modalities, it was observed that different activities captured varying numbers of pairwise differences between countries. Additionally, it was noted that a pairwise difference between countries could be broken down into differences in specific activities. Consequently, two countries could exhibit differences in one activity while showing similarities in another activity, as indicated by the sensor data (see Appendix A). Unlike the analysis of sensor modalities, there was no specific activity that stood out for its diversity across countries. However, more than half of the activities had at least five pairwise differences between countries. Furthermore, a single pairwise difference between countries could be broken down into as many as seven activities out of the 12 possible, which is greater than the number observed for modalities (1-3 out of 9 possible). Taken together, these findings suggest that different countries may exhibit variations in multiple ways while engaging in a particular activity. This could pose a challenge to the generalization of ADL inference models and may explain why country-specific models perform better in prior work [5].

In response to RQ3, we have shown the relevance of taking into account both sensor data and target attribute (ADL) when assessing country diversity in mobile sensing datasets. Our proposed DS2 for countries revealed that significant differences exist between countries in terms of activity diversity, and that these differences are distinct from those observed in DS1, which captures sensor modality diversity. We also noted that no activity particularly captured country diversity, but many exhibited a substantial number of country pairwise differences (>= 5). Lastly, we found that up to seven activities could account for significant country pairwise differences. In summary, our results highlight the importance of considering both target ADL and sensor data in evaluating country diversity, as they provide complementary perspectives on the issue.

7 DISCUSSION

7.1 Summary of Results

In this study, we examined the country-level diversity of a multimodal, multi-country dataset collected from 689 participants across eight countries in the context of a 12-class ADL inference task. Our investigation aimed to disentangle the influence of sensor modalities and the target attribute on cross-country generalization.

7.1.1 RQ1. We demonstrated that individual sensor modalities could somewhat infer the *country of origin* of users and are complementary, indicating that sensors can capture significant country-level information, enabling country-level comparisons. However, the ADL inference from sensor data proved to be more challenging. Overall, we provided motivation as to why sensor-level analysis is needed for to understand cross-country model generalization issues.

7.1.2 RQ2. Further analysis was conducted to assess the effectiveness of different sensor modalities in capturing country differences. Our findings indicate that the 'App usage' and 'Location' modalities were particularly effective in this regard. This highlights the importance of understanding country differences in these modalities for achieving better cross-country generalization. Interestingly, we found that the two countries differ, at most, by only three sensor modalities, but the specific sensors varied across different country pairs. This suggests that country differences are captured by only a few sensors and that investigating the content of these sensors could provide a better understanding of the factors that make countries distinct. Additionally, the country-level diversity scores for sensor modalities (DS1) revealed that countries such as Italy and Denmark differ greatly in terms of diversity. Specifically, Italy exhibits a high degree of diversity with respect to both sensor modalities and country differences, while Denmark does not. Further analysis

Table 4: Statistically significant differences in sensing features by ADL by users of different countries. PERMANOVA F statistic is shown if PERMANOVA p-value < 0.05 (statistically significant) and left empty if PERMDISP p-value > 0.05 (not statistically significant).

	Attend class	Studying	Sleeping	Eating	Online com./ Social media	Watching some-thing	Resting	Shopping	Reading	Walking

Denmark-UK		2.0						1.9		

Table 5: Country-level diversity across activities. The country count corresponds to the number of pairwise differences for the given country. The activities count is the number of unique activities involved in these pairwise differences.

Country	Diversity Score (DS2)	Country count	Activities count	Involved activities
UK	15	6	9	Eating, Online comm./Social media, Reading, Resting, Shopping, Sleeping, Studying, Walking, Watching something
China	13	6	7	Attending class, Eating, Online comm./Social media, Resting, Sleeping, Studying, Watching something
India	12	7	5	Attending class, Eating, Online comm./Social media, Sleeping, Studying
Mongolia	12	5	7	Eating, Online comm./Social media, Reading, Resting, Shopping, Sleeping, Studying
Italy	10	3	7	Attending class, Eating, Online comm./Social media, Sleeping, Studying, Walking, Watching something
Mexico	9	4	5	Online comm./Social media, Resting, Sleeping, Studying, Watching something
Paraguay	9	3	6	Attending class, Eating, Online comm./Social media, Resting, Sleeping, Studying
Denmark	5	2	3	Online comm./Social media, Shopping, Studying

of the impact of these differences could aid in understanding the challenges of cross-country generalization.

7.1.3 RQ3. Furthermore, our analysis revealed that a large number of activities exhibited numerous pairwise country differences, suggesting that there might be important variations in how users in different countries carry out daily activities, as shown by all sensors. Specifically, we found that two countries could differ in as many as seven activities, further highlighting the challenges in cross-country ADL inference. Moreover, the country-level diversity score for activities highlighted the existence of significant diversity among countries, with highly diverse countries such as the UK exhibiting a diversity score (DS2) of 16, while less diverse countries such as Denmark had a diversity score of 6. This gap in diversity scores is an important factor to consider when developing cross-country models and merits further investigation.

In summary, our study highlights the importance of considering both sensor modalities and target attributes when assessing country diversity in mobile sensing datasets. We have provided evidence of differences in country diversity across sensor modalities and activities, which have implications for the cross-country generalization of models.

7.2 Implications, Limitations, and Future Work

Our findings suggest potential implications for future research to deepen the understanding of the relationship between country-level diversity and performance/generalization. Can the proposed Diversity Scores be used as a proxy for generalization in cross-country datasets? Firstly, it would be valuable to investigate whether there is a correlation between the ability of sensor modalities to capture country differences and the performance of models trained on them. For instance, one could study if a model, when trained on modalities that capture a high number of country differences, generalizes better. Secondly, our observation that the difference between two countries can be explained by a limited number of sensor modalities

raises questions about whether accuracy differences between test countries are primarily due to the modalities where the countries differ or to other factors. In terms of practical implications, utilizing the proposed diversity scores to design experiments could facilitate a better understanding of how different countries generalize. For example, one could investigate whether training with countries that exhibit high country-level diversity scores (DS1) outperforms training with countries that exhibit low country-level diversity scores in terms of performance and generalization. Additionally, examining the impact of the country-level diversity of a test set on performance and generalization across sensor modalities and activities could provide insights into how to design more robust mobile sensing models. Finally, it may be worthwhile to explore the potential benefits of adding a diverse country to an existing dataset to improve performance and generalization.

This study has several limitations that should be taken into account. The first point to consider pertains to the dataset. The data was collected in the Fall of 2020 during the COVID-19 pandemic, a time when participants, who were university students from eight different countries, spent a significant amount of time at home. Therefore, we should not assume that this cohort represents the entire university student population of these countries. It is important to consider these aspects when interpreting the results. Additionally, regarding sample sizes, the number of unique students per country varied from 20 (Mexico) to 240 (Italy), with a median of 41 unique students. Although these numbers are statistically sufficient for testing, larger sample sizes are necessary to draw more robust conclusions at scale. Secondly, the proposed country-level diversity score (DS2) across ADL relies on tests that evaluate country differences in sensor data for combined sensors. Although this provides insights of the relationship between country differences and ADL at the smartphone level, it would be interesting to explore further how country differences relate to activities for each individual modality. However, this analysis was not provided because the applicability of the method on all sensor modalities needed to be tested first. These analyses could help disentangle the relationship between countries, sensor modalities, and target attributes. Thirdly, statistical tests were used on the user embeddings of country pairs to assess country differences. By examining the embeddings (see Appendix A), it was observed that assessing two-country differences is not always straightforward. To facilitate the tests, it may be worth exploring techniques that increase data separation prior to applying statistical tests, such as applying Linear Discriminant Analysis (LDA) [15] on embeddings prior to testing. Fourthly, this study focused solely on a specific target attribute (ADL). It would be interesting to investigate whether other target attributes, such as social context and mood, produce the same country-level diversity scores (DS2) as ADL. Exploring different target attributes could provide additional insights into country distributional shifts understanding. As a fifth point, this work focused on investigating the differences captured by sensor modalities and sensor data for the country of origin. It could be worthwhile to investigate how different states or regions within a country differ. Additionally, the proposed methodology could be extended to inherent diversity attributes like gender and age to investigate their impact on sensor modalities, the target attribute, and generalization. Understanding how differences exist across users, how they are captured by sensor modalities, and how they can potentially influence generalization is particularly important for the health and well-being related mobile sensing-related applications. Finally, for the country-level diversity scores, the choice was made to add the count of pairwise country differences and individual sensor modalities/target attribute differences. Future work could explore other ways of computing these scores (e.g., a weighted average) that are more appropriate for understanding generalization issues, depending on the requirement.

Our work adds to the important topic of generalization across countries, which has been studied in images [9] and text [21], but less on mobile datasets. Our work also contributes analysis of a multi-country dataset that includes both Global North and South countries with the goal of designing for all of them while taking into account their specificities.

8 CONCLUSION

Our study, which focuses on ADL inference, utilized a large-scale, multimodal, multi-country dataset to investigate country-level diversity across sensor modalities and activities, with the aim of disentangling both in order to gain insights on how to achieve better generalization in cross-country datasets. By proposing two country-level diversity scores for sensor modalities and activities, we identified statistically significant differences between countries that can be explained by specific sensor modalities and ADL. Our results indicate that Italy has the highest country-level diversity across sensor modalities, the UK has the highest across activities, and Denmark has the lowest for both country-level diversities. However, we observe that these diversity scores do not seem to correlate, except for Paraguay and Denmark, which have the same score. In terms of country pairwise differences, our analysis shows that the 'App usage' and 'Location' sensors have the highest ability to distinguish between countries. On the other hand, we found that no single activity stands out in terms of the ability to distinguish between countries, but many activities have a high ability to do so. Finally, we discovered that country pairwise differences could be explained by only 1-3 sensor modalities and 1-7 activities, which indicates that cross-country differences between two countries may be captured by only a few sensors but many activities. As discussed, our work opens several research directions towards diversity-aware mobile sensing systems.

A APPENDIX

In this Appendix, we present two visualization plots that depict country differences across all activities (Figure 6) and between 'Eating' and 'Shopping' (Figure 7), as revealed by sensor data from all modalities. When the p-value approaches the significance threshold, a closer examination of the embeddings can aid in a better understanding of country differences. For example, when we inspect the differences between Mongolia and the UK, which had a low PERMANOVA p-value and a low PERMDISP p-value (left plot in Figure 6), we observe that the embeddings of both countries are mixed in one of the clusters, indicating that the significant PERMANOVA test might be due to dispersion. Conversely, when we examine the UMAP plot for the UK and India (right plot in Figure 6), the separation between the two countries' embeddings is more distinct. Similarly, ADL differences can be visualized. For instance, the UK and China display differences in 'Eating' but not in 'Shopping' (see Figure 7).

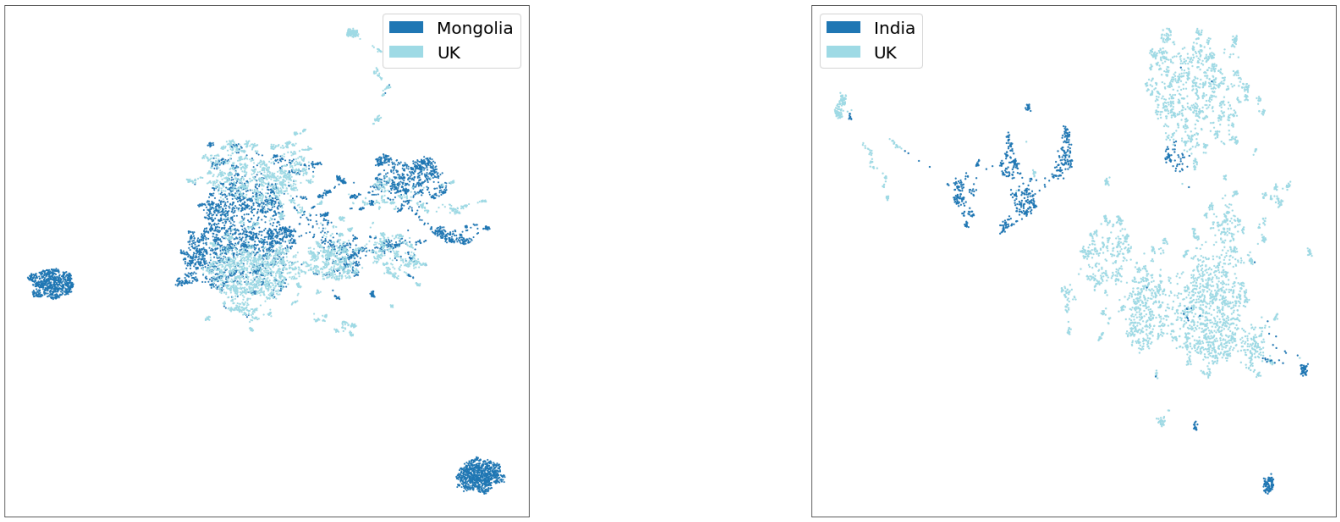

Figure 6: On the left, UMAP plot comparing Mongolia and the UK users. On the right, UMAP plot comparing the UK and India users. Each dot on a plot is the 2D projection of a user embedding capturing sensor data (all modalities) across all activities

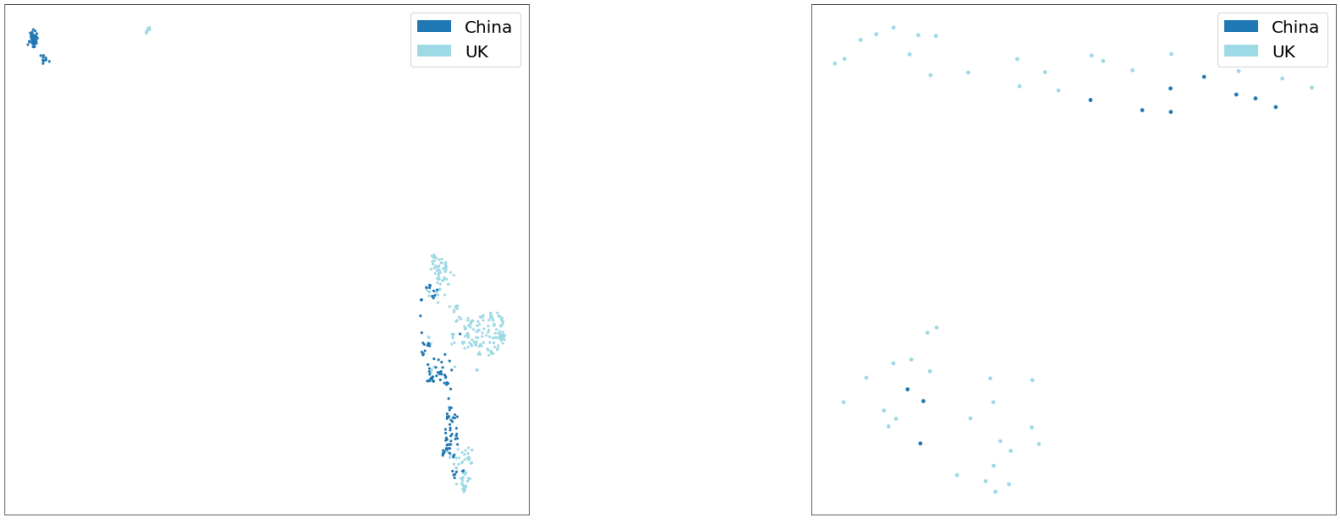

Figure 7: On the left, UMAP plot comparing China and the UK users while 'Eating'. On the right, UMAP plot comparing China and the UK users while 'Shopping'. Each dot on a plot is the 2D projection of a user embedding capturing sensor data (all modalities) for a given activity

A Deep Dive into Dataset Imbalance and Bias in Face Identification

ABSTRACT

As the deployment of automated face recognition (FR) systems proliferates, bias in these systems is not just an academic question, but a matter of public concern. Media portrayals often center imbalance as the main source of bias, i.e., that FR models perform worse on images of non-white people or women because these demographic groups are underrepresented in training data. Recent academic research paints a more nuanced picture of this relationship. However, previous studies of data imbalance in FR have focused exclusively on the face *verification* setting, while the face *identification* setting has been largely ignored, despite being deployed in sensitive applications such as law enforcement. This is an unfortunate omission, as 'imbalance' is a more complex matter in identification; imbalance may arise in not only the training data, but also the testing data, and furthermore may affect the proportion of identities belonging to each demographic group *or* the number of images belonging to each identity. In this work, we address this gap in the research by thoroughly exploring the effects of each kind of imbalance possible in face identification, and discuss other factors which may impact bias in this setting.

1 INTRODUCTION

Automated face recognition is becoming increasingly prevalent in modern life, with applications ranging from improving user experience (such as automatic face-tagging of photos) to security (e.g., phone unlocking or crime suspect identification). While these advances are impressive achievements, decades of research have demonstrated disparate performance in FR systems depending on a subject's race [4, 32], gender presentation [1, 2], age [23], and other factors. This is especially concerning for FR systems deployed in sensitive applications like law enforcement; incorrectly tagging a personal photo may be a mild inconvenience, but incorrectly identifying the subject of a surveillance image could have life-changing consequences. Accordingly, media and public scrutiny of bias in these systems has increased, in some cases resulting in policy changes.

One major source of model bias is dataset imbalance; disparities in rates of representation of different groups in the dataset. Modern FR systems employ neural networks trained on large datasets, so naturally much contemporary work focuses on what aspects of the training data may contribute to unequal performance across demographic groups. Some potential sources that have been studied include imbalance of the proportion of data belonging to each group [17, 41], low-quality or poorly annotated images [13], and confounding variables entangled with group membership [1, 23, 24].

Dataset imbalance is a much more complex and nuanced issue than it may seem at first blush. While a naive conception of 'dataset imbalance' is simply as a disparity in the *number* of images per

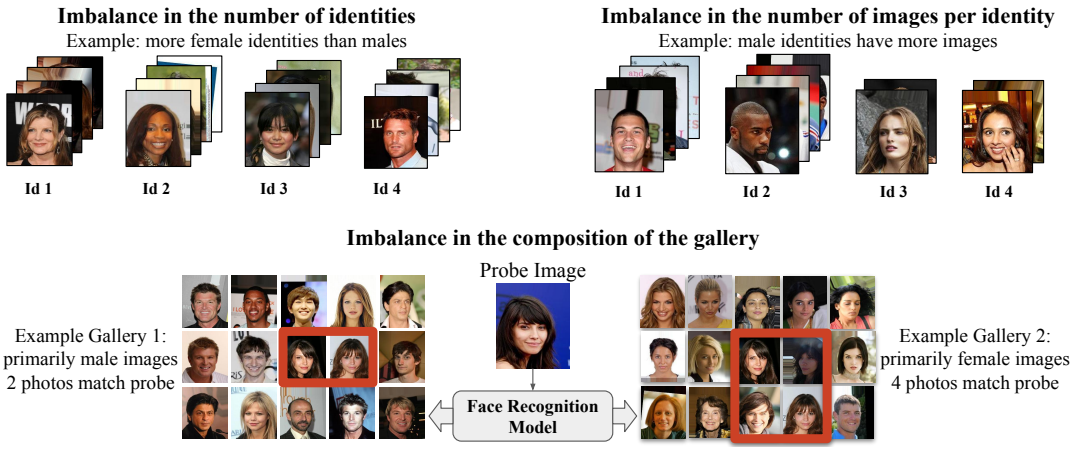

Figure 1: Examples of imbalance in face identification. Top left: data containing more female identities than male identities. Top right: data containing the same number of male and female identities, but more images per male identity. Bottom: two possible test (gallery) sets showing how the effects of different kinds of imbalance may interact.

group, this disparity can manifest itself as either a gap in the number of identities per group, or in the number of images per identity. Furthermore, dataset imbalance can be present in different ways in both the training and testing data, and these two source of imbalance can have radically different (and often opposite) effects on downstream model bias.

Past work has only considered the *verification* setting of FR, where testing consists of determining whether a pair of images belongs to the same identity. As such, 'imbalance' between demographic groups is not a meaningful concept in the test data. Furthermore, the distinction between imbalance of identities belonging to a certain demographic group versus that of images per identity in each demographic group has not been carefully studied in either the testing or the training data. All of these facets of imbalance are present in the face *identification* setting, where testing involves matching a probe image to a gallery of many identities, each of which contains multiple images. We illustrate this in Figure 1.

In this work, we unravel the complex effects that dataset imbalance can have on model bias for face identification systems. We separately consider imbalance (both in terms of identities or images per identity) in the train set and in the test set. We also consider the realistic social use case in which a large dataset is collected from an imbalanced population and then split at random, resulting in similar dataset imbalance in both the train and test set. We specifically focus on imbalance with respect to gender presentation, as (when restricting to only male- and female-identified individuals) this allows the proportion of data in each group to be tuned as a single parameter, as well as the availability of an ethically obtained identification dataset with gender presentation metadata of sufficient size to allow for subsampling without significantly degrading overall performance.

Our findings show that each type of imbalance has a distinct effect on a model's performance on each gender presentation. Furthermore, in the realistic scenario where the train and test set are similarly imbalanced, the train and test imbalance have the potential to interact in a way that leads to systematic underestimation of the true bias of a model during an audit. Thus any audit of model bias in face identification must carefully control for these effects.

The remainder of this paper is structured as follows: Section 2 discusses related work, and Section 3 introduces the problem and experimental setup. Sections 4 and 5 give experimental results related to imbalance in the training set and test set, respectively, and Section 6 gives results for experiments where the imbalance in the training set and test set are identical. In Section 7.1, we evaluate randomly initialized feature extractors on test sets with various levels of imbalance to further isolate the effects of this imbalance from the effects of training. In Section 7.2, we investigate the correlation between the performance of models trained with various levels of imbalance and human performance.

2 RELATED WORK

2.1 Imbalance in verification

Even before the advent of neural network-based face recognition systems, researchers have studied how the composition of training data affects verification performance Phillips et al. [32] compared algorithms from the Face Recognition Vendor Test [33] and found that those developed in East Asia performed better on East Asian Faces, and those developed in Western countries performed better on Caucasian faces Klare et al. [23] expanded on these results by comparing performance across race, gender presentation, and age cohorts, observing that training exclusively on images of one demographic group improved performance on that group and decreased performance on the others. They further conclude that training on data that is "well distributed across all demographics" helps prevent extreme bias.

Multiple verification datasets have been proposed in the interest of eliminating imbalance as a source of bias in face verification. The *BUPT-BalancedFace* dataset [41] contains an approximately equal number of identities and images of four racial groups[1]. *Balanced Faces in the Wild* [35] goes a step further, balancing identities and

[1]This work also introduces *BUPT-GlobalFace*, which instead approximately matches the distribution across races to that of the world population.

images across eight categories of race-gender presentation combinations. Also of note is the *BUPT-CBFace* dataset [43], which is class-balanced (each identity possesses the same number of images), rather than demographically balanced.

Some recent work in verification has questioned whether perfectly balanced training data is in fact an optimal setting for reducing bias Albiero et al. [1] studied sources of bias along gender presentation; among their findings, they observe that balancing the amount of male and female training images and identities in the training data reduces, but does not eliminate, the performance gap between gender presentations. Similarly, [17] trained models on data with different racial makeups, finding that models which were trained with more images of African subjects had lower variance in performance on each race than those which were trained on balanced data.

2.2 Bias in Identification

Although the effect of imbalance on bias has only been explicitly studied in face verification, there is some research on identification which is relevant. The National Institutes of Standards and Technology performed large-scale testing of commercial identification algorithms, finding that many (though not all) exhibit gender presentation or racial bias [16]. The evaluators speculate that the training data or procedures contribute to this bias, but could not study this hypothesis due to the proprietary nature of the models. [13] evaluated commercial and academic models on a variant of identification in which each probe image is compared to 9 gallery images of distinct identities, but belonging to the same skin type and gender presentation. They find that academic models (and some, but not all, commercial models) exhibit skin type and gender presentation bias despite a testing regime which makes imbalance effectively irrelevant.

2.3 Imbalance in Deep Learning

Outside the realm of facial recognition, there is much study about the impacts of class imbalance in deep learning. In standard machine learning techniques, i.e., non-deep learning, there are many well-studied and proven techniques for handling class imbalances like data-level techniques [5, 6, 39], algorithm-level methods [15, 25, 28], and hybrid approaches [7, 29, 37]. In deep learning, some take the approach of random over or under sampling [19, 26, 34]. Other methods adjust the learning procedure by changing the loss function [42] or learning cost-sensitive functions for imbalanced data [22]. We refer the reader to [3, 21], for a thorough review of deep learning-based imbalance literature. Much of the class-imbalance work has been on computer vision tasks, though generally has not examined specific analyses like we present in this work like network initialization, face identification, or intersectional demographic imbalances.

2.4 Other sources of bias in facial recognition

Face recognition is a complex, sociotechnical system where biases can originate from the algorithms [11], preprocessing steps [14], and human interpretations [9]. While we do not explicitly examine these sources, we refer the reader to [31, 38] for a broader overview of sources of bias in machine learning.

3 FACE IDENTIFICATION SETUP

Face recognition has two tasks: face verification and face identification. The first refers to verifying whether a person of interest (called the *probe image*) and a person in a reference photo are the same. This is the setting that might be applied, e.g., to phone unlocking or other identity confirmation. In contrast, face identification involves matching a probe image against a set of images (called the *gallery*) with known identities. This application is relevant to search tasks, such as identifying the subject of a photo from a database of driver's license or mugshot photos.

In a standard face recognition pipeline, an image is generally first pre-processed by a face detection system which may serve to locate and align target faces to provide more standardized images to the recognition model. State-of-the-art face recognition models exploit deep neural networks which are trained on large-scale face datasets for a classification task. At test time, the models work as feature extractors, so that the similarity between a probe image and reference photo (in verification) or gallery photos (in identification) is computed in the feature space. In verification, the similarity score is then compared with a predefined threshold, while in identification a k-nearest neighbors search is performed using the similarity scores with the gallery images.

We focus on the face identification task in our experiments and explore how different kinds of data balance affect the models performance across demographic groups (specifically, the disparity in performance on male and female targets). We also analyze how algorithmic bias correlates with human bias on InterRace, a manually curated dataset specifically designed for bias auditing, with challenging face recognition questions and provided annotations for gender presentation and skin color [13].

Our experiments use state-of-the-art face recognition models. We train MobileFaceNet [8], ResNet-50, and ResNet-152 [18] feature extractors each with a CosFace and ArcFace head which improve the class separability of the features by adding angular margin during training [12, 40]. For training and evaluation we use the CelebA dataset [30], which provides annotations for gender presentation. As our main research questions focus on the impact of class imbalance, we pay special attention to the balance of the gender presentation attribute in our training. The original dataset contains more female identities. As such, we create a balanced training set containing 140,000 images from 7,934 identities with equal number of identities and total number of images from each gender presentation. We also create a perfectly balanced test set containing 14,000 images from 812 identities. The identities in the train and test sets are disjoint. We call these the *default train* and *default test* sets. All models are trained with class-balanced sampling to ensure equal contribution of identities to the loss. We additionally include results for models trained without over-sampling in Appendix A.5.

Recall that our research question is to investigate how class imbalances affect face identification. In order to answer this question, we train models on a range of deliberately imbalanced subsamples of the default training set, and test models on a range of deliberately imbalanced subsamples of the default test set, in order to explore the impact on the model's performance for each gender presentation.

To evaluate the models, we compute rank-1 accuracy over the test set. Specifically, for each test image we treat the rest of the

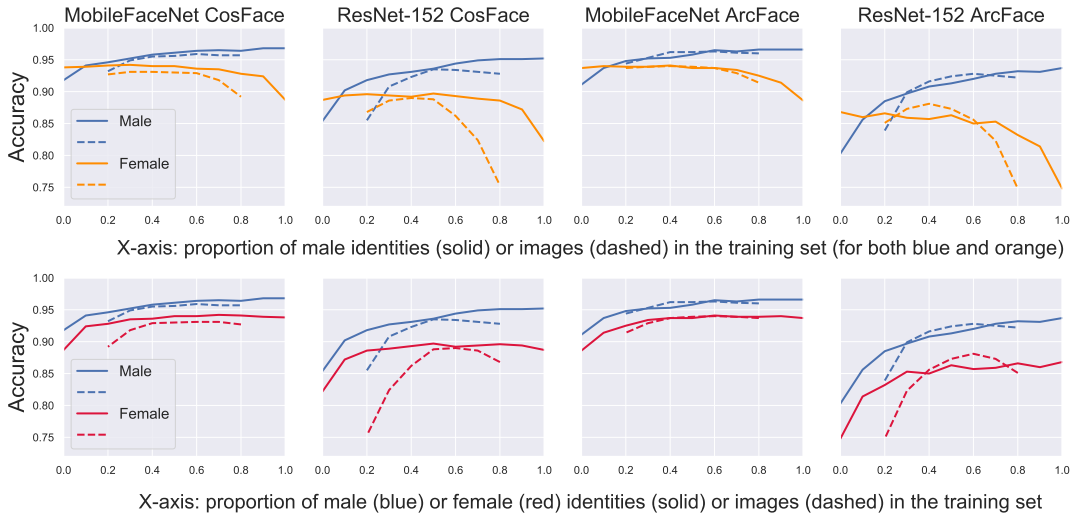

Figure 2: Train Set Imbalance. Results of experiments that change the train set gender presentation balance. Top row: male and female accuracy are plotted against the proportion of male data in the train set. Bottom row: for an alternate view, female accuracy is flipped horizontally, so that it is plotted against the proportion of *female* data in the train set. All models are tested on the default balanced test set.

test set as gallery images and find if the closest gallery image in the feature space (as defined by cosine similarity) of a model is an image of the same person.

When we make comparisons with human performance (Section 7.2), we use the InterRace dataset [13]. Since the InterRace dataset is derived from both the CelebA and LFW [20] datasets, we additionally train models on the InterRace-train split of CelebA, containing images of identities not included in the InterRace dataset. Similar to other experiments, we train models with varying levels of either identity and image imbalance.

4 BALANCE IN THE TRAIN SET

4.1 Balancing the number of identities

Experiment Description. To explore the effect of train set balance in the number of identities on gender presentation bias, we construct train data splits with different ratios of female and male identities, while ensuring that the average number of images per identity is the same across gender presentations. Therefore, in all splits we have the same total number of images and total number of identities, but the proportion of female and male identities varies. We consider splits with $0:10$, $1:9$, $2:8$, ..., $10:0$ ratios, each having 70,000 total images from 3967 identities. We evaluate the models on the (perfectly balanced) default test set and report rank-1 face identification accuracy as described in Section 3. More details of train set splits can be found in Table 1.

Results. We compute accuracy scores separately for male and female test images for models trained on each of the train splits and depict them in Figure 2 with solid lines. From the first row plots, we observe that a higher proportion of male identities in the train set leads to an increase in male accuracy and decrease in female accuracy, with the most significant drops occurring near the extreme $10:0$ imbalance. This indicates that it is very important to have at least a few identities from the target demographic group in the train set; once the representation of the minority group reaches 10%, the marginal gain of additional identities becomes less. We also observe that for most models, the female accuracy drops slightly when the proportion of female identities exceeds 80% of the training data, which does not happen to the male group. Consult Table 2 for the numerical results.

Regarding the model architectures, MobileFaceNet models trained with both CosFace and ArcFace heads outperform ResNet models on both female and male images and have smaller absolute accuracy gap. However, the error ratio is similar across the models, see Table 2. Finally, the accuracy gap is closed for all models when the train set consists of about 10% male and 90% female identities.

In addition, in the second row of Figure 2 we compare how similar these trends are for females and males by plotting female accuracy against the proportion of *female* identities in the train set. One can see that for MobileFaceNet models the accuracy on male and female images increases similarly when increasing the proportion of "target" identities up to 80%. However, for ResNet models adding more female identities in the train set results in smaller gains compared to the effect of adding more male identities on male accuracy.

4.2 Balancing the number of images per identity

In the previous subsection, we fixed the average number of images per identity in each gender presentation and adjusted the number of identities. We now will do the reverse: fix the number of identities and vary the images per identity.

Experiment Description. We change the average number of images per male and female identity, but fix the number of identities of each gender presentation. We consider ratios $2:8$, ..., $8:2$, each

Figure 3: Test Set Imbalance. Results of experiments that change the test set gender presentation balance. Top row: male and female accuracy are plotted against the proportion of male data in the test set. Bottom row: for an alternate view, female accuracy is flipped horizontally, so that it is plotted against the proportion of *female* data in the test set. All models are trained on the default balanced train set. For each experiment, the test set was split with 5 random seeds, and the results are averaged across seeds.

having 70,000 images from 7,934 identities. We do not consider more extreme ratios, which would result in identities with fewer than 3 images.

Results. The dashed lines in Figure 2 illustrate the accuracy of the models trained on described data splits. From the first row plots we see that, similar to the previous experiment, increasing the number of male images in the train set leads to increased accuracy on male and decreased accuracy on female images. Interestingly, we observe a decrease in performance for both demographic groups when the images of that group constitute more than 60% of train data; this is most easily visible in the second row of Figure 2. However, we find that this effect results from the widely used class-balanced sampling training strategy, and models trained without the default oversampling are more robust to imbalance in the number of images per identity, see details in Section A.5 and Figure 8. The "fair point" where female accuracy is closest to male accuracy occurs when around 20% of images are of males.

When comparing the effect of imbalance in the number of identities and the number of images per identity (solid and dashed lines respectively in Figure 2), we see that ResNet models are more susceptible to image imbalance than to identity imbalance, which is also a phenomenon specific to the common class-balanced sampling.

5 BALANCE IN THE TEST SET

5.1 Balancing the number of identities

Experiment Description. Analogous to the train set experiments, we split the test data (the gallery) with different ratios of female and male identities, while keeping the same average number of images per identity for both demographic groups. For each ratio, we split the test data with 5 random seeds and report average rank-1 accuracy of the models trained on default train data. The results are shown in the solid lines of Figure 3, as well as in Table 4.

Results. We observe that increasing the proportion of identities of a target demographic group in the test set hurts the model's performance on that demographic group, and this trend is similar for male and female images. Intuitively, this is because face recognition models rarely match images to one of a different demographic group; therefore by adding more identities of a particular demographic group, we add more potential false matches for images from that demographic group, which leads to higher error rates. We also see that ResNet models are more sensitive to the number of identities in the gallery set than MobileFaceNet models.

5.2 Balancing the number of images per identity

Experiment Description. Now, we investigate how increasing or decreasing the number of images per identity affects the performance and bias of the models. Again, we split the test sets with different ratios of total number of images across gender presentations, but same number of identities, each with 5 random seeds. These results are recorded as dashed lines in Figure 3, as well as in Table 5.

Results. Unlike the results with identity balance, increasing the average number of images per identity leads to performance gains, since this increases the probability of a match with an image of the same person. Also, image balance affects the performance more significantly than identity balance, and these trends are similar across all the models and both gender presentations. Finally, we note that the "fair point" for image balance in the test set occurs

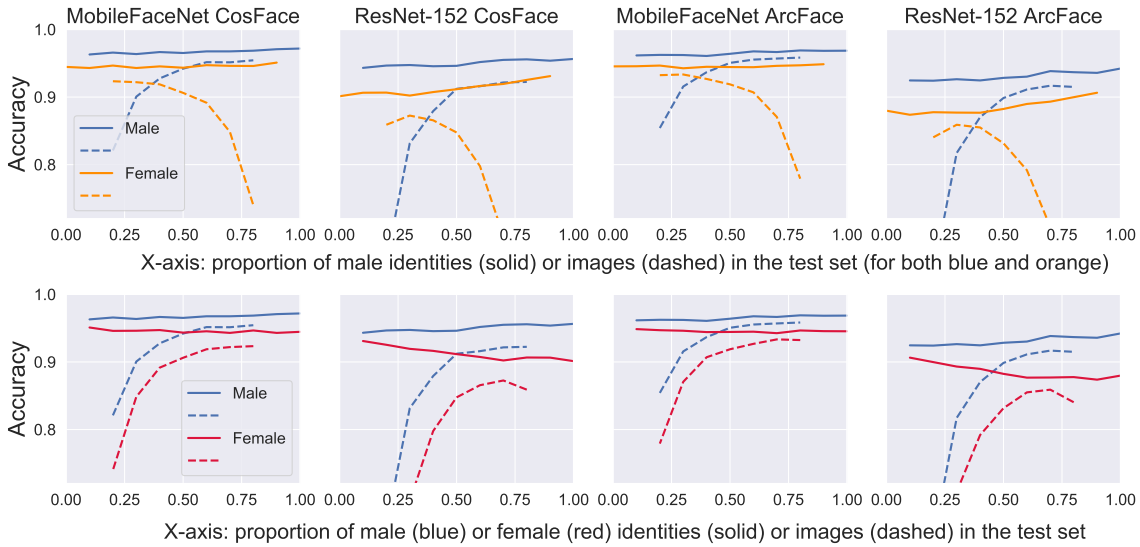

Figure 4: Train & Test Set Imbalance. Results of experiments that adjust the gender presentation balance in both the train and test set. Top row: male and female accuracy are plotted against the proportion of male data used in both the train and test set. Bottom row: for an alternate view, female accuracy is flipped horizontally, so that it is plotted against the proportion of *female* data in both the train and test set. For each experiment, the test set was split with 5 random seeds, and the results are averaged across seeds.

at about 30% male images; contrast this with identity balance, for which no fair point appears to exist.

6 A CAUTIONARY TALE: MATCHING THE BALANCE IN THE TRAIN AND GALLERY DATA

Using our findings from above, we conclude that common machine learning techniques to create train and test splits can lead to Simpson's paradoxes which lead to a false belief that a model is unbiased. It is standard practice to make random train/test splits of a dataset. If the original dataset is imbalanced, as is commonly the case, the resulting splits will be imbalanced in similar ways. As we have seen above, the effects of imbalance in the train and test splits may oppose one another, causing severe underestimation of model bias when measured using the test split. This occurs because the minority status of a group in the train split will bias the model towards low accuracy on that group, while the correspondingly small representation in the test split will cause an increase in model accuracy, partially or entirely masking the true model bias. The results for these experiments are presented in Figure 4 and Tables 6, 7.

Balancing the number of identities We create train and test sets with identical distributions of identities. Recalling the results from prior experiments, increasing the number of identities for the target group in the training stage improves accuracy on that group, while adding more identities in the gallery degrades it. Interestingly, when we increase the proportion of male identities in *both* train and test sets, we observe gains in both male and female accuracy, and that trend is especially strong for ResNet models.

Balancing the number of images per identity Having more images is beneficial in both train and test stages. Therefore, the effect of image balance is amplified when both train and test sets are imbalanced in a similar way. Similar to the train set experiments, having more than 70% female images in both train and test sets leads to slight drops in female accuracy on ResNet models, which again is a result of the default class-balanced oversampling strategy.

7 BIAS COMPARISONS

We ask two concluding questions: one about whether class imbalance captures all the inherent bias and the other about how the bias we see compares to human biases. First, we explore how data imbalances cause biases in random networks and find surprising conclusions. Then, we ask how class imbalances in machines compare to how humans exhibit bias on face identification tasks.

7.1 Bias in random feature extractors

Given a network with random initializations, we would expect that evaluation on a balanced test set would result in equal performance on males and females, and likewise that male performance on a set with a particular proportion of male identities would be the same as female performance when that proportion is reversed. However, this is not the case. We test randomly initialized feature extractors on galleries with varying levels of image imbalance. Figure 5 summarizes the results of these experiments. We observe that both models have higher male performance when the test set is perfectly balanced, and that performance on males is higher when they make up 80% of the test set than female performance when they make up 80% of the test set. This provides strong evidence

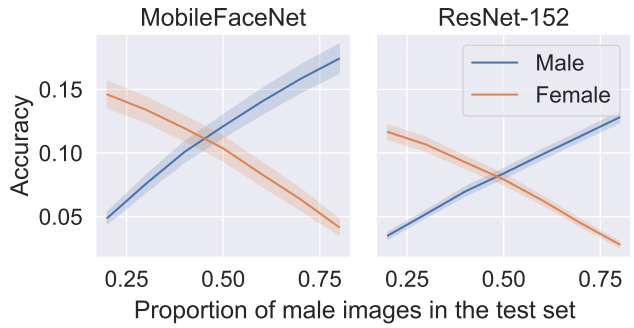

Figure 5: Random Feature Extractors. The plot illustrates male (blue) and female (orange) accuracy of random feature extractors against the proportion of male images in the test set. The standard deviation is computed across 10 random initializations.

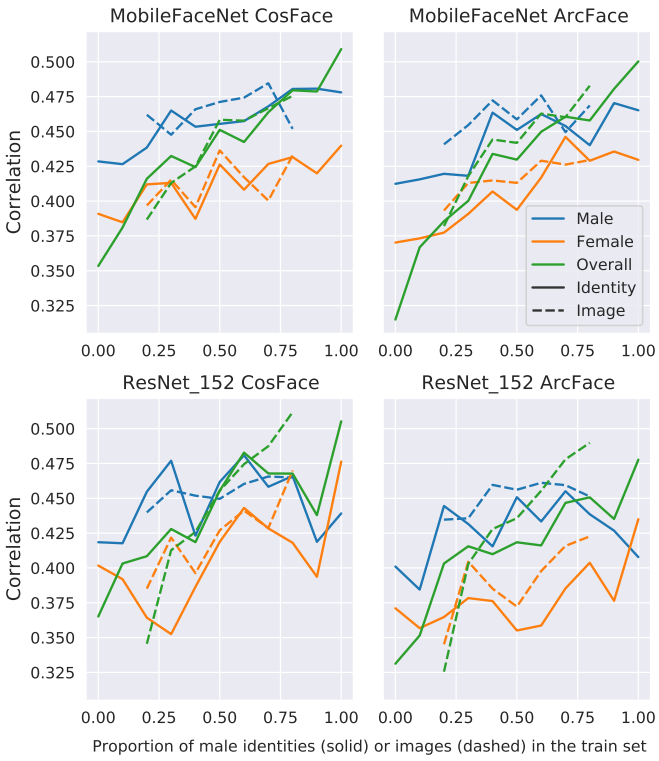

Figure 6: Pearson correlation of $L2$ ratio vs. human accuracy for various models as proportion of male training data varies.

that there are sources of bias that lie outside what we explore here and which are potential confounders to a thorough study of bias in face identification; further work on this is warranted.

7.2 Are models biased like humans?

Numerous psychological and sociological studies have identified gender, racial, and other biases in human performance on face recognition tasks. [13] studied whether humans and FR models exhibit similar biases. They evaluated human and machine performance on the curated InterRace test questions, and found models indeed tend to perform better on the same groups as, and with comparable gender presentation bias ratios to, humans. In this section, we use their human survey data to explore two related questions: how correlated are model and human performance *at the question level*, and how does this change with different levels of imbalance in training data?

To answer these questions, we define a metric which allows us to distinguish how well a model performs on each InterRace identification question. Let

$$L_2 \text{ ratio} = \frac{\|v_{probe} - v_{false}\|_2}{\|v_{probe} - v_{true}\|_2 + \|v_{probe} - v_{false}\|_2},$$

where v_{probe}, v_{true}, v_{false} are the feature representations of the probe image, the correct gallery image, and the nearest incorrect gallery image, respectively.[2] This value is 1 when the probe and correct image's representations coincide, 0 when the probe and incorrect image's representations coincide and 0.5 when the probe's representation is equidistant from those of the correct and incorrect image. Figure 7 depicts examples of scatterplots comparing model confidence to human accuracy on each InterRace question.

Figure 6 shows the correlation between $L2$ ratio and human performance for various models at each of the training imbalance settings that we have considered in earlier experiments. We see that the correlation between these values over *all* questions tends to rise as the proportion of male training data increases. However, the correlation when separately considering male and female questions does not rise as monotonically, or as much, from left to right as the overall correlation does. This suggests that the correlation between human and machine performance is largely driven by the fact that models and humans both find identifying females more difficult than identifying males, and that this disparity is exacerbated when the model in question is trained on male-dominated data. On the other hand, the *particular* males and females that are easier or harder to identify appear to differ between models and humans, which suggests the *reasons* for bias in humans and machines are different.

8 ACTIONABLE INSIGHTS

We note five actionable insights for machine learning engineers and other researchers from this work. First, **overrepresenting the target demographic group can sometimes hurt that group**. Sometimes having more balanced data is the key. Also, class-balanced sampling might hurt representation learning when the data is not balanced with respect to the number of images per identity. Second, **gallery set balance is as important as train set balance**, contrary to how face verification class imbalances work. Third, **having the same distribution of identities and average number of images per identity is not an unbiased way to evaluate a model**,

[2]We note that other measures of confidence in a k-nearest neighbors setting, such as those discussed in [10], are inappropriate for this application.

since the effects of balance in train and test sets can be amplified (in case of images) or cancel each other (in case of identities). Fourth, **train and test class imbalances are not the only cause of bias** in face identification evaluation since even random models do not perform equally poorly on female and male images. Finally, even though both humans and machine find female images more difficult to recognize, **it seems that the reasons for bias are different in people and models**. We know that this work sheds light on common mistakes in bias computations for many facial recognition tasks and hope that auditors and engineers will incorporate our insights into their methods.

A APPENDIX

A.1 Broader impact and limitations

In this work we explore the effects of various forms of data imbalance on bias in face identification, and we hope that practitioners will take our findings into account when performing bias auditing. However, it is important to understand that biases can originate from various sources besides data imbalance and therefore models should be carefully evaluated for other bias factors.

The availability of high quality datasets, which are suitable for the identification task (as opposed to verification), have demographic metadata/annotation for both train and test sets, and contain enough identities and images belonging to each demographic group to allow for subsampling, is extremely limited. For this reason we focus solely on gender bias and leverage CelebA dataset, which meets these criteria. Also, using a binary demographic attribute (such as gender, when restricting only to male- and female-presenting identities) allows the proportion of data in each group to be conveniently tuned as a single parameter, which in turn makes interpreting results more straightforward.

A.1.1 Details on CelebA. CelebA is a publicly available dataset, which is constructed from CelebFaces dataset [36] and contains face images collected from the Internet.

A.2 Training details

We pre-process CelebA images by aligning them using the provided facial landmarks and cropping to 112x112 size. All face recognition models are trained with Focal loss [27] using SGD for 100 epochs with learning rate of 0.1, momentum of 0.9 and weight decay of 5e-4. The learning rate is reduced by 10 times at epochs 35, 65 and 95. Horizontal flip data augmentation is used during training. For the model architectures, we use implementation from publicly available github repository `face.evoLVe.PyTorch`[3]. We run our experiments on NVIDIA GeForce RTX 2080 Ti machines and each experiment takes from 6 to 12 hours of compute time on one GPU.

A.3 Experimental details

A.4 Model vs. human scatterplots

Figure 7 shows two example scatterplots comparing model L2 ratio (our proxy for confidence defined in section 7.2) against human accuracy on each question in the InterRace identification dataset [13].

A.5 Results for models trained without class-balanced sampling.

To explore the effect of class-balanced sampling on the results of our experiments, we train additional models without any oversampling strategies. Figures 8 - 10 show results of our experiments for MobileFaceNet and ResNet-152 models trained without oversampling. We find that most trends are similar to ones observed in the models trained with class-balanced sampling, however models trained without oversampling are more robust to balance in the number of images per identity, see Figure 8. In particular, the effect of balancing the number of images (dashed lines) is similar to the effect of balancing the number of identities (solid lines) for all models, but ResNet-152 trained with ArcFace head. This leads us to a conclusion that using class-balanced sampling strategy is not beneficial in scenarios of severe imbalance in number of images per identity in face recognition models.

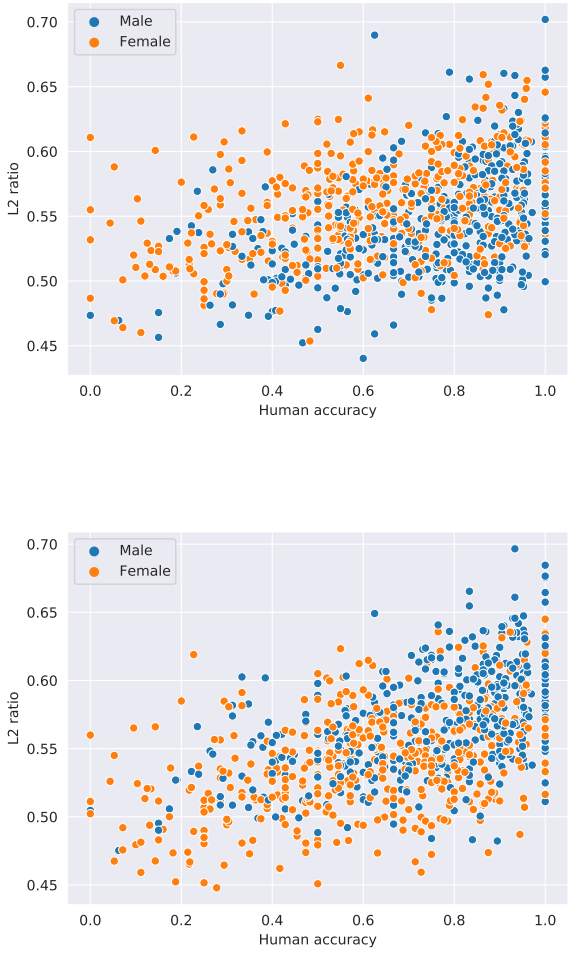

Figure 7: Scatterplots of model L2 ratio vs. human accuracy on each question in the InterRace identification dataset. Both models are MobileFaceNets trained with CosFace loss. (Left) a model trained on exclusively female images. (Right) a model trained on exclusively male images.

A.6 Additional Plots and Tables

Figures 11 - 14 supplement those in sections 5 - 6. Figure 11 shows the results of the train set imbalance experiment when evaluated on the InterRace test set. Figures 12 - 14 show results for ResNet-50 (with ResNet-152 results shown again for comparison). Tables 2 - 7 precisely detail the number of male and female identities and images used in each experiment, as well as the accuracy on male and female targets and the female-to-male error ratio.

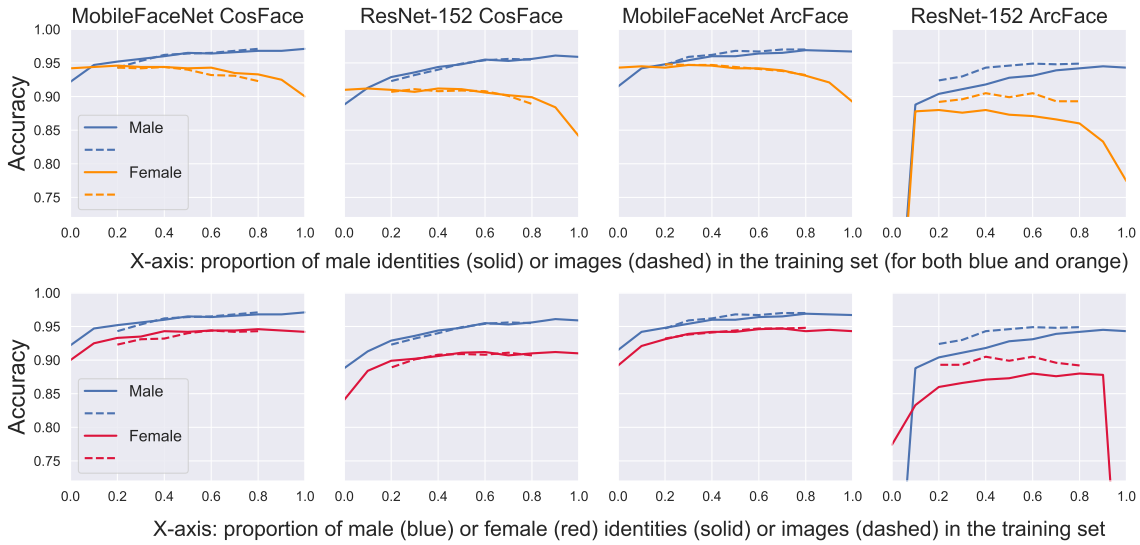

Figure 8: Train Set Imbalance. Results of experiments that change the train set gender presentation balance for MobileFaceNet and ResNet-152 models trained without class-balanced sampling. Top row: male and female accuracy are plotted against the proportion of male data in the train set. Bottom row: for an alternate view, female accuracy is flipped horizontally, so that it is plotted against the proportion of *female* data in the train set. All models are evaluated on the default balanced test set.

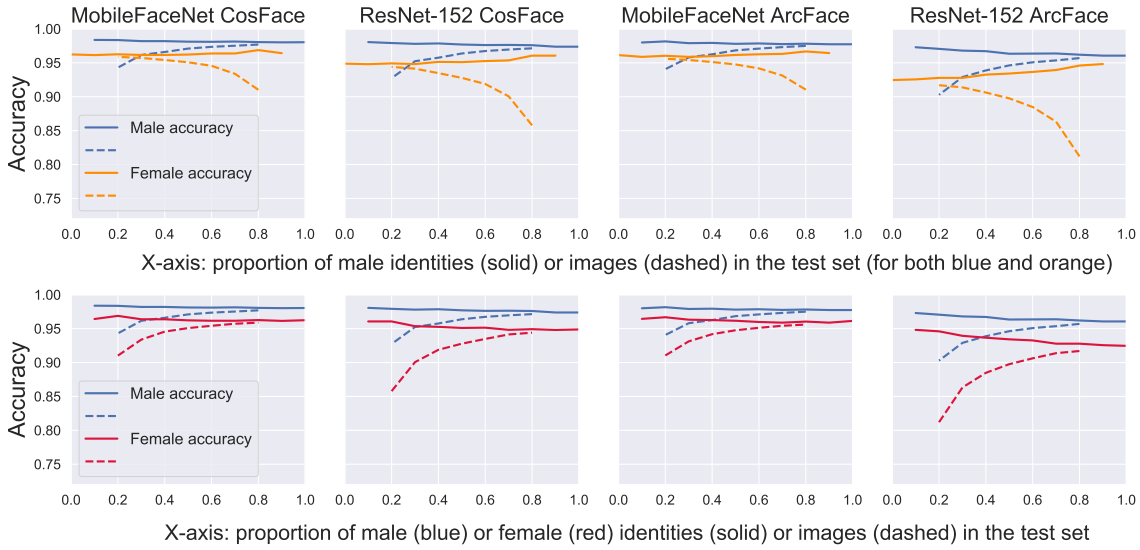

Figure 9: Test Set Imbalance. Results of experiments that change the test set gender presentation balance for MobileFaceNet and ResNet-152 models trained without class-balanced sampling. Top row: male and female accuracy are plotted against the proportion of male data in the test set. Bottom row: for an alternate view, female accuracy is flipped horizontally, so that it is plotted against the proportion of *female* data in the test set. All models are trained on the default balanced train set. For each experiment, the test set was split with 5 random seeds, and the results are averaged across seeds.

Table 1: Details on the number of identities, total number of images and average number of images per identity used in experiments with train and test data balance. We also report statistics for the default train and test sets. M denotes male, F denotes female.

Setting	M ids	F ids	Total M imgs	Total F imgs	M imgs/id	F imgs/id	Total ids	Total imgs
Train default	3967	3967	70k	70k	17.65	17.65	7934	140k
Train id balance	0 - 3967	0 - 3967	0 - 70k	0 - 70k	17.65	17.65	3967	70k
Train img balance	3967	3967	14k - 56k	14k - 56k	3.53 - 14.11	3.53 - 14.11	7934	70k
Test default	406	406	7k	7k	17.24	17.24	812	14k

Iterative Partial Fulfillment of Counterfactual Explanations: Benefits and Risks

Yilun Zhou
MIT CSAIL
Cambridge, MA, USA
yilun@csail.mit.edu

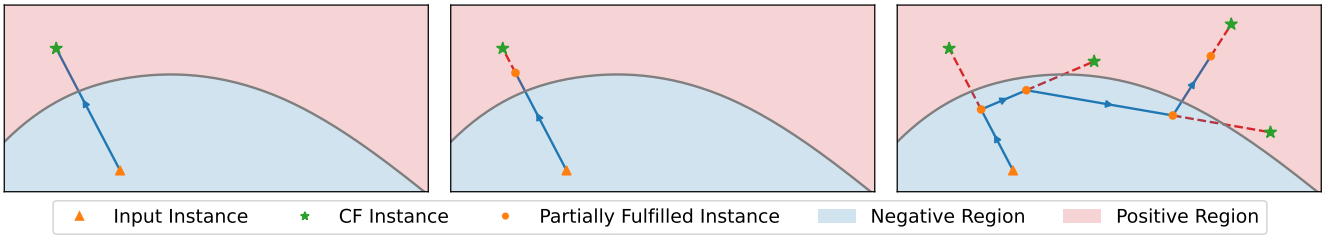

Figure 1: Left: a counterfactual (CF) explanation (green star) of an negative input instance (orange triangle) is often assumed to be fulfilled (i.e., achieved) completely, thus guaranteeing a positive subsequent prediction. In this paper, we consider *partial fulfillment*, where the subject, by choice or by necessity, stops in the middle (orange circle). Middle: if the CF explanation is far from the decision boundary, then a partial fulfillment near the goal could be sufficient for a positive prediction while saving improvement cost. Right: however, CF algorithms often use local gradient ascent and/or randomized search, which could result in a long and winding path towards the final positive prediction and much higher total cost.

ABSTRACT

Counterfactual (CF) explanations, also known as contrastive explanations and algorithmic recourses, are popular for explaining machine learning models in high-stakes domains. For a subject that receives a negative model prediction (e.g., mortgage application denial), the CF explanations are similar instances but with positive predictions, which informs the subject of ways to improve. While their various properties have been studied, such as validity and stability, we contribute a novel one: their behaviors under *iterative partial fulfillment* (IPF). Specifically, upon receiving a CF explanation, the subject may only partially fulfill it before requesting a new prediction with a new explanation, and repeat until the prediction is positive. Such partial fulfillment could be due to the subject's limited capability (e.g., can only pay down two out of four credit card accounts at this moment) or an attempt to take the chance (e.g., betting that a monthly salary increase of $800 is enough even though $1,000 is recommended). Does such iterative partial fulfillment increase or decrease the total cost of improvement incurred by the subject? We mathematically formalize IPF and demonstrate, both theoretically and empirically, that different CF algorithms exhibit vastly different behaviors under IPF. We discuss implications of our observations, advocate for this factor to be carefully considered in the development and study of CF algorithms, and give several directions for future work.

1 INTRODUCTION

Recently, machine learning models have been increasingly deployed in high-stakes domains in finance, law and medicine, performing tasks such as loan approval [8], recidivism prediction [21] and medical diagnosis [13]. For these domains, the reason why a particular prediction is made is often as important as the prediction itself, especially since most of the high performing models, such as neural networks and random forests, are black-box in nature. In some jurisdictions, the "right to explanation" is even legally required for people receiving adverse model predictions (e.g., mortgage application denial) to understand the reason and available recourses.

For these purposes, counterfactual (CF) explanations, also known in the literature as contrastive explanations or algorithmic recourses, have been a popular choice due to their desirable properties in human psychology and cognition theories [26]. For a particular input x with a certain model prediction $\tilde{y}$, its CF explanation is another input similar to x but with a prediction $\tilde{y}'$ different from $\tilde{y}$. Thus, this explanation indicates how the input would need to change in order for the model prediction to also change, as shown in Fig. 1

(left). When $\tilde{y}$ is a negative prediction (e.g., mortgage application denial) and $\tilde{y}'$ is a positive one (e.g., application approval), this CF explanation essentially gives as a direction for the applicant to improve their situation and get the application approved the next time, given that it is feasible (e.g., not changing immutable features such as gender and race), which automatically avoids the unfaithfulness problem of many feature attribution explanations [23, 33, 36] where the salient features are not really important for the model's decision making [1, 47, 48].

Over the past few years, there have been many investigations into various properties of these counterfactual explanations, such as their validity, action feasibility and cost, stability with respect to input perturbations and model updates, and agreement with the underlying causal mechanism, which are reviewed in Sec. 2. Taken as a whole, they generate quality profiles for various CF explanation algorithms and establish their relative strengths and weaknesses.

In this paper, we propose a novel aspect of these explanations, which, to the best of our knowledge, has not been studied before. Specifically, in real life scenarios, the subject of the prediction (e.g., the mortgage applicant) may not completely fulfill the CF explanation for various reasons. First, the subject may not be able to do so. For example, the CF explanation requires the subject to pay down all four credit card accounts, but they can only pay down two of them with their current saving. Second, the subject may want to take their chance and get a favorable outcome with less effort. For example, the CF explanation recommends the subject to increase their monthly salary by $1,000 but they wonder if an increase of just $800 would be sufficient. Last, the subject may misunderstand the wording of a CF explanation (e.g., a bullet list in the notice of denial) as taking any *subset* of actions rather than all of them. In all cases, we have a *partial* fulfillment of the CF explanation followed by a re-query for the model prediction and CF explanation, repeating until a positive prediction is obtained. We term this process as the *iterative partial fulfillment* (IPF) of CF explanations.

How does IPF, compared to a one-shot complete fulfillment, affect the subject welfare? In particular, does the subject need to make more total improvement under IPF? Intuitively, the effect can be positive, negative or neutral.

A positive effect could result from CF algorithms that generate instances landing well into the positive model prediction region. A less complete fulfillment (e.g., a salary increase of $800 rather than the recommended $1,000) is still sufficient, allowing the subject to incur a lower cost of improvement, as shown in Fig. 1 (middle).

By contrast, if the initial partial fulfillment (e.g., paying down two out of the four recommended credit card accounts) is unsuccessful, the new CF explanation may suggest some other factors to change and effectively "reset" the progress, resulting in a larger total cost of improvement, as shown in Fig. 1 (right). In the most extreme case, an oscillation may even occur among the series of explanations, leaving the subject stuck in an infinite loop.

Last, if, for an input x and its CF explanation x', the CF explanations for all partially fulfilled input states along the trajectory of $x \to x'$ are also the same counterfactual explanation x', and no partial fulfillment results in a positive prediction, then the total improvement cost under IPF is the same as that under one-shot complete fulfillment, since both will lead to the subject achieving x' in the end. Such as scenario is possible if the CF algorithm works by either finding the exact closest input with a different target prediction or returning a CF instance from a small set of candidates.

In practice, the specifics of a CF algorithm, such as the optimization method and considerations for stochasticity and diversity, determine the net effect of these three possibilities, making certain CF algorithms preferable to others from the IPF welfare perspective.

In this paper, we investigate this problem by first formalizing the notion and implementation of IPF in Sec. 3. Then in Sec. 4 we theoretically prove that certain CF algorithms can exhibit positive, negative and neutral effects on IPF welfare (i.e., total improvement cost compared to the one-shot complete fulfillment), as conceptually explained above. Empirically, in Sec. 5 using two financial datasets, three CF algorithms and four CF generation configurations per algorithm (for a total of 24 setups), with the widely used `DiCE-ML` package[1], we confirm that the generated explanations indeed possess different IPF characteristics. Thus, from these two pieces of evidence, we argue that an IPF assessment should be part of a comprehensive evaluation of CF algorithms. Finally, in Sec. 6, we discuss the broader technical and societal implications of IPF and its future directions.

2 RELATED WORK

In this section, we discuss works on the algorithms and properties of counterfactual explanations, with focus on impact, recency and relevance to IPF. For much more detailed discussions, we refer the readers to standalone surveys, such as those by Byrne [3], Guidotti [11], Keane et al. [18] and Verma et al. [42].

CF explanations are popularized by Wachter et al. [46], who proposed a gradient ascent algorithm to search for a counterfactual instance that both achieves the target model prediction and is close to the original input being explained. Subsequent works have extended the basic idea to make CF explanations diverse [27, 34], in-distribution [30, 41], aware of the causal mechanism [17], and less susceptible to gaming [4]. In addition, different optimization methods have also been proposed, such as those that do not require model differentiability or gradient access [27, 29], as well as those based on integer programming [34, 40], constraint satisfaction [16] and optimal transport [6].

A recent line of work aims to generate a *sequence* of instances from the input to the final CF explanation [15, 28, 31, 43]. This sequence provides an explicit path for the subject to follow, and is argued to be more user-friendly and actionable. While our proposed IPF setup also results in a sequence of explanations, it is fundamentally different in both goals and constraints. In sequential generation, the explanation algorithm has full control of the generated sequence and only the last sequence element needs to be the CF explanation (i.e., inducing the target prediction). By comparison, in IPF, the algorithm needs to work with whatever partially fulfilled instance provided by subject and generate a valid CF explanation.

Kenny and Keane [19] and Aryal and Keane [2] proposed to generate semi-factual explanations, defined as data instances which move towards the decision boundary but have not crossed it. These explanations could be used to construct "even if" explanations: e.g., *even if the down payment is $10,000 more, the mortgage would still not be approved.* A partially fulfilled CF in IPF and a semi-factual

[1] https://github.com/interpretml/DiCE

instance are both on the way to some CF instance, but they are otherwise distinct concepts – one is an intermediate state of the subject and the other is an explanation.

On the evaluation and analysis side, various properties of CF explanations have been proposed. The two core desiderata of CF explanations are validity and feasibility. The former is just the success rate of the CF generation, while the latter, conceptually defined as the ease for the subject to follow the CF recommendation, is much more nuanced. Different approaches have been proposed to enforce and evaluate it, such as ensuring a close distance to the original data point [46], lying in a high-density region of the data distribution [41], satisfying causal constraints [17], and respecting custom limitations in modifying feature values [27, 40].

Most relevant to our IPF proposal are two notions of stability. The first is with respect to input perturbations, where Dominguez-Olmedo et al. [7] and Virgolin and Fracaros [44] found that a given input can be adversarially but minimally perturbed into an instance with a very different CF explanations. Maragno et al. [25] proposed a robust optimization formulation to find stable CF explanations. Slack et al. [37] demonstrates that a model could be trained to make this behavior more prevalent and hide discrimination issues. The second one is with respect to the model update, where a new model is trained on an updated version of the dataset. Rawal et al. [32] found that many CF algorithms are often unstable under model update in that very different explanations are generated for the new model and the original ones are no longer valid, and Upadhyay et al. [39] proposed an algorithm to find CF instances that are stable under model update.

From this perspective, our IPF property can be considered as a third notion of stability: the stability of CF explanations for inputs along the path of improvement. If the CF explanations are stable, then the subject will follow a mostly consistent path of improvement, while if not, the subject may be given unrelated or even contradicting recommendations after every partial fulfillment.

3 ITERATIVE PARTIAL FULFILLMENT

3.1 Background

In this section, we formalize the concept of iterative partial fulfillment (IPF) of CF explanations. Due to the variety of real world human behaviors, there are many ways to formalize IPF. As we are the first to do so, we provide and analyze one canonical setup, and discuss other design choices and extensions in Sec. 6.

Let $\mathcal{X}$ be the input space with D features, and $\mathcal{X}_d$ for $d \in \{1, ..., D\}$ be the set of values for the d-th feature. We consider categorical and numerical features, where X_d is a finite set for the former and (a subset of) $\mathbb{R}$ for the latter. Thus, an $x \in \mathcal{X}$ can be written as $(x_1, ..., x_D)$ with $x_d \in \mathcal{X}_d$. For notational simplicity, we restrict ourselves to binary classification tasks, and represent the model prediction function as $m : X \to [0, 1]$ that returns the predicted probability of the positive class. Thus, $m(x) \geq 0.5$ indicates a positive prediction. In the ensuing discussion, we consider negatively predicted input instances $m(x) < 0$ and their positively predicted counterfactuals $m(x') \geq 0.5$.

We denote a CF explanation algorithm as $A : \mathcal{X} \to \mathcal{X}$, which takes an input instance and returns another instance. Since some algorithms are stochastic, we allow $A(x)$ to return a random x' sampled from the corresponding distribution. In addition, some algorithms generate a set of diverse CF explanations, and the subject chooses one of them as the goal using some strategy, such as picking the most similar one or selecting one uniformly at random. In this case, we let $A(\cdot)$ to manage this CF selection procedure so that it always returns a single (but possibly stochastic) CF explanation. To simplify notation, we write $x' = A(x)$ if A is deterministic on x and $x' \sim A(x)$ for a sampled value.

For x and x', to represent the cost of change between the two, we define a cost metric

$$c(x, x') = \sum_{d=1}^{D} c_d(x_d, x'_d), \tag{1}$$

where $c_d(x_d, x'_d)$ is the per-feature cost. If the feature is categorical, we have $c_d(x_d, x'_d) = \mathbb{1}\{x_d \neq x'_d\}$. Otherwise, we have $c_d(x_d, x'_d) = |F_d(x_d) - F(x'_d)|$ where F is cumulative distribution function of the feature values, following Ustun et al. [40], to account for the feature value density, with the maximal change incurring a cost of 1. Given a sequence of N instances $\mathbf{x} = (x^{(1)}, ..., x^{(N)})$, the total cost for this sequence is the sum of pairwise neighbor costs $c(\mathbf{x}) = \sum_{n=1}^{N-1} c(x^{(n)}, x^{(n+1)})$.

3.2 Partial Fulfillment

We now formalize the partial fulfillment as follows.

Definition 1 (u-partial fulfillment). For current state x and goal state x' (e.g., as generated by the CF algorithm), the u-partial fulfillment $w \in \mathcal{X}$, with $u \in [0, 1]$, is generated by the following operation on each feature:

- if the feature is continuous, the new feature value w_d is an interpolation between the two feature values: $(1-u) \cdot x_d + u \cdot x'_d$, except that when $|x_d - x'_d| \leq \epsilon$, the new value is x'_d;
- if the feature is categorical, the new feature value w_d takes x_d with probability $1 - u$ and x'_d with probability u.

Since categorical feature values are generated stochastically, we use $\phi(x, x', u)$ to denote the distribution of partial fulfillment w.

Conceptually, from the subject's perspective, when partially fulfilling x' from x, at an effort level u, for every continuous feature, they will move an amount proportional to u towards the goal feature value, and for every categorical feature, they will choose to make the change with probability u. Thus, the partial fulfillment result is stochastic as long as there is at least one categorical feature value change required. A technical exception is put on continuous features, where the partially fulfilled value is set to the CF value if the value difference is small. This ensures the success of IPF when the CF instance lies exactly on the decision boundary.

Given this partial fulfillment definition, we model the iterative partial fulfillment (IPF) process in Alg. 1. The subject starts with an input x, and repeatedly requests a counterfactual explanation to partially fulfill, until receiving a positive prediction or reaching a maximum number of iterations. The algorithm returns $\mathbf{x}$, a sequence of states that the subject has been. For effort level u, maximum number of iterations T, model m and CF algorithm A, we use $\xi(x, u, T, m, A)$ to represent the distribution of realized state trajectories $\mathbf{x}$. When it is clear from the context, we omit some of the input arguments, such as m. The most direct measure of subject

Algorithm 1: The iterative partial fulfillment (IPF) process.

Input: initial input x, model m, CF explanation algorithm A, fulfillment effort level u, maximum number of iterations T;
$t \leftarrow 0$;
$\mathbf{x} \leftarrow [x]$;
while $m(x) < 0.5$ *and* $t < T$ **do**
  $x' \leftarrow A(x)$;
  $x \leftarrow \phi(x, x', u)$;
  $\mathbf{x}$.append(x);
  $t \leftarrow t + 1$;
end
return $\mathbf{x}$;

welfare under IPF is the total improvement cost $c(\mathbf{x})$. Other metrics include final success rate and number of steps. If we are interested in the fairness implications of IPF (i.e., whether one demographic group is disproportionately affected by IPF), we can also compute these metrics separately for each group, as we conduct in Sec. 5.

4 THEORETICAL ANALYSIS

4.1 IPF Stability

Does IPF always increase or decrease the total improvement costs? As we demonstrate in this section, its effects on different CF algorithms are different. First, we formally define the concept of IPF stability discussed at the end of Sec. 2, which is a sufficient condition for cost preservation (i.e., IPF does not increase the total cost).

Definition 2 (IPF stable). A CF algorithm A is IPF stable at x if
(1) A is deterministic at x, and
(2) $\forall w \in \Phi(x, A(x))$, A is deterministic at w and $A(w) = A(x)$.
A CF algorithm A is IPF stable globally if it is IPF stable at all $x \in \mathcal{X}$.

For IPF stable CF algorithms, we are assured that IPF never makes the total cost higher, compared to one-shot complete fulfillment.

Theorem 3. *If a CF algorithm A is IPF stable at x, then for all u and T, $\mathbb{E}_{\mathbf{x}\sim\xi(x,u,T,A)}[c(\mathbf{x})] \le c(x, A(x))$.*

The proof is straightforward. At every iteration of IPF, the same CF explanation is given. Thus, the total improvement cost is upper bounded by $c(x, A(x))$. If the model gives a positive prediction in some intermediate step (or T is not large enough to achieve $A(x)$ or a positive prediction), the total improvement cost is strictly less, which could happen when A is configured to be "conservative" and gives a CF instance of high model confidence.

4.2 Cost-Preserving/Decreasing CF Under IPF

Do IPF stable CF algorithms exist? Obviously, a constant-valued CF algorithm that always produces the same CF instance $A(\cdot) = x'$ is stable, but this serves as a terrible CF explanation for most of the dissimilar input instances. More usefully, we show that the optimal cost CF algorithm is also stable.

Theorem 4. *For $p \ge 0.5$, the optimal cost CF algorithm*

$$A_{\mathrm{OC}}(x) = \underset{x': m(x') \ge p}{\arg\min}\ c(x, x'), \tag{2}$$

which gives the instance closest to x with model prediction at least p (using deterministic tie-breaking if necessary), is IPF stable globally.

Proof. We first consider the case of all numerical features and no categorical features. Recognizing the feature-wise absolute value CDF distance function $c_d = |F_d(x'_d) - F_d(x_d)|$, we define sign flag $s_d = \mathrm{sgn}(x'_d - x_d)$, and have

$$c(x, x') = \sum_{d=1}^{D} s_d (F_d(x'_d) - F_d(x_d)). \tag{3}$$

Therefore, the search over the best CF can be reduced to that in 2^D "quadrants," with one value of $s = (s_1, ..., s_D)$ specifying one quadrant Q_s. Denote the globally optimal CF as x^*. We need to show that IPF preserves the optimality of x^* within the quadrant and across different quadrants.

For within-quadrant optimality, without loss of generality, suppose that x^* lives in Q_s with $s = (1, ..., 1)$. Consider the new state $w = (1-u)x + ux^*$ resulting from the partial fulfillment. For all $x' \in Q_s$,

$$c(x^*, x) \le c(x', x) \tag{4}$$
$$\implies \sum_d F_d(x^*) - F_d(x) \le \sum_d F_d(x') - F_d(x) \tag{5}$$
$$\implies \sum_d F_d(x^*) \le \sum_d F_d(x') \tag{6}$$
$$\implies \sum_d F_d(x^*) - F_d(w) \le \sum_d F_d(x') - F_d(w) \tag{7}$$
$$\implies \sum_d c_d(x^*, w) \le \sum_d c_d(x', w) \tag{8}$$
$$\implies c(x^*, w) \le c(x', w). \tag{9}$$

The last line establishes the within-quadrant optimality of x^* for w. For across-quadrant optimality, consider the s^* for the quadrant of x^* and s' for that of an CF instance x' in a different quadrant. For a feature d such that $s^*_d = s'_d$, w_d makes the same amount of improvement towards both CFs (except when w overshoots with respect to x'_d, which offsets the improvement on x'_d), while for d such that $s^*_d \ne s'_d$ (which must exist because $s^* \ne s'$), the improvement towards x^*_d strictly makes the distance to x'_d worse. Thus, if x^* is optimal for x across all quadrants, it is still optimal for w.

Combining within-quadrant and across-quadrant optimality together, we see that IPF preserves the optimality of $A_{\mathrm{OC}}(x)$ (for inputs of all numerical features).

For a categorical feature d that needs change (i.e., $x^*_d \ne x_d$), if $w_d = x_d$, it does not change the feature-wise cost c_d for any target instance (including x^*), while if $w_d = x^*_d$, it reduces the cost for x^* by 1, and it reduces that for any other x' by at most 1, if $x'_d = x^*_d$). Thus, the cost reduction for x^* is as fast as any other x', so adding the cost for categorical features to the overall cost c does not affect the optimality of x^*. This completes the proof. □

With similar proofs, the theorem also applies to l_1 distance functions, including the case of different features scaled differently (e.g., by respective mean absolute deviation as used by Wachter et al. [46]), or with F_d being arbitrary monotonic functions. These variations greatly increases the generality of the theorem.

This algorithm is considered as the gold standard by many works that propose approximate procedures due to the intractability of the exact optimization, such as local gradient ascent [46] or randomized search [27, 29]. Hence, we see that IPF is not a concern in the ideal case. In fact, for conservative A_{OC} with $p > 0.5$, it is likely that the total cost of IPF is smaller due to early stopping.

Moreover, the result extends easily to look-up based CF algorithms, as defined below.

Theorem 5. *A look-up based CF algorithm*

$$A_{\text{LU}}(x) = \arg\min_{x' \in S} c(x, x'), \tag{10}$$

which selects the instance closest to x from a (finite) set of candidates S (using deterministic tie-breaking if necessary), is IPF stable globally.

The proof is analogous. A natural choice of S (for a negatively predicted instance x) is the set of correctly predicted positive training instances. Indeed, using the training set as a constraint or regularization is a common ingredient in many CF algorithms [30, 41], often to make the CF explanations more realistic and thus feasible, while this theorem demonstrates an added benefit of it.

Putting everything together, we reiterate the central results of this section with the following corollary:

Corollary 6. *Both optimal cost and look-up based CF algorithms (A_{OC} and A_{LU}) are IPF stable.*

4.3 Cost-Increasing CF Under IPF

Next, we demonstrate that two popular approximation methods, gradient ascent and randomized search, are prone to increasing the total improvement cost, possibly without limit.

For differentiable models, gradient ascent is often used from the current input to find a CF instance that offers a good trade-off between the model prediction and distance, sometimes with other considerations. Different works have proposed different objective functions, with the earliest one proposed by Wachter et al. [46] as

$$g(x') = \lambda(1 - m(x'))^2 + d_{\text{MAD}}(x, x'), \tag{11}$$

where d_{MAD} is the l_1 distance weighted by the inverse median absolute deviation (MAD) per feature, and λ controls the trade-off. We define a gradient ascent CF function A_{GA} as the one that follows the gradient of $g(\cdot)$ from x to the local minimum or the boundary of $\mathcal{X}$. If this end state does not achieve the required model prediction p, we return a default positive instance (which can be a fixed correctly classified positive training instance).

It turns out that A_{GA} could lead to arbitrarily bad IPF behaviors due to an oscillation phenomenon.

Theorem 7. *There exists a model m, input instances $x^{(1)}, x^{(2)}$ with all continuous features, and effort level u, such that $\phi(x^{(1)}, A_{\text{GA}}(x^{(1)}), u) = x^{(2)}$ and $\phi(x^{(2)}, A_{\text{GA}}(x^{(2)}), u) = x^{(1)}$.*

In this case, starting at $x^{(1)}$ and making partial fulfillment with effort level of u results in an oscillation of $x^{(1)} \to x^{(2)} \to x^{(1)} \to x^{(2)} \to \ldots$ for T steps. A concrete example is illustrated in Fig. 2, which plots gradient field of the 2-dimensional objective function $g(\cdot)$ as gray arrows pointing in the *ascent* direction. A "valley" (blue dashed line) separates the inputs into two regions. We have two instances, represented by orange and green circles. For each

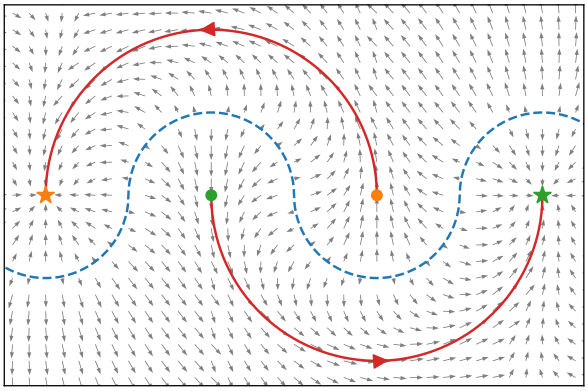

Figure 2: An example illustrating the oscillation behavior of gradient-ascent CF algorithms under partial fulfillment.

instance, the gradient ascent yields the red trajectory to the star marker of the same color. However, starting from the orange circle, a 0.5-partial fulfillment towards the orange star lands exactly on the green circle, whose counterfactual explanation is the green star, but a 0.5-partial fulfillment goes back to the orange circle again.

The root cause for this issue is the non-optimality of the gradient ascent algorithm, in that it may only find farther local minima by following the gradient, such that a partial fulfillment (which move in the straight-line path, not along the gradient) could reset the progress. While the above example can be easily solved by caching the CF explanations found so far and returning the closest one if the gradient ascent cannot do better, models trained on real-world datasets with a large number of features may have many local minima in the high-dimensional input space, as evidenced by the prevalence of adversarial examples [10, 22], rendering such caching effort mostly futile.

A realistic example can be constructed as follows for the mortgage approval task. Consider two features, current saving x_s and current debt x_d, where the model makes positive predictions on $\langle x_s, x_d \rangle = \langle \$10k, \$1k \rangle$ and $(\$40k, \$4k\rangle$. Now consider $x^{(\text{CF},1)} = \langle \$20k, \$2k \rangle$ and $x^{(\text{CF},2)} = \langle \$30k, \$3k \rangle$. Due to the shape of the objective function, the gradient ascent optimizes $\langle \$20k, \$2k \rangle$ to $\langle \$40k, \$4k \rangle$, and $\langle \$30k, \$3k \rangle$ to $\langle \$10k, \$1k \rangle$. As a result, starting at either $x^{(1)}$ or $x^{(2)}$ leads to an oscillation between the two.

Another popular approach, especially for non-differentiable models, is based on randomized search. Generally speaking, a randomized search algorithm A_{RS} draw samples from the input space $\mathcal{X}$ using some strategy (e.g., uniformly at random or weighted towards the input instance x), and returns the best sampled instance according to some objective function (e.g., Eq. 11). However, this approach is also prone to increasing the total improvement cost under IPF.

Theorem 8. *There exists a model m, an input instance x, and an effort level u, such that*

$$\mathbb{E}_{\mathbf{x} \sim \xi(x,u,T,m,A_{\text{RS}})}[c(\mathbf{x})] > E_{x' \sim A_{\text{RS}}(x)}[c(x, x')] \tag{12}$$

Intuitively, this theorem should not be surprising: at step t and state $x^{(t)}$, when a new CF goal $x^{(\text{CF},t+1)}$ is set, some of the effort expended during the previous round of partial fulfillment becomes

wasted if the new goal requires a different fulfillment operation from the previous state $x^{(t-1)}$; i.e., $x^{(t)} \notin \Phi(x^{(t-1)}, x^{(\mathrm{CF},t+1)})$.

As a simple example, consider a probabilistic CF algorithm A that gives one of two CF explanations, $x^{(\mathrm{CF},1)}$ and $x^{(\mathrm{CF},2)}$. For an input x, let d_1 and d_2 be the Euclidean distance to them respectively (assuming all continuous features). We have

$$A(x) = \begin{cases} x^{(\mathrm{CF},1)} & \text{with (unnormalized) probability } d_1^{-1}, \\ x^{(\mathrm{CF},2)} & \text{with (unnormalized) probability } d_2^{-1}. \end{cases} \quad (13)$$

Thus, if we have the initial state starting at the middle of these two CF states, $x = (x^{(\mathrm{CF},1)} + x^{(\mathrm{CF},2)})/2$, with $u = 0.5$ (i.e., fulfilling halfway through the CF explanation), then the probability of CF always recommending the same counterfactual is

$$\frac{3}{4} \cdot \frac{7}{8} \cdot \frac{15}{16} \cdot \frac{31}{32} \ldots \approx 0.58, \quad (14)$$

meaning that 42% of times, there is at least one step that erases the effort of an earlier step. On our earlier mortgage approval example, these two states could represent the two ways of getting approved (high saving and high debt, or low saving and low debt), and a partially fulfilling applicant risks receiving contradictory feedback every time they make an application.

Using a Monte Carlo simulation, Fig. 3 (blue line) shows the total improvement cost at different effort levels u relative to that under single-shot complete fulfillment. Analogous results for the same setup but with three to five counterfactual states arranged on a regular polygon (with initial state x at the center) are also presented in different colors.

As we can see, a smaller value of u and a larger number of candidate CF instances of all exacerbates the total improvement cost under IPF. In particular, with just five CF instances and an effort level of 0.5, the total improvement cost increases 10-fold relative to the one-shot complete fulfillment ($u = 1$). An effort level of 0.1 increases the cost more than 40,000 times!

4.4 Summary

In this section, we characterize four basic algorithmic approaches to generating CF explanations by their IPF cost property. On the positive side, the optimal algorithm that performs an exhaustive search and its finite search space variant are both IPF stable and thus cost preserving. In addition, if these algorithms are configured to be conservative, in that they only return instances with model prediction over a $p > 0.5$, it is likely that IPF can save total cost by rewarding subjects who take chance.

On the contrary, algorithms based on gradient descent and randomized search risk increasing the total cost under IPF. The issue can be attributed to the same underlying reason: since these algorithms are not guaranteed to always return the closest CF instance, partial fulfillments in the earlier iterations may be "cancelled" by later ones, resulting in increased total costs. In addition, many CF algorithms [27, 34] aim to generate multiple CF instances at the same time in order to provide more diversity and options to the subject. In this case, if the choice made by the subject is not consistent across iterations, the net effect is similar to a randomized search CF algorithm, with higher total improvement cost.

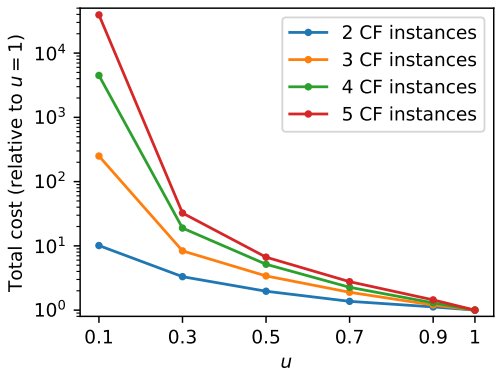

Figure 3: Total improvement cost as a multiple of the one-shot complete improvement for different effort levels u.

5 EMPIRICAL ANALYSIS

5.1 Experiment Setup

In this section, we empirically study the IPF behaviors of CF algorithms. We use two datasets, Adult Income [20] and German Credit [8] The first dataset is about predicting whether the annual salary is above $50k or not from demographic information collected in the 1994 Census. The second dataset is about predicting whether a person is likely to repay a loan or not from the information about the person's finance and that of the loan.

For each dataset, we use a 80%/20% train/test split and apply one-hot encoding to the categorical features and train a random forest classifier as the model. To compute counterfactual explanations, we use the `DiCE-ML` package, which is one of the most popular Python packages for tabular data and non-differentiable classifiers. For all the experiments, we focus on correctly classified negative instances and generate positively predicted CF explanations for them. This scenario is the most common use case of CF explanations as recourses, but our analysis applies to any model input and prediction. Tab. 1 gives summary statistics about the dataset and model performance, and Tab. 2 presents some inputs and CF instances.

`DiCE-ML` package searches for diverse CF explanation diversity Mothilal et al. [27] in various ways. Since the random forest classifier is not meaningfully differentiable (zero gradient almost everywhere), we study random search – the default method, genetic search algorithm – based on the method by Schleich et al. [35], and prototype-guided search with KD tree – based on the method by Van Looveren and Klaise [41]. The generated CF explanations are post-processed for sparsity with a feature selection procedure.

In addition, `DiCE-ML` can generate multiple CF explanations. We study two setups, a single CF explanation (which is still stochastic for random and genetic algorithm search), and 20 CF explanations.

Table 1: Statistics about the dataset and the model.

Dataset	# Instance	# Feature (Cat./Num.)	Acc	F1
Adult Income	32,561	13 (8/5)	0.84	0.66
German Credit	1,000	24 (17/7)	0.74	0.83

Table 2: One sample input instance and two counterfactual explanations for Adult Income (top) and German Credit (bottom). Non-changed feature values are marked with "-". Some non-changed features are omitted for presentation.

Age	Work Class	Education	Education Num	Marital Status	Occupation	Relationship	Race	Gender	Capital Gain	Capital Loss	Work Hours	Native Country	$m(x)$
42	Self-Employed	HS-Grad	9	Married	Craft-Repair	Husband	White	Male	0	0	35	United States	$\leq \$50k$
-	-	Doctorate	15	-	-	-	-	-	-	-	-	-	$> \$50k$
-	Local Gov	-	14	-	Manager	-	-	-	-	-	-	-	$> \$50k$

-	-	-	12	Other	-	1	0	-	-	True	0-200	-	Approve

Figure 4: Final success rate of IPF.

In the latter case, we consider three CF selection strategies carried out by the subject:

(1) closest: select the closest CF instance,
(2) weighted: sample a CF instance from a softmax function (with temperature 1) on the negative distance, and
(3) uniform: select one CF instance uniformly at random.

In other words, closest and uniform selections are equivalent to weighted selection with temperature approaching 0 and ∞ respectively. We call the setup where only one CF is generated (and hence no selection necessary) as "single CF."

For IPF, we use a maximum number of $T = 30$ iterations and evaluate effort level u from the set of $\{0.1, 0.3, 0.5, 0.7, 0.9\}$ along with one-shot complete fulfillment $u = 1$. At the lowest effort level of $u = 0.1$, if the counterfactual explanations were consistent each round, after 30 rounds the input would be to more than 95% towards the CF ($1 - 0.9^{30} = 95.8\%$). We do not employ the ϵ parameter as none of the algorithms return CF instances exactly on the boundary.

5.2 Results

We first answer the most fundamental question. Can CF algorithms lead to positive predictions in the face of IPF? Fig. 4 shows the success rate of IPF (up to the maximum number of 30 iterations). Most runs with effort level $u \geq 0.3$ succeed *eventually* without any issue (i.e., getting a positive model prediction). For $u = 0.1$, Genetic and Prototype algorithms struggle the most, especially when the final CF is stochastically selected from a diverse set with weighted or uniform distributions.

Focusing on the input instances for which all methods succeed (to ensure a fair comparison), we study the main quantity of interest, total improvement cost under IPF, relative to the one-shot baseline, as plotted in Fig. 5. We observe a variety of behaviors across

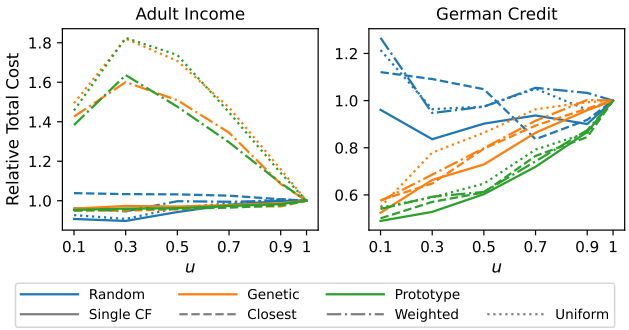

Figure 5: Average total cost at each effort level u relative to that of the one-shot fulfillment $u = 1$ for different setups.

different setups. The trade-off between cost decrease due to conservatism of CF algorithms (i.e., outputting instances far from the decision boundary) and cost increase due to their non-optimality is best shown on the Adult Income dataset by Genetic and Prototype algorithms, under uniform and weighted selection strategies. In this cases, taking very small steps of $u = 0.1$ results in lower total improvement cost than taking medium steps of $u = 0.3$ and 0.5 which may incur a 80% higher cost, because the small steps in the former helps stop closer to the decision boundary, yet all three choices are inferior to even larger u values, where the inconsistency in different iterations of the search is largely avoided. By comparison, the total improvement cost in other setups of Adult Income are not too sensitive to IPF, although it can have both mildly negative (for Random search with Closest selection) and mildly positive effects (for the remaining setups).

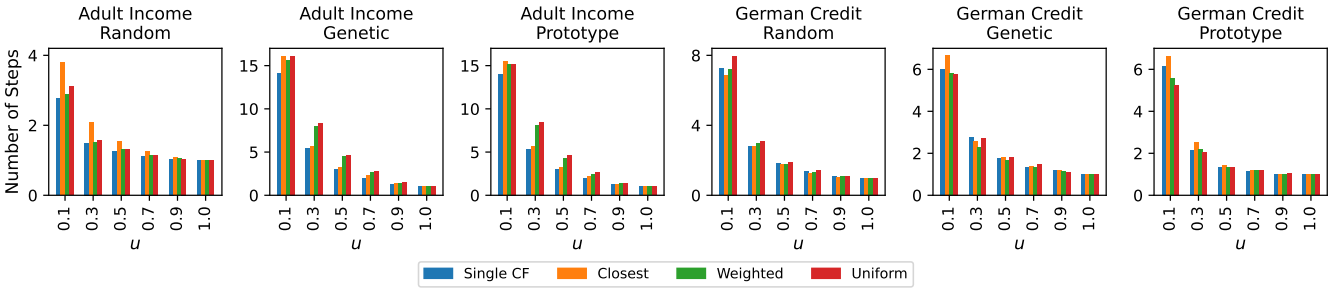

Figure 6: Average number of steps (for successful runs) incurred under different levels of partial fulfillment effort u.

On German Credit, the Genetic and Prototype algorithms exhibit the opposite effect, showing a monotonic cost decrease with less effort level u. One possible reason for this phenomenon is the high-dimensionality of the input space of German Credit vs. Adult Income (24 vs. 13), with more than twice as many categorical features. Thus, it is more likely for *some* categorical features to be changed in German Credit, which, in conjunction with conservative CF explanations, results in smaller total cost under low effort levels. The performance of the Random CF algorithm is similar to that in Adult Income, though with slightly higher variance.

Fig. 6 plots the average number of steps until success (for runs that do succeed). As expected, the number increases with decreasing u, but the speed of increase varies a lot, with those for Genetic and Prototype algorithms on Adult Income being the largest. Interestingly, the closest selection strategy for the Random search algorithm (orange bar on the leftmost plot) performs markedly worse than the rest, suggesting that such strictly greedy selection from a random sample may be especially suboptimal under IPF. For German Credit, the profiles across different algorithms are largely similar, confirming again that properties of the dataset can be influential in the IPF behaviors of the CF algorithms.

Overall, the three analyses above demonstrates a variety of behaviors of algorithms under IPF, and hence we advocate for them to be included in a standard suite of evaluations for CF algorithms, as well as considered when developing new CF algorithms. From a human perspective, it may also be necessary to for model users (e.g., banks) to provide explicit guidelines to subjects (e.g., mortgage applicants) to calibrate their expectations on this aspect, which may require new policies to be established on this issue. We provide more discussions in Sec. 6.

For the rest of this section, we demonstrate how IPF can be incorporated in other, existing aspects of analysis. In particular, as a preliminary investigation, we study the fairness of CF algorithms under IPF. Additional ideas are again discussed in Sec. 6. At a high level, the fairness property requires that different demographic groups (e.g., male vs. female, white vs. other race, etc.) should be treated "equally," with different criteria implementing this notion differently. The criterion that we use is demographic parity [9, 14, 24], one of the simplest and most popular, which basically asserts that for a fair metric (e.g., mortgage application approval), its average value is the same across different demographic groups. Viewed from this angle, we study the fairness of total improvement cost and number of steps under the concept of demographic parity.

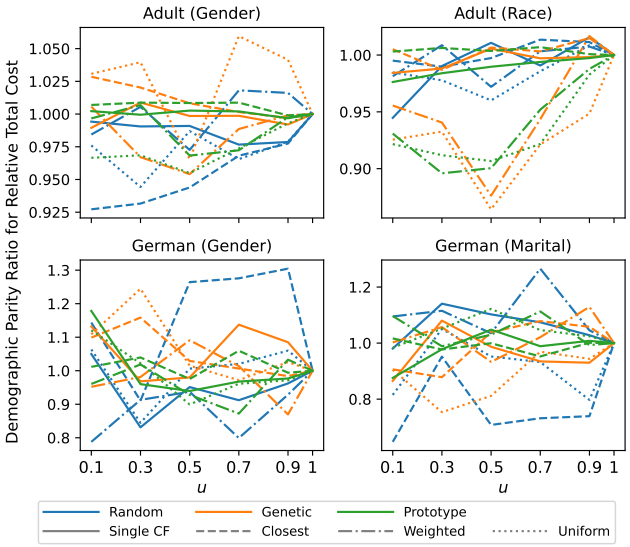

Figure 7: Demographic parity ratio for relative total cost.

We consider four demographic group splits in the fairness evaluation, commonly used in the literature [5, 37, 38]. For Adult Income, we study gender with a male/female split, and race with a white/non-white split. For German Credit, we use the same gender split, along with marital status with a married/single split. For each group, we take the second value (e.g., female) as the potentially disadvantaged group and study the ratio of the target of investigation in the disadvantaged group to that in the advantaged group.

We first study the total improvement cost. Note that we compute the ratio of *relative* total cost (relative to $u = 1$), to assess whether IPF *further* exacerbate the fairness issue, on top of what is already observed in the literature for vanilla CF explanations [45], the same target as in Fig. 5. The ratio for these four groups are plotted in Fig. 7, and while we could not identify any clear and consistent trend, IPF could increase the fairness issue as measured by demographic parity by as much as 30% for the German Credit model in some settings.

On the number of steps to achieve success, Fig. 8 plots the ratio. The trend is more pronounced. In most setups, the ratio increases as u gets smaller, indicating that IPF has a disproportionately higher impact on the disadvantaged group. Given that the total cost does

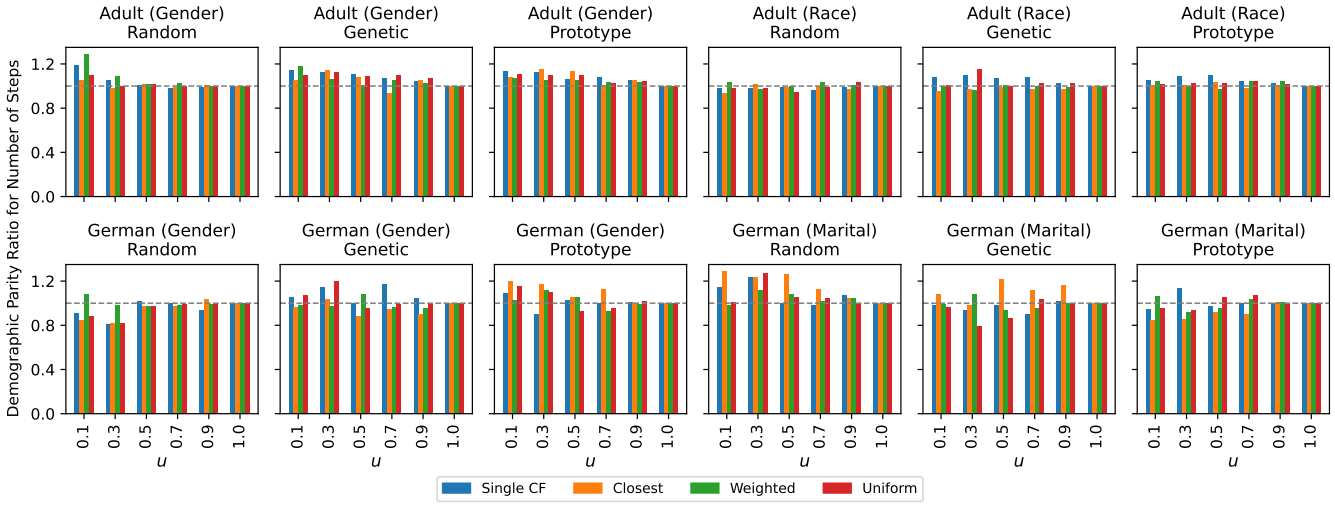

Figure 8: Demographic parity ratio for number of steps.

not demonstrate a clear trend, this means that the per-step improvement cost is *smaller* for the disadvantaged group, which means that the generated CF instances are closer to the queried inputs in the first place. Nonetheless, we leave a definitive verification and further exploration of the implications to future work.

6 DISCUSSION

In this paper, we propose the concept of iterative partial fulfillment, which, to the best of our knowledge, is the first formal study of the situation where the subject of a negative model prediction (e.g., denied mortgage application) does not completely fulfill the given counterfactual (CF) explanation before asking for an updated prediction, for many reasons. First, the subject may intentionally decide to take a chance (e.g., betting that a monthly salary increase of $800 is enough even though the CF instance requires $1,000), hoping that a state less qualified than the given CF state is sufficient to secure a positive prediction. Second, the subject may not be able to fully satisfy the CF state (e.g., can only pay down two out of four credit card accounts), especially if given a time limit on the CF validity guarantee (e.g., within the next six months). Furthermore, the subject may misinterpret the CF explanation, such as fulfilling any one of the action items rather than all of them when it is presented as a bullet list. When the partial fulfillment does not result in a positive model prediction, the subject receives a new CF state as part of the rejection and performs an improvement towards the new state. This process repeats until the model prediction is positive, and we call it *iterative partial fulfillment* (IPF).

Given that virtually all CF algorithms are memoryless (i.e., the CF explanation is generated from only the current input), and most employ local gradient-based or randomized search, it is possible that the CF explanation for a (still negative) partially fulfilled state is different from that of the original input, guiding the subject on a different path of improvement. As a result, the net effect of IPF on the welfare of the subject, most directly measured by final success rate and total improvement cost, could be positive or negative.

A positive effect could occur when the generated CF instance is conservative, i.e., lying far into the positive prediction region. Such a CF algorithm configuration could be preferred if the model user (e.g., the bank) wants to ensure that the subject is likely to get a positive prediction even if they cannot perfectly follow the CF recommendation. The exact same reasoning allows the subject to engage proactively in partial fulfillment and save on the improvement cost. By contrast, a negative effect could occur when the CF explanation provides different and conflicting advice at different rounds of partial fulfillment.

In our theoretical analysis, we prove that the optimal cost CF algorithm and its finite search approximation version are guaranteed to not increase total cost under IPF. However, the same could not be said for two popular practical algorithms, gradient ascent and randomized search, both of which worsen subject welfare, sometimes significantly and even potentially unboundedly in theory.

In our experimental investigation on two datasets, Adult Income and German Credit, totalling 24 CF explainer configurations, we identified both positive and negative effects of IPF, suggesting that IPF is sensitive to properties of the dataset and explainer. As a result, we recommend IPF analysis to be included as part of a standard evaluation suite of CF algorithms.

For future work, one direction is to consider alternative formulations of IPF. We use a deterministic, fixed-proportion model for continuous features (i.e., for current feature value of x_d and target value x'_d, partial fulfillment results in $(1-u)\cdot x_d + u \cdot x'_d$), but this step could be made stochastic by sampling from some distribution centered on $(1-u)\cdot x_d + u \cdot x'_d$, or a fixed-magnitude model could be used where the amount of improvement Δ_d on each feature is specified. Alternative models on categorical features could also be developed. Last, improvements on some features may be correlated, due to the underlying causal relationships (e.g., change in job title $\rightarrow$ change in salary), so incorporating causal information, potentially in the form of a causal graph, could be explored. Moreover, finding CF algorithms that are stable with respect to more than

one IPF notion would be desirable, as different subjects are likely to employ different IPF approaches.

Additionally, the temporal aspect of the IPF could be studied with more real-world elements. As time goes by in the IPF process, some feature values, such as age, would change in certain manners, which is ignored in the current formulation. Moreover, the very act of querying for a new model prediction may have an impact on some features, such as the bank account balance due to the payment of an application fee, or the credit score due to the bank pulling the credit report, which, at least in the United States, results in a small decrease of the credit score.

One direction to extend the IPF analysis is to integrate it with other aspects of evaluations. We give a demonstration for the case of fairness, and future work could focus on aspects such as its stability to input perturbations [7, 44] and model shifts [32].

In addition, we focus on IPF analyses of existing CF algorithms, but as a recurring theme of research, the other side of the coin naturally follows: developing new CF algorithms or regularizing existing ones to behave well under IPF scenarios, following analogous works for other CF properties such as robustness [38] and fairness [12].

Finally, given the diverse and potentially discriminative effects exhibited by IPF, society needs to be better informed and aware of it, especially as some subjects have already been engaging in such behaviors. For example, when the rejection letter of a mortgage application provides some CF explanations as recommendations, the bank may want to, or even be required to, include information about possible outcomes of a re-application with only partial fulfillment. In addition, the application process could allow the applicant to voluntarily reveal their previous applications, so that more stable and consistent CF explanations can be computed, in order to minimize the possibility of conflicting improvement recommendations given to the applicant. All of these changes require not only technical innovations but also policy discussions, for which we hope that this paper serves as a good starting point for such conversations.

ABSTRACT

We show how to take a regression function $\hat{f}$ that is appropriately *multicalibrated* and efficiently post-process it into an approximately error minimizing classifier satisfying a large variety of fairness constraints. The post-processing requires no labeled data, and only a modest amount of unlabeled data and computation. The computational and sample complexity requirements of computing $\hat{f}$ are comparable to the requirements for solving a single fair learning task optimally, but it can in fact be used to solve *many* different downstream fairness-constrained learning problems efficiently. Our post-processing method easily handles intersecting groups, generalizing prior work on post-processing regression functions to satisfy fairness constraints that only applied to disjoint groups. Our work extends recent work showing that multicalibrated regression functions are *omnipredictors* (i.e. can be post-processed to optimally solve unconstrained ERM problems) to constrained optimization problems.

1 INTRODUCTION

A now common technical framing of fair machine learning is that of constrained optimization. The goal is to solve an empirical risk minimization problem over some class of models $\mathcal{H}$, subject to fairness constraints. For example, we might ask to find the best performing model $h \in \mathcal{H}$ that equalizes false positive rates, false negative rates, overall error rates, or positive classification rates across some collection of groups $\mathcal{G}$ [7, 13]). For each of these notions of fairness, there is a continuum of relaxations to consider: rather than asking that (e.g.) false positive rates be exactly equalized across groups, we could ask that they differ by no more than 5%, or 10%, or 15%, etc. Because these relaxations trade off with model accuracy (tracing out Pareto frontiers), it is common to explore the range of tradeoffs for a family of fairness constraints[1] (see e.g. [1, 18]).

Each of these are distinct problems that seemingly require training distinct models from scratch based on training data. Moreover, each of these problems can be computationally expensive to solve: for example, the approach of [1] requires solving roughly $\log |\mathcal{G}|/\epsilon^2$ empirical risk minimization problems over $\mathcal{H}$ to produce an ϵ-approximately optimal solution to any one of them, and the computation of one solution is not used to reduce the cost of the others. The goal of our work is to understand when we can precompute a *single* regression model $\hat{f}$ which is sufficient to find optimal solutions to *all* of the fair machine learning problems described above, each as only a computationally easy *post-processing* of $\hat{f}$.

1.1 Our Results in Context

The idea of *post-processing* a trained model $\hat{f}$ in order to satisfy fairness constraints is not new. For example, [13] propose a simple post-processing of a regression function $\hat{f}$ to derive a classifier subject to false positive or negative rate constraints, and a number of more recent works have refined this approach (see our discussion in the related work). However, the conditions under which such post-processing approaches work are still not yet fully understood. The original work of [13] handles the case in which the groups $\mathcal{G}$ are disjoint, by finding a different *thresholding* of $\hat{f}$ for each group $g \in \mathcal{G}$—but this approach does not scale well to intersecting groups, since it would naively require tuning a different threshold to each of the possibly 2^k intersections of k underlying groups. [13] and [4] show that this post-processing yields the Bayes Optimal fair classifier if $\hat{f}$ is the true conditional label distribution—a very strong assumption. In this work, we show how to efficiently post-process a regression function to obtain a variety of "fair" classifiers, even when the groups $\mathcal{G}$ in question intersect, and give accuracy guarantees under substantially weaker assumptions on $\hat{f}$ than that it correctly encodes the true conditional label distribution.

Post Processing for Intersecting Groups. Suppose we have $k = |\mathcal{G}|$ groups that are intersecting (e.g. divisions of a population by race, gender, income, nationality, etc.) A naive reduction to the post-processing approach of [13] would consider all 2^k (now disjoint) intersections of groups, and find a separate thresholding of $\hat{f}(x)$ for each one. We show that even when groups intersect, for a variety of fairness constraints, the optimal post-processing $\hat{h}$ remains a

[1] Hereafter, we refer to such constraints as "fairness constraints", and models which satisfy the constraint or constraints of interest as "fair"; we will specify precisely which set of constraints we handle in Section 2. Assume fairness constraints are defined with respect to a collection of groups $\mathcal{G}$.

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08…$15.00
https://doi.org/10.1145/3600211.3604683

thresholding that depends on only k parameters λ_g, one for each group g. The value at which to threshold $\hat{f}(x)$ now depends only on these k parameters and the subset of groups that x is contained in. We give a simple, efficient algorithm to compute these optimal post-processings. The algorithm is efficient in the worst case — i.e. it does not have to call any heuristic "learning oracle" as direct learning approaches do [1, 18], and requires access only to a modest amount of *unlabeled* data from the underlying distribution.

Accuracy Guarantees from Multicalibration. As in [13] when given the Bayes optimal regression function $\hat{f}$ (i.e. $\hat{f}(x)$ is the expected value of y given x), our post-processing $\hat{h}$ yields the Bayes optimal fair classifier. However, one generally cannot hope to learn the Bayes optimal regression function $\hat{f}$ given a polynomial amount of data and computation. Fortunately, we show one can inexpensively compute the most accurate fair classifier in a class $\mathcal{H}$ from a much weaker regression function, namely, from a model $\hat{f}$ which is *multicalibrated* with respect to a class of models $\mathcal{H}$, a class of groups $\mathcal{G}$, and a simple class of functions derived from $\mathcal{H}$ and $\mathcal{G}$. Learning such a multicalibrated predictor with respect to these classes can be done with polynomial sample complexity in an oracle-efficient manner whenever $\mathcal{H}$ and $\mathcal{G}$ have polynomial VC dimension — and so both the sample and computational complexity of computing $\hat{f}$ are comparable to what would be required to directly solve a single instance of a fairness constrained optimization problem over $\mathcal{H}$.

Taken together, our results suggest that even when a downstream task requires a fairness notion which approximately equalizes statistical loss across groups, this is *not* necessarily what should be trained. Aiming instead for group-wise fidelity in the form of *multicalibration* provides the flexibility to deploy an optimal downstream model subject to a variety of fairness constraints without destroying information that would be needed to later relax or tighten those constraints, to remove them or to add more, or to change their type.

1.2 Additional Related Work

There are a number of other papers that study the problem of converting a regression (or "score") function into a classification rule in the context of fair machine learning. For example, [21] shows that post-processing a learned binary classification model to satisfy fairness constraints can be substantially suboptimal even when the hypothesis class under consideration contains the Bayes optimal predictor, which motivates a focus on post-processing regression functions instead. [22] study the structure of the Bayes optimal fair classifier for several notions of fairness when groups are intersecting, under a continuity assumption on the underlying distribution; they do not consider utility guarantees for post-processing a regression function that does not completely represent the underlying probability distribution. [20] and [2] give post-processing algorithms that transforms a score function into a classification function that optimizes different measures of accuracy subject to a variety of fairness constraints using a similar primal/dual perspective that we use in this paper. But these papers do not address the two main questions we raise in our work: intersecting groups, and efficiently learnable conditions on the score function that lead to utility guarantees (they assume that in the limit the true conditional label distribution is learnable and given as input to their algorithm).

In proving our accuracy bounds, we draw on a recent line of work on multicalibration [8, 12, 14, 16, 19]. In particular, [11] showed that regression functions that are multicalibrated with respect to a class of models $\mathcal{H}$ are *omnipredictors* with respect to $\mathcal{H}$, which means that they can be post-processed to perform as well as the best model in $\mathcal{H}$ with respect to any convex loss function satisfying mild technical conditions. The results in our paper can be viewed as being a *constrained optimization* parallel to [11], which studies *unconstrained* optimization.

Several other papers also use multicalibration of intermediate statistical products to argue for the utility of downstream models. [23] consider the problem of calibrating a model to the utility function of a downstream utility maximizing decision maker to preserve the usefulness of the model for the decision-maker. [5] show that a proxy model for a protected attribute can be useful in enforcing fairness constraints on a downstream model when the real protected attribute is not available if the proxy is appropriately multicalibrated. [10] study how refining a regression function affects the fairness and accuracy of downstream models derived from it; they propose in their discussion that multicalibration might provide a means to provide guarantees for overlapping populations; our work can be seen as carrying out this proposal.

[15] independently study a problem similar to ours. Our two papers derive a closely related but incomparable set of results. [15] tackles a more general problem, and studies a richer set of objective functions and constraints (whereas we restrict attention to the classification error objective and fairness motivated constraints). In contrast, in our paper, we are able to take advantage of the additional structure of our problem to derive improved bounds. In particular, we can handle intersecting groups (with running time and sample complexity depending polynomially on the number of groups), whereas [15] requires taking all of the exponentially many group intersections to recover disjoint groups—which leads to an exponential (in the number of groups) loss in the running time and sample complexity. Similarly, they require more precise multicalibration as more groups are added, whereas we derive results from a multicalibrated predictor with parameter that is independent of the number of groups.

1.3 Limitations

This work (and the literature to which it contributes) explores algorithmic approaches that reduce complex and and ambiguous social ideas of fairness to mathematical formalisms (such as equality of false positive rates between coarse-grained groups of individuals). Our work can be applied only when evaluating the membership of an individual in a group is well-defined, when consideration of group membership is legal[2], and when the training data is representative of the underlying population. There will be contexts in which these assumptions are either false, overly simplistic, or bypass larger questions. As an example, an application might be fair in its performance but fundamentally unethical in the first place, or groups may be systematically underrepresented in datasets. In the latter case, the guarantees of our work cannot be interpreted as

[2]Note that in some contexts such as consumer lending in the United States, direct consideration of membership in protected groups such as race is illegal. However, demographic information can be used when designing and auditing a decision-making process, so long as those characteristics are not part of the real-time lending decisions.

guarantees relative to the optimal predictor for the true distribution over groups.

It is worth noting that while the assumption that we can define group membership of individuals simplifies the complexities of personal identity, this work does improve on the existing literature on post-processing approaches to fairness in that it allows for *non-disjoint*, or intersectional, group membership. In general, this work (and all work in algorithmic fairness) should not be assumed to "solve" fairness. Instead it should be taken as a tool in a larger system to evaluate and remediate issues of fairness and ethics in machine learning.

2 PRELIMINARIES

We study regression and binary classification problems. Let $\mathcal{X}$ be an arbitrary feature space and $\mathcal{Y} = \{0, 1\}$ be a binary label space. A classification problem is defined by an underlying data distribution $\mathcal{D} \in \Delta(\mathcal{X} \times \mathcal{Y})$. In general we will not have direct access to the data distribution, but rather only to samples drawn i.i.d. from $\mathcal{D}$. We let D denote a dataset of size n, drawn i.i.d. from $\mathcal{D}$: $D \sim \mathcal{D}^n$.

We will study both regression functions $f : \mathcal{X} \to \mathbb{R}$ and classification functions (classifiers) $h : \mathcal{X} \to \{0, 1\}$. In general we will use f and variants (f^*, $\hat{f}$, etc.) when speaking of regression functions and h and variants (h^*, $\hat{h}$, etc.) when speaking of classification functions. Our interest will be in regression functions used to estimate conditional label expectations in binary prediction problems, and so the natural range of our regression functions will be (discrete subsets of) $[0, 1]$. When discussing classification error, we will use ℓ to denote the 0-1 loss function.

Definition 1 (Bayes Optimal Regression Function). *We let f^* denote the* Bayes optimal regression function $f^* = \arg\min_f \mathbb{E}_{(x,y)\sim\mathcal{D}}(f(x) - y)^2$ *which takes value:*

$$f^*(x) = \mathop{\mathbb{E}}_{(x',y')\sim\mathcal{D}}[y'|x' = x]$$

Remark 1. *f^* encodes the true conditional label expectations. We use property of Bayes optimality going forward. We do not use that f^* also minimizes squared error.*

Let $\mathcal{D}_{\mathcal{X}}$ denote the marginal distribution on features induced by projecting $\mathcal{D}$ onto $\mathcal{X}$. Note that we can equivalently sample a pair $(x, y) \sim \mathcal{D}$ by first sampling $x \sim \mathcal{D}_{\mathcal{X}}$ and then sampling $y = 1$ with probability $f^*(x)$ and $y = 0$ otherwise.

Given a classifier $h : \mathcal{X} \to \mathcal{Y}$, and a data distribution $\mathcal{D}$, we can refer to various notions of error. We will be interested in both overall error and on subsets of the data that we call *groups* (which we might think of as demographic groups when the data represents people). We will represent groups by group indicator functions:

Definition 2. *Let $\mathcal{G}$ denote a collection of* groups, *each represented by a group indicator function $g : \mathcal{X} \to \{0, 1\}$. If $g(x) = 1$ we call x a* member *of group g. Let I denote the group containing all elements ($I(x) = 1$ for all x). We will always assume that $I \in \mathcal{G}$.*

We allow $\mathcal{G}$ to contain arbitrarily intersecting groups. We now use this notation to denote the error rates and false positive rates a classifier has over these groups.

Definition 3. *The error of a classifier $h : \mathcal{X} \to \mathcal{Y}$ on a group g as measured over distribution $\mathcal{D}$ is:*

$$err(h, g, \mathcal{D}) = \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[\ell(h(x), y)|g(x) = 1]$$

The false positive rate (FPR) of a classifier $h : \mathcal{X} \to \mathcal{Y}$ on a group g is:

$$\rho(h, g, \mathcal{D}) = \mathbb{P}_{(x,y)\sim\mathcal{D}}[h(x) = 1|y = 0, g(x) = 1]$$

When h is a randomized classifier, the probabilities are computed over the randomness of h as well. For convenience, we write $err(h) = err(h, I, \mathcal{D})$, $\rho_g(h) \equiv \rho(h, g, \mathcal{D})$, and $\rho(h) \equiv \rho(h, I, \mathcal{D})$.

Definition 4. *We say that classifier $h : \mathcal{X} \to \mathcal{Y}$ satisfies γ-False Positive (FP) Fairness with respect to $\mathcal{D}$ and $\mathcal{G}$ if for all $g \in \mathcal{G}$,*

$$w_g \left|\rho_g(h) - \rho(h)\right| \leq \gamma.$$

where $w_g = \mathbb{P}_{(x,y)\sim\mathcal{D}}[y = 0, g(x) = 1]$.

Remark 2. *In the above definition, we include a multiplicative factor that provides slack in the fairness guarantee for groups with small weight over the distribution. This approximation parameter is necessary for learning from a finite sample, as statistical estimation over small groups is inherently more difficult. An equivalent alternative would be to remove the w_g term in our constraints and provide guarantees only for groups for whom w_g is sufficiently large.*

Remark 3. *We will find it convenient to work with an equivalent formulation of error and false positive rates which do not explicitly condition on $g(x) = 1$, but instead multiply by $g(x)$:*

$$\begin{aligned}
err(h, g) &= \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[\ell(h(x), y)|g(x) = 1] \\
&= \sum_v v \cdot \mathbb{P}_{(x,y)}[\ell(h(x), y) = v|g(x) = 1] \\
&= \sum_v v \cdot \frac{\mathbb{P}_{(x,y)}[\ell(h(x), y) = v \cap g(x) = 1]}{\mathbb{P}[g(x) = 1]} \\
&= \sum_v v \cdot \frac{\mathbb{P}_{(x,y)}[\ell(h(x), y) \cdot g(x) = v]}{\mathbb{P}[g(x) = 1]} \\
&= \mathop{\mathbb{E}}_{x,y}[\ell(h(x), y) \cdot g(x)] \cdot \frac{1}{\mathbb{P}[g(x) = 1]}
\end{aligned}$$

For the sake of brevity, in the main body of this paper we prove all results in the context of γ-False Positive Fairness. We discuss the modifications necessary to extend the results to other fairness notions in Appendix A.

We will study how to derive classifiers with optimal error properties, subject to fairness-motivated constraints on group-wise error rates, from regression functions satisfying *multicalibration* constraints [14]. Informally, if $\hat{f}$ is multicalibrated with respect to a class of functions C, then $\hat{f}(x)$ takes values equal to $f^*(x)$ in expectation, even conditional on both the value of $\hat{f}(x)$ and on the value of $c(x)$ for each $c \in C$. We use two variants. The first (multicalibration in expectation) was defined and studied in [11]:

Definition 5 (Multicalibration in Expectation [11, 14]). *Fix a distribution $\mathcal{D}$ and C a collection of functions $c : \mathcal{X} \to \{0, 1\}$. Fix a predictor $\hat{f} : \mathcal{X} \to R$ where R is some discrete domain $R \subset [0, 1]$.*

We say $\hat{f}$ is α-approximately multicalibrated with respect to C if for every $c \in C$:

$$\sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \left| \mathbb{E}\left[(\hat{f} - f^*)(x) c(x) \middle| \hat{f}(x) = v \right] \right| \leq \alpha.$$

We will require this notion of multicalibration with respect to the set of groups $\mathcal{G}$ with which we define our fairness constraints, for the classifiers $h \in \mathcal{H}$, and for the intersection of these classes $\mathcal{G} \times \mathcal{H} = \{g(x) \cdot h(x) | g \in \mathcal{G}, h \in \mathcal{H}\}$. We will also need a variant of multicalibration that is tailored to two-argument functions $c : \mathcal{X} \times R \to \{0, 1\}$ in order to argue about the properties of thresholding functions, which take both a value $x \in \mathcal{X}$ and a threshold in a discrete domain $R \subseteq [0, 1]$, and which threshold predictions to $\{0, 1\}$.

In this definition, when we condition on $\hat{f}(x) = v$, we also condition on the second argument of c taking the same value v. We call this *joint* multicalibration. It is only a modest generalization of multicalibration: we verify in Appendix C that existing algorithms for obtaining multicalibrated predictors easily extend to our definition of joint multicalibration.

Definition 6 (Joint Multicalibration in Expectation). *We say that a predictor $\hat{f} : \mathcal{X} \to R$ where R is some discrete domain $R \subseteq [0, 1]$ is α-approximately jointly multicalibrated with respect to a class C of functions $c : \mathcal{X} \times R \to \{0, 1\}$ if for every $c \in C$:*

$$\sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \left| \mathbb{E}\left[(\hat{f} - f^*)(x) \cdot c(x, v) \middle| \hat{f}(x) = v \right] \right| \leq \alpha.$$

3 THE STRUCTURE OF AN OPTIMAL POST-PROCESSING

In this section, we consider a fairness-constrained optimization problem of finding a model (or distribution over models) in $\mathcal{H}$ that minimizes error subject to a constraint on group-wise false positive rates:

$$\begin{aligned} \min_{h \in \Delta\mathcal{H}} \quad & \text{err}(h) \\ \text{s.t.} \quad & w_g |\rho_g(h) - \rho(h)| \leq \gamma \quad \text{for each } g \in \mathcal{G}, \end{aligned} \tag{1}$$

where $w_g, \rho_g(h)$, and $\rho(h)$ are defined as in Definition 3.

We now rewrite this error minimization optimization in a more convenient and more general form below. First, we describe the error of h with respect to an arbitrary regression function f, which is just how far h is from matching f's conditional label distribution. This error total error can be broken down into events $h(x) = 1$, of which an $1 - f(x)$ fraction should be 0; and where $h(x) = 0$, of which an $f(x)$ fraction should be 1. We rewrite the constraint in a similar fashion, switching from conditioning on group membership to multiplying by the indicator function as described in Remark 3.

Definition 7. *Let $f : \mathcal{X} \to R \subseteq [0, 1]$ be some regression function and let $\gamma \in \mathbb{R}_+$. Define $\psi(f, \gamma, \mathcal{H})$ to be the following optimization problem:*

$$\begin{aligned} \min_{h \in \Delta\mathcal{H}} \quad & \mathop{\mathbb{E}}_{x \sim \mathcal{D}_\mathcal{X}} [(1 - f(x)) \cdot \ell(h(x), 0) \\ & \quad + f(x) \cdot \ell(h(x), 1)] \\ \text{s.t. for each } g \in \mathcal{G}: \quad & |\mathbb{E}[(1 - f(x)) \cdot \ell(h(x), 0) \cdot g(x)] \\ & \quad - \beta_g \mathbb{E}\left[(1 - f(x)) \cdot \ell(h(x), 0)\right]| \leq \gamma, \end{aligned}$$

where $\beta_g = \mathbb{P}[g(x) = 1 | y = 0]$.

For $f = f^*$, this definition is equivalent to 1:

Lemma 1. *optimalfair Let f^* be the Bayes optimal regression function over $\mathcal{D}$. Then optimization problem $\psi(f^*, \gamma, \mathcal{H})$ is equivalent to the fairness-constrained optimization problem* (1).

The proof is in Appendix B. We will be interested in the properties of the optimal solution to $\psi(f, \gamma, \mathcal{H})$, which will be elucidated via its Lagrangian. Note that the optimization problem has $2|\mathcal{G}|$ linear inequality constraints. Let $\lambda = \{\lambda_g^\pm\}_{g \in \mathcal{G}}$ denote the vector of $2|\mathcal{G}|$ dual variables corresponding to those constraints, and write $\lambda_g = \lambda_g^+ - \lambda_g^-$.

Definition 8 (Lagrangian). *Given any regression function f, we define a Lagrangian of the optimization problem $\psi(f, \gamma, \mathcal{H})$ as $L_f : \mathcal{H} \times \mathbb{R}^{2|\mathcal{G}|} \to \mathbb{R}$:*

$$\begin{aligned} L_f(h, \lambda) = \mathop{\mathbb{E}}_{x \sim \mathcal{D}_\mathcal{X}} \Big[& f(x)\ell(h(x), 1) + (1 - f(x))\ell(h(x), 0) \\ & + \sum_{g \in \mathcal{G}} \lambda_g^+ (1 - f(x)) \big(\ell(h(x), 0) g(x) \\ & - \beta_g (1 - f(x)) \ell(h(x), 0) - \gamma \big) \\ & + \sum_{g \in \mathcal{G}} \lambda_g^- \left(\beta_g \ell(h(x), 0)(1 - f(x)) \right. \\ & \left. - (1 - f(x)) \ell(h(x), 0) g(x) - \gamma \right) \Big]. \end{aligned}$$

For convenience, given a Bayes optimal regressor f^*, we write $L^* = L_{f^*}$. Given any regressor $\hat{f}$, we write $\hat{L} = L_{\hat{f}}$.

Let $\mathcal{H}_A = 2^\mathcal{X}$ be the set of all Boolean functions $h : \mathcal{X} \to \{0, 1\}$. We will consider solving our optimization problem over $\mathcal{H}_A$.

3.1 Computing the optimally post-processed classifier

To approximate h given f, we need to compute an approximately optimal solution to the linear program $\psi(f, \gamma, \mathcal{H}_A)$. We accomplish this by playing a no-regret vs. best response algorithm over the primal and dual variables of the linear program [9]. The dual player is playing gradient descent over the set of dual variables λ and the primal player best responds by updating their current hypothesis.

To implement the gradient step in practice, we need to estimate the losses of h with respect to f from a finite sample. We can do this using a sample of unlabelled data of size which scales logarithmically in the number of constraints and linearly in the number of rounds T of the no-regret dynamics.

The full formulation of the optimization problem as a zero-sum game and the main algorithm, Algorithm 4, is in Appendix B.

We now introduce notation to describe the structure of the functions output by Algorithm 4, which will be useful when we discuss the necessary multicalibration requirements in the following subsection.

Definition 9 (Set of thresholding functions $\mathcal{B}(C)$). *Let $x_\mathcal{G} \in \{0, 1\}^{|\mathcal{G}|}$ denote the group membership indicator vector of some point x. Define the function*

$$d(v) := \frac{2v - 1}{1 - v}.$$

Then, let for any λ, x, β

$$s_\lambda(x, v) := 1[\langle \lambda, x_{\mathcal{G}} - \beta \rangle \geq d(v)].$$

Define $\mathcal{B}(C) = \{s_\lambda | \lambda \in \Lambda(C), \beta = \beta_{g_1}, \ldots, \beta_{g_{|\mathcal{G}|}}\}$, where $\Lambda(C) = \left\{\lambda \in \mathbb{R}^{2|\mathcal{G}|} \middle| \|\lambda\|_1 \leq C\right\}$ and $\beta_g = \mathbb{P}_{(x,y)\sim\mathcal{D}}[g(x) = 1 | y = 0]$, as defined in Definition 7.

Informally, these functions take an example, and map it to a vector of its group membership, indicating whether a λ-weighting of the example's group membership is larger than some threshold $d(v)$. In the following section, we use joint multicalibration with respect to such functions in order to relate the estimated error to the approximate LP solution to its true error. These thresholding functions $\mathcal{B}(C)$ have a natural relationship to the deterministic thresholded models that we compute at each round of algorithm: we show in Appendix B that the solution at each iteration of Algorithm 4 is exactly a function belonging to $\mathcal{B}(C)$.

Theorem 1. *algmain Let* OPT *be the objective value of the optimal solution to $\psi(f, \gamma, \mathcal{H}_A)$. Then, for any $C \in \mathbb{R}$, after $T = \frac{1}{4} \cdot C^2 \cdot \left(C^2 + 4|\mathcal{G}|\right)^2$ iterations, Algorithm 4 outputs a randomized hypothesis $\bar{h}$ with the following properties:*

- *the error of the output satisfies $err(\bar{h}) \leq \text{OPT} + \frac{2}{C}$*
- *the constraint violation of the output satisfies $w_g|\rho_g(\bar{h}) - \rho(\bar{h})| \leq \gamma + \frac{1}{C} + \frac{2}{C^2}$*
- *the output $\bar{h}$ is the uniform mixture over T constituent models, each of which belong to the set of threshold functions $\mathcal{B}(C)$.*

The full proof of Theorem 6 is in Appendix B.

Remark 4. *Although we use the standard techniques of Freund and Schapire [9] to solve the LP formulation of the problem, we provide a full description of the techniques and our application of them in Appendix B. We do so to emphasize that this choice is crucial to our solution. The chosen approach allows us to fully specify a post-processing function by deterministically breaking ties in each individual round of the zero-sum game dynamics and then uniformly randomizing over these iterates, each of which are threshold functions belonging to $\mathcal{B}(C)$, to give a final solution which approximately satisfies the desired constraints.*

3.2 From a Multicalibrated Regression Function $\hat{f}$

Thus far, we have considered the optimization problem $\psi(f, \gamma, \mathcal{H}_A)$ in the abstract, have characterized its optimal solution h, and have given a simple algorithm to find $\bar{h}$, an approximately optimal solution. When $f = f^*$, $h = h^*$ is the Bayes optimal fair classifier, and $\bar{h}$ is approximately Bayes optimal. But in practice, we will not have access to f^*, but will instead only have some surrogate function, which we will call $\hat{f}(x)$. We will argue that if $\hat{f}$ is appropriately *multicalibrated*, then it is good enough for our purposes. We will compare the approximate solution $\bar{h}$ produced by Algorithm 4 to the optimization problem $\psi(\hat{f}, \gamma, \mathcal{H}_A)$ which has corresponding Lagrangian $\hat{L}(\hat{h}, \hat{\lambda})$, as defined in Definition 8 to the optimal solution (h^*, λ^*) to the optimization problem $\psi(f^*, \gamma, \mathcal{H})$ for some constrained class $\mathcal{H}$, and show conditions under which they are close.

In order to proceed, we first need to determine what our surrogate function ought to be multicalibrated with respect to. In addition to being α-approximately multicalibrated in expectation with respect to $\mathcal{G}$ and $\mathcal{H}$, we will require that $\hat{f}$ be α-approximately multicalibrated with respect to $\mathcal{G} \times \mathcal{H} = \{g(x) \cdot h(x) | g \in \mathcal{G}, h \in \mathcal{H}\}$. Furthermore, we will need to require that $\hat{f}$ be α-approximately *jointly* multicalibrated in expectation with respect to the set of functions $\mathcal{B}(C) \times \mathcal{G}$.

Remark 5. *When the groups of interest are disjoint, joint multicalibration with respect to the class $\mathcal{B}(C)$ is implied by multicalibration with respect to $\mathcal{G}$. But when groups can intersect, this is not an implication, and satisfying joint multicalibration with respect to $\mathcal{B}(C)$ adds new constraints on $\hat{f}$.*

With these preliminaries behind us, we can now state our main theorem, which shows that for any class of models $\mathcal{H}$ and class of groups $\mathcal{G}$, given an appropriately multicalibrated $\hat{f}$ (with multicalibration requirements depending on $\mathcal{H}$, $\mathcal{G}$, and $\mathcal{B}(C)$), the model $\bar{h}$ output by Algorithm 4 achieves an error rate and fairness guarantees comparable to the optimal solution to $\psi(f^*, \gamma, \mathcal{H})$:

Theorem 2. *finalerror Set $C = \sqrt{1/\alpha}$. Let $\hat{f}$ be α-approximately multicalibrated in expectation with respect to $\mathcal{G}$, $\mathcal{H}$, and $\mathcal{G} \times \mathcal{H}$ and α-approximately jointly multicalibrated in expectation with respect to $\mathcal{G} \times \mathcal{B}(C)$. Let $\bar{h}$ be the result of running Algorithm 4 with input $\hat{f}$ and C. Then, $err(\bar{h}) \leq err(h^*) + \alpha(5 + 2\sqrt{1/\alpha}) + 2\sqrt{\alpha}$, and for all $g \in \mathcal{G}, w_g \left|\rho_g(\bar{h}) - \rho(\bar{h})\right| \leq w_g \left|\rho_g(h^*) - \rho(h^*)\right| + 2\alpha$.*

Proof Sketch. Generalizing notation from the previous sections, let $\text{err}(h) = \mathbb{E}_{x\sim\mathcal{D}_X}[f^*(x)\ell(h(x), 1) + (1 - f^*(x))\ell(h(x), 0)]$ denote the true error of h on the distribution (i.e. as measured according to the true conditional label distribution f^*), and let $\widehat{\text{err}}(h) = \mathbb{E}_{x\sim\mathcal{D}_X}[\hat{f}(x)\ell(h(x), 1) + (1 - \hat{f}(x))\ell(h(x), 0)]$ denote the error of h as estimated using the surrogate function $\hat{f}$. At a high level, the proof of Theorem 7 will proceed as follows:

$$\begin{aligned}
\text{err}(h^*) &= L^*(h^*, \lambda^*) && (2)\\
&\geq L^*(h^*, \hat{\lambda}) && (3)\\
&\approx \hat{L}(h^*, \hat{\lambda}) && (4)\\
&\geq \hat{L}(\hat{h}, \hat{\lambda}) && (5)\\
&= \widehat{\text{err}}(\hat{h}) && (6)\\
&\approx \widehat{\text{err}}(\bar{h}) && (7)\\
&\approx \text{err}(\bar{h}). && (8)
\end{aligned}$$

Each of these steps takes a lemma (presented in full in the appendix) to justify, but the logic is at a high level as follows: The equalities on Lines 2 and 6 follow from complimentary slackness: at the optimal solution (h^*, λ^*) it must be that for each constraint g either the constraint is exactly tight so that its "violation" term in the Lagrangian evaluates to 0, or its corresponding dual variable $\lambda_g^{\pm} = 0$. Thus, all terms in the Lagrangian other than the objective evaluate to 0. The inequality in Line 3 follows from the dual optimality condition that $\lambda^* \in \arg\max_\lambda L^*(h^*, \lambda)$ and similarly the inequality in Line 5 follows from the primal optimality condition that $\hat{h} \in \arg\min_{h\in\mathcal{H}_A} \hat{L}(h, \hat{\lambda})$. Line 7 follows from the fact that $\bar{h}$ is an approximately optimal solution to $\psi(\hat{f}, \gamma, \mathcal{H}_A)$. Lines 4 and 8

follow from our multicalibration guarantees, the former from multicalibration with respect to groups and our hypothesis class, and the latter from joint multicalibration with respect to the functions $\mathcal{B}(C) \times \mathcal{G}$.

We provide the proof of Lines 4 and 8 below. The first to demonstrate how we use multicalibration to show closeness of the Lagrangian with respect to the Bayes optimal regressor f^* and the Lagrangian with respect to the multicalibrated regressor $\hat{f}$; the second to demonstrate how we use joint multicalibration to show that the error of the solution output by Algorithm 4 with respect to the multicalibrated regressor $\hat{f}$ is close to its error with respect to the Bayes optimal regressor f^*. The remainder of the proof is in Appendix B.

Lemma 2. *lagrclose(Bounding Equation 3 by Equation 4) Fix any λ. If $\hat{f}$ is α-multicalibrated with respect to $\mathcal{G}, \mathcal{H}$, and $\mathcal{G} \times \mathcal{H} = \{g(x) \cdot h(x) | g \in \mathcal{G}, h \in \mathcal{H}\}$, then then we have*

$$\left|\hat{L}(h^*, \lambda) - L^*(h^*, \lambda)\right| \leq \alpha(3 + 2\|\lambda\|_1).$$

Proof. Define $\kappa = 1 + \sum_{g \in \mathcal{G}} \lambda_g (g(x) - \beta_g)$ Observe that we can write:

$$\hat{L}(h, \lambda) = L_1(h, \lambda) - \gamma \sum_{g \in \mathcal{G}} (\lambda_g^+ + \lambda_g^-) - \hat{L}_2(h, \lambda),$$

where

$$L_1(h, \lambda) = \mathop{\mathbb{E}}_{x \sim \mathcal{D}_X}\left[\ell(h(x), 0) \cdot \kappa\right],$$
$$\hat{L}_2(h, \lambda) = \mathop{\mathbb{E}}_{x \sim \mathcal{D}_X}\left[\hat{f}(x)\Big(-\ell(h(x), 1) + \ell(h(x), 0) \cdot \kappa\Big)\right].$$

Similarly, we can write:

$$L^*(h, \lambda) = L_1(h, \lambda) - \gamma \sum_{g \in \mathcal{G}} (\lambda_g^+ + \lambda_g^-) - L_2^*(h, \lambda),$$

where

$$L_2^*(h, \lambda) = \mathop{\mathbb{E}}_{x \sim \mathcal{D}_X}\left[f^*(x)\Big(\ell(h(x), 0) \cdot \kappa - \ell(h(x), 1)\Big)\right].$$

Observe that the L_1 term does not depend on $\hat{f}$ or f^* and so is common between $\hat{L}$ and L^*. We can bound $\hat{L}_2$ as follows:

$$\begin{aligned}
\hat{L}_2(h^*, \lambda) &= \mathop{\mathbb{E}}_{x \sim \mathcal{D}_X}\left[\hat{f}(x)\Big(-\ell(h^*(x), 1) + \ell(h^*(x), 0) \cdot \kappa\Big)\right] \\
&= \mathop{\mathbb{E}}_{x \sim \mathcal{D}_X}\left[\hat{f}(x)\Big(-(1 - h^*(x)) + h^*(x) \cdot \kappa\Big)\right] \\
&= \sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[\hat{f}(x)\Big(-(1 - h^*(x)) \right. \\
&\qquad \left. + h^*(x) \cdot \kappa\Big) \middle| \hat{f}(x) = v\right] \\
&\leq \sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[f^*(x)\Big(-(1 - h^*(x)) \right. \\
&\qquad \left. + h^*(x)(\kappa)\Big) \middle| \hat{f}(x) = v\right] \\
&\qquad + \alpha\left(3 + \sum_{g \in \mathcal{G}} \lambda_g(1 + \beta_g)\right) \\
&\leq L_2^*(h^*, \lambda) + \alpha\left(3 + 2\|\lambda\|_1\right),
\end{aligned}$$

where the first inequality follows from the fact that $h^* \in \mathcal{H}$ and $\hat{f}$ is multicalibrated with respect to $\mathcal{G}, \mathcal{H}$, and $\mathcal{G} \times \mathcal{H}$, which we verify below:

$$\begin{aligned}
&\sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[\Big(f^*(x) - \hat{f}(x)\Big)\Big(-(1 - h^*(x)) \right. \\
&\qquad \left. + h^*(x) \cdot \kappa\Big) \middle| \hat{f}(x) = v\right] \\
&= \sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[\Big(f^*(x) - \hat{f}(x)\Big)\Big(-1 + 2h^*(x) \right. \\
&\qquad \left. + h^*(x) \sum_{g \in \mathcal{G}} \lambda_g(g(x) - \beta_g)\Big) \middle| \hat{f}(x) = v\right] \\
&= -\sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[\hat{f}^*(x) - \hat{f}(x) \middle| \hat{f}(x) = v\right] \\
&\quad + 2\sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[(f^*(x) \right. \\
&\qquad \left. - \hat{f}(x))h^*(x) \middle| \hat{f}(x) = v\right] \\
&\quad + \sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \sum_{g \in \mathcal{G}} \lambda_g \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[(f^*(x) \right. \\
&\qquad \left. - \hat{f}(x))h^*(x)g(x) \middle| \hat{f}(x) = v\right] \\
&\quad - \sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \sum_{g \in \mathcal{G}} \lambda_g \beta_g \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[(f^*(x) \right. \\
&\qquad \left. - \hat{f}(x))h^*(x) \middle| \hat{f}(x) = v\right]
\end{aligned}$$

$$\leq 3\alpha + \sum_{g\in\mathcal{G}} \lambda_g(1+\beta_g)\alpha$$
$$\leq 3\alpha + \alpha \sum_{g\in\mathcal{G}} \lambda_g(1+\max_{g'\in\mathcal{G}} \beta_{g'})$$
$$\leq 3\alpha + \alpha \sum_{g\in\mathcal{G}} \lambda_g(1+1)$$

$$\leq 3\alpha + 2\|\lambda\|_1\alpha$$

Similarly, we can show that $L^*(h^*,\lambda) - \hat{L}(h^*,\lambda) \leq \alpha\,(3+2\|\lambda\|_1)$. Putting everything together, we get that:

$$\left|\hat{L}(h^*,\lambda) - L^*(h^*,\lambda)\right| \leq \alpha(3+2\|\lambda\|_1).$$

This concludes the proof. □

We now provide the proof of Line 8.

Lemma 3 (Bound of Equation 7 by Equation 8). *Let $\hat{f}$ be α-approximately jointly multicalibrated with respect to $\mathcal{B}(C)\times\mathcal{G}$. Then,*

$$\left|\widehat{err}(\bar{h}) - err(\bar{h})\right| \leq 2\alpha.$$

Proof. Since $\bar{h}$ is a randomized model that mixes uniformly over model $\hat{h}_t$ for $t \in [T]$, it suffices to show that for every $t \in [T]$,

$$\left|\widehat{\mathrm{err}}(\hat{h}_t) - \mathrm{err}(\hat{h}_t)\right| \leq 2\alpha.$$

We can compute:

$$\begin{aligned}
\widehat{\mathrm{err}}(\hat{h}_t) &= \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\left[\hat{f}(x)\ell(\hat{h}_t,1) + (1-\hat{f}(x))\ell(\hat{h}_t(x),0)\right],\\
&= \sum_{v\in R} \mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=0]\cdot\\
&\qquad \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}[\hat{f}(x)\ell(\hat{h}_t(x),1) + (1-\hat{f}(x))\cdot\\
&\qquad\qquad \ell(\hat{h}_t(x),0)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=0]\\
&\quad + \sum_{v\in R} \mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\cdot\\
&\qquad \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}[\hat{f}(x)\ell(\hat{h}_t(x),1) + (1-\hat{f}(x))\cdot\\
&\qquad\qquad \ell(\hat{h}_t(x),0)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1].
\end{aligned}$$

By Lemma 16, $\hat{h}_t(x) = s_{\lambda_{t-1}}(x,\hat{f}(x))$, and so in particular conditioning on $\hat{f}(x)=v$ and $s_{\lambda_{t-1}}(x,v)$ fixes the value of $\hat{h}_t(x)$. So, we can rewrite the above as

$$\begin{aligned}
\widehat{\mathrm{err}}(\hat{h}_t) &= \sum_{v\in R} \mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=0]\cdot\\
&\qquad \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}[\hat{f}(x)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=0]\\
&\quad + \sum_{v\in R} \mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\cdot\\
&\qquad \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}[1-\hat{f}(x)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\\
&\leq \sum_{v\in R} \mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=0]\cdot\\
&\qquad \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}[f^*(x)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=0] + \alpha\\
&\quad + \sum_{v\in R} \mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\cdot\\
&\qquad \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}[1-f^*(x)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1] + \alpha\\
&= \mathop{\mathbb{E}}_{x\sim D_X}[f^*(x)\ell(\hat{h}_t(x),1) + (1-f^*(x))\ell(\hat{h}_t(x),0)] + 2\alpha\\
&= \mathrm{err}(\hat{h}_t) + 2\alpha,
\end{aligned}$$

where the inequality comes from our α-approximate joint multicalibration guarantee. The same argument yields the opposite direction, completing the proof. □

4 CONCLUSION

We describe a post-processing method that takes as input a regression function and, using a reasonable amount of unlabeled data, outputs an approximately optimal classifier which satisfies a variety of fairness constraints over intersecting demographic groups. The main contribution we make is answering two questions about understanding post-processing methods for fairness constrained optimization: how should we post-process a base regressor to obtain a valuable downstream classifier and for what (weak) conditions of the base regressor (weaker than Bayes optimality, for example) can we give provable guarantees of the post-processing? We show that the algorithmic description of an error-minimizing and fair post-processing is a simple linear threshold function and that beginning with a multicalibrated base regressor results in an approximately optimal and fair classifier.

A GENERALIZATION TO OTHER FAIRNESS NOTIONS

We find it convenient to have notation for two quantities which appear repeatedly in the following exposition. Let $\kappa = 1 + \sum_{g \in \mathcal{G}} \lambda_g (g(x) - \beta_g)$ and $\mu = 1 + \kappa$, and κ_t, μ_t the same quantites for $\lambda_{g,t}$, respectively.

A.1 False Negative (FN) Fairness

Definition 10. *The false negative rate of a classifier $h : \mathcal{X} \to \mathcal{Y}$ on a group g is:*

$$\rho_{FN}(h, g, \mathcal{D}) = \mathbb{P}_{(x,y)\sim\mathcal{D}}[h(x) \neq y | y = 1, g(x) = 1]$$

When h is a randomized classifier, the probabilities are computed over the randomness of h as well. $\rho_g^{FN}(h) \equiv \rho_{FN}(h, g, \mathcal{D})$, and $\rho_{FN}(h) \equiv \rho(h, I, \mathcal{D})$.

Definition 11. *We say that classifier $h : \mathcal{X} \to \mathcal{Y}$ satisfies γ-False Negative (FN) Fairness with respect to $\mathcal{D}$ and $\mathcal{G}$ if for all $g \in \mathcal{G}$,*

$$w_g^{FN} \left| \rho_g^{FN}(h) - \rho_{FN}(h) \right| \leq \gamma.$$

where $w_g^{FN} = \mathbb{P}_{(x,y)\sim\mathcal{D}}[g(x) = 1, y = 1]$.

We consider the following fairness-constrained optimization problem:

$$\begin{aligned} &\min_{h \in \Delta\mathcal{H}} && \text{err}(h) \\ &\text{s.t. for each } g \in \mathcal{G}: && w_g^{\text{FN}} |\rho_g^{\text{FN}}(h) - \rho_{\text{FN}}(h)| \leq \gamma, \end{aligned} \tag{9}$$

Definition 12. *Let $f : \mathcal{X} \to R \subseteq [0, 1]$ be some regression function and let $\gamma \in \mathbb{R}_+$. Define $\psi_{FN}(f, \gamma, \mathcal{H})$ to be the following optimization problem:*

$$\begin{aligned} &\min_{h \in \Delta\mathcal{H}} && \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}[f(x)\ell(h(x), 1) + (1 - f(x))\ell(h(x), 0)] \\ &\text{s.t. for each } g \in \mathcal{G}: && \left| \mathbb{E}[\ell(h(x), 1)g(x)f(x)] - \beta_g^{FN} \mathbb{E}[\ell(h(x), 1)f(x)] \right| \leq \gamma, \end{aligned}$$

where $\beta_g^{FN} = \mathbb{P}[g(x) = 1 | y = 1]$.

Lemma 4. *Let f^* be the Bayes optimal regression function over $\mathcal{D}$. Then optimization problem $\psi_{FN}(f^*, \gamma, \mathcal{H})$ is equivalent to the fairness-constrained optimization problem 9.*

Proof. Note that the objective function is equivalent to that of Equation 1, and hence proof of the objectives being equivalent is identical to that of Lemma 12. For the constraints, note that

$$\begin{aligned} w_g^{\text{FN}} |\rho_g^{\text{FN}}(h) - \rho_{\text{FN}}(h)| &= \mathbb{P}[g(x) = 1, y = 1] \, |\mathbb{P}[h(x) = 0 | g(x) = 1, y = 1] - \mathbb{P}[h(x) = 0 | y = 1]| \\ &= \mathbb{P}[g(x) = 1, y = 1] \left| \frac{\mathbb{P}[h(x) = 0, g(x) = 1, y = 1]}{\mathbb{P}[g(x) = 1, y = 1]} - \frac{\mathbb{P}[h(x) = 0, y = 1]}{\mathbb{P}[Y = 1]} \right| \\ &= \left| \mathbb{P}[h(x) = 0, g(x) = 1, y = 1] - \frac{\mathbb{P}[g(x) = 1, y = 1]\mathbb{P}[h(x) = 0, y = 1]}{\mathbb{P}[Y = 1]} \right| \\ &= \left| \mathbb{E}[\ell(h(x), 1)g(x)f^*(x)] - \frac{\mathbb{P}[g(x) = 1, y = 1]}{\mathbb{P}[Y = 1]} \mathbb{E}\left[\ell(h(x), 1)f^*(x)\right] \right| \\ &= \left| \mathbb{E}[\ell(h(x), 1)g(x)f^*(x)] - \mathbb{P}[g(x) = 1 | Y = 0] \mathbb{E}\left[\ell(h(x), 1)f^*(x)\right] \right| \\ &= \left| \mathbb{E}[\ell(h(x), 1)g(x)f^*(x)] - \beta_g^{\text{FN}} \mathbb{E}\left[\ell(h(x), 1)f^*(x)\right] \right|. \end{aligned}$$

The result follows. □

Definition 13 (Lagrangian). *Given any regression function f, we define a Lagrangian of the optimization problem $\psi_{FN}(f, \gamma, \mathcal{H})$ as $L_f^{FN} : \mathcal{H} \times \mathbb{R}^{2|\mathcal{G}|} \to \mathbb{R}$:*

$$\begin{aligned} L_f^{FN}(h, \lambda) = \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X} \Bigg[& f(x)\ell(h(x), 1) + (1 - f(x))\ell(h(x), 0) \\ & + \sum_{g \in \mathcal{G}} \lambda_g^+ \left(\ell(h(x), 1)g(x)f(x) - \beta_g \ell(h(x), 1)f(x) - \gamma \right) \\ & + \sum_{g \in \mathcal{G}} \lambda_g^- \left(\beta_g \ell(h(x), 1)f(x) - \ell(h(x), 1)g(x)f(x) - \gamma \right) \Bigg] \end{aligned}$$

Lemma 5.

$$L_f^{FN}(h,\lambda) = \mathbb{E}_{x\sim\mathcal{D}_X}\Bigg[\ell(h(x),0) - \gamma\sum_{g\in\mathcal{G}}(\lambda_g^+ + \lambda_g^-) + f(x)\left(-\ell(h(x),0) + \ell(h(x),1)\left(1 + \sum_{g\in\mathcal{G}}\lambda_g(g(x) - \beta_g^{FN})\right)\right)\Bigg]$$

Proof. Distributing out like terms in the expression for the Lagrangian in Definition 13 gives us

$$\begin{aligned}
L_f(h,\lambda) &= \mathbb{E}_{x\sim\mathcal{D}_X}\Bigg[\ell(h(x),0) - \gamma\sum_{g\in\mathcal{G}}(\lambda_g^+ + \lambda_g^-) \\
&\quad + f(x)\left(\ell(h(x),1) - \ell(h(x),0) + \ell(h(x),1)\sum_{g\in\mathcal{G}}(\lambda_g^+(g(x)-\beta_g) + \lambda_g^-(\beta_g - g(x))\right)\Bigg] \\
&= \mathbb{E}_{x\sim\mathcal{D}_X}\Bigg[\ell(h(x),0) - \gamma\sum_{g\in\mathcal{G}}(\lambda_g^+ + \lambda_g^-) \\
&\quad + f(x)\left(-\ell(h(x),0) + \ell(h(x),1)\left(1 + \sum_{g\in\mathcal{G}}(\lambda_g^+ - \lambda_g^-)(g(x)-\beta_g)\right)\right)\Bigg].
\end{aligned}$$

Recall that $\lambda_g = \lambda_g^+ - \lambda_g^-$, so we are done. □

Lemma 6. *The optimal post-processed classifier h of $\psi(f,\gamma,\mathcal{H}_A)$ for some regressor f takes the following form:*

$$h(x) = \begin{cases} 1, & \text{if } f(x) > \frac{1}{\mu} \text{ and } \mu > 0, \\ 0, & \text{if } f(x) < \frac{1}{\mu} \text{ and } \mu > 0, \\ 1, & \text{if } f(x) < \frac{1}{\mu} \text{ and } \mu < 0, \\ 0, & \text{if } f(x) > \frac{1}{\mu} \text{ and } \mu < 0. \end{cases}$$

In the edge case in which $f(x) = \frac{1}{\mu}$, $h(x)$ could take either value and might be randomized.

Proof. Note that since we are optimizing over the set of all binary classifiers, h optimizes the Lagrangian objective pointwise for every x. In particular, we have from Lemma 5 that:

$$h(x) = \arg\min_p\left[\ell(p,0) + f(x)\left(-\ell(p,0) + \ell(p,1)\left(1 + \sum_{g\in\mathcal{G}}\lambda_g(g(x)-\beta_g)\right)\right)\right].$$

In order to determine the threshold, we need to check when setting $p = 1$ leads to a value less than setting $p = 0$. In other words, we need to solve for $f(x)$ when

$$\begin{aligned}
1 - f(x) &< f(x)\left(1 + \sum_{g\in\mathcal{G}}\lambda_g(g(x)-\beta_g)\right) \\
\Rightarrow f(x) &> \frac{1}{2 + \sum_{g\in\mathcal{G}}\lambda_g(g(x)-\beta_g)}.
\end{aligned}$$

Thus,

$$h(x) = \begin{cases} 1, & \text{if } f(x) > \frac{1}{\mu} \text{ and } \mu > 0, \\ 0, & \text{if } f(x) < \frac{1}{\mu} \text{ and } \mu > 0, \\ 1, & \text{if } f(x) < \frac{1}{\mu} \text{ and } \mu < 0, \\ 0, & \text{if } f(x) > \frac{1}{\mu} \text{ and } \mu < 0. \end{cases}$$

□

From Lemma 6, we can now define a best-response model and use Algorithm 1 to generate an optimally post-processed model that preserves γ−False Negative fairness. The algorithm's error bounds may be derived using symmetric arguments to sections 3.1 and 3.2, where $\hat{f}$ is required to be α-approximately jointly multicalibrated in expectation with respect to $s_\lambda(x,v) := 1[\langle \lambda, x_{\mathcal{G}} - \beta\rangle \geq (1-2v)/v]$ following the same arguments as used in Lemma 16.

Algorithm 1 Projected Gradient Descent Algorithm for γ-False Negative Fairness

Input: D: dataset, $f : \mathcal{X} \to [0,1]$: regression function, $\mathcal{G}$: groups, γ: tolerance on fairness violation, C: bound on dual ($\|\lambda\|_1 \leq C$), η: learning rate
Initialize dual vector $\lambda^0 = \mathbf{0}$ and set $T = \frac{1}{4} \cdot C^2 \cdot (C^2 + 4|\mathcal{G}|)^2$.
for $t = 1, \ldots, T$ **do**
  Primal player updates h_t

$$h_t(x) = \begin{cases} 1, & \text{if } f(x) \geq \frac{1}{\mu_{t-1}} \text{ and } \mu_{t-1} > 0, \\ 0, & \text{if } f(x) < \frac{1}{\mu_{t-1}} \text{ and } \mu_{t-1} > 0, \\ 1, & \text{if } f(x) < \frac{1}{\mu_{t-1}} \text{ and } \mu_{t-1} < 0, \\ 0, & \text{if } f(x) \geq \frac{1}{\mu_{t-1}} \text{ and } \mu_{t-1} < 0, \\ 0 & \text{if } \mu_{t-1} = 0 \end{cases}$$

  Compute

$$\hat{\rho}_{g,t} = \mathop{\mathbb{E}}_{(x,y)\sim D}[\ell(h_t(x),1)g(x)f(x)] \text{ for all } g \in \mathcal{G},$$
$$\hat{\rho}_t = \mathop{\mathbb{E}}_{(x,y)\sim D}[\beta_g \ell(h_t(x),1)f(x)], \text{ where } \beta_g = \mathbb{P}[g(x)=1|y=0]$$

  Dual player updates

$$\lambda_{g,t,+} = \max(0, \lambda_{g,t,+} + \eta \cdot (\hat{\rho}_{g,t} - \hat{\rho}_t - \gamma)),$$
$$\lambda_{g,t,-} = \max(0, \lambda_{g,t,-} + \eta \cdot (\hat{\rho}_t - \hat{\rho}_{g,t} - \gamma)).$$

  Dual player sets $\lambda_t = \sum_{g\in\mathcal{G}} \lambda_{g,t,+} - \lambda_{g,t,-}$.
  if $\|\lambda_t\|_1 > C$ **then**
    set $\lambda_t = \arg\min_{\{\tilde{\lambda}\in\mathbb{R}^{2\mathcal{G}} | \|\tilde{\lambda}\|_1 \leq C\}} \|\lambda_t - \tilde{\lambda}\|_2^2$.
  end if
end for
Output: $\bar{h} := \frac{1}{T}\sum_{t=1}^{T} \hat{h}_t$, a uniformly random classifier over all rounds' hypotheses.

A.2 Error Fairness

Definition 14. *We say that classifier $h : \mathcal{X} \to \mathcal{Y}$ satisfies γ-Error (E) Fairness with respect to $\mathcal{D}$ and $\mathcal{G}$ if for all $g \in \mathcal{G}$,*

$$w_g^E \, |err(h,g,\mathcal{D}) - err(h,\mathcal{D})| \leq \gamma,$$

where $w_g^E = \mathbb{P}_{(x,y)\sim\mathcal{D}}[g(x)=1]$.

We consider the following fairness-constrained optimization problem:

$$\begin{aligned} &\min_{h\in\Delta\mathcal{H}} && \text{err}(h) \\ &\text{s.t. for each } g \in \mathcal{G}: && w_g^{\text{E}} \, |\text{err}(h,g,\mathcal{D}) - \text{err}(h,\mathcal{D})| \leq \gamma, \end{aligned} \tag{10}$$

Definition 15. *Let $f : \mathcal{X} \to R \subseteq [0,1]$ be some regression function and let $\gamma \in \mathbb{R}_+$. Define $\psi_E(f,\gamma,\mathcal{H})$ to be the following optimization problem:*

$$\begin{aligned} &\min_{h\in\Delta\mathcal{H}} \mathop{\mathbb{E}}_{x\sim\mathcal{D}_\mathcal{X}}[f(x)\ell(h(x),1) + (1-f(x))\ell(h(x),0)] \\ &\textit{s.t. for each } g \in \mathcal{G}: \\ &|\mathbb{E}[\ell(h(x),1)g(x)f^*(x) + \ell(h(x),0)g(x)(1-f^*(x)) \\ &\quad - w_g^E(\ell(h(x),1)f^*(x) - w_g^E\ell(h(x),0)(1-f^*(x)]| \leq \gamma, \end{aligned}$$

where $w_g^E = \mathbb{P}_{(x,y)\sim\mathcal{D}}[g(x) = 1]$ *as in the previous definition.*

Lemma 7. *Let* f^* *be the Bayes optimal regression function over* $\mathcal{D}$*. Then optimization problem* $\psi_E(f^*, \gamma, \mathcal{H})$ *is equivalent to the fairness-constrained optimization problem 10.*

Proof. Note that the objective function is equivalent to that of Equation 1, and hence proof of the objectives being equivalent is identical to that of Lemma 12. For the constraints, note that

$$\begin{aligned}
w_g^{\mathrm{E}}|\mathrm{err}(h,g,\mathcal{D})| - \mathrm{err}(h,\mathcal{D}) &= \mathbb{P}[g(x)=1]\Big|\mathbb{P}[y=1|g(x)=1]\mathbb{P}[h(x)=0|g(x)=1,y=1] \\
&\quad + \mathbb{P}[y=0|g(x)=1]\mathbb{P}[h(x)=1|g(x)=1,y=0] \\
&\quad - (\mathbb{P}[y=1]\mathbb{P}[h(x)=0|y=1] + \mathbb{P}[y=0]\mathbb{P}[h(x)=1|y=0])\Big| \\
&= \mathbb{P}[g(x)=1]\Big|\mathbb{P}[y=1|g(x)=1]\frac{\mathbb{P}[h(x)=0,g(x)=1,y=1]}{\mathbb{P}[g(x)=1,y=1]} \\
&\quad + \mathbb{P}[y=1|g(x)=1]\frac{\mathbb{P}[h(x)=1,g(x)=1,y=0]}{\mathbb{P}[g(x)=1,y=0]} \\
&\quad - \mathbb{P}[y=1]\frac{\mathbb{P}[h(x)=0,y=1]}{\mathbb{P}[y=1]} - \mathbb{P}[y=0]\frac{\mathbb{P}[h(x)=1,y=1]}{\mathbb{P}[y=0]}\Big| \\
&= |\mathbb{E}[\ell(h(x),1)g(x)f^*(x) + \ell(h(x),0)g(x)(1-f^*(x)) \\
&\quad - w_g^{\mathrm{E}}(\ell(h(x),1)f^*(x) - w_g^{\mathrm{E}}\ell(h(x),0)(1-f^*(x))]|
\end{aligned}$$

□

Definition 16 (Lagrangian). *Given any regression function* f*, we define a Lagrangian of the optimization problem* $\psi_E(f, \gamma, \mathcal{H})$ *as* $L_f^E : \mathcal{H} \times \mathbb{R}^{2|\mathcal{G}|} \to \mathbb{R}$*:*

$$\begin{aligned}
L_f^E(h,\lambda) = \mathbb{E}_{x\sim\mathcal{D}_X}\Bigg[& f(x)\ell(h(x),1) + (1-f(x))\ell(h(x),0) \\
&+ \sum_{g\in\mathcal{G}} \lambda_g^+\big(\ell(h(x),1)g(x)f(x) + \ell(h(x),0)g(x)(1-f(x)) \\
&\qquad - w_g^E\ell(h(x),1)f(x) - w_g^E\ell(h(x),0)(1-f(x)) - \gamma\big) \\
&+ \sum_{g\in\mathcal{G}} \lambda_g^-\big(w_g^E\ell(h(x),1)f(x) + w_g^E\ell(h(x),0)(1-f(x)) \\
&\qquad - \ell(h(x),1)g(x)f(x) - \ell(h(x),0)g(x)(1-f(x)) - \gamma\big)\Bigg].
\end{aligned}$$

Lemma 8.

$$\begin{aligned}
L_f^E(h,\lambda) = \mathbb{E}_{x\sim\mathcal{D}_x}\Bigg[& \ell(h(x),0)\Big(1 + \sum_{g\in\mathcal{G}}\lambda_g(g(x) - w_g^E)\Big) - \gamma\sum_{g\in\mathcal{G}}(\lambda_g^+ + \lambda_g^-) \\
&+ f(x)\Bigg(-\ell(h(x),0)\Big[1 + \sum_{g\in\mathcal{G}}\lambda_g(g(x) - w_g^E)\Big] \\
&\qquad + \ell(h(x),1)\Big[1 + \sum_{g\in\mathcal{G}}\lambda_g(g(x) - w_g^E)\Big]\Bigg)\Bigg]
\end{aligned}$$

Proof. Distribute out like terms as shown previously. □

Lemma 9. *The optimal post-processed classifier* h *of* $\psi(f, \gamma, \mathcal{H}_A)$ *for some regressor* f *takes the following form:*

$$h(x) = \begin{cases} 1, & \text{if } f(x) > \frac{1+\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E)}{2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E)} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E) > 0, \\ 0, & \text{if } f(x) < \frac{1+\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E)}{2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E)} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E) > 0, \\ 1, & \text{if } f(x) < \frac{1+\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E)}{2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E)} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E) < 0, \\ 0, & \text{if } f(x) > \frac{1+\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E)}{2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E)} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E) > 0. \end{cases}$$

In the edge case in which $f(x) = \frac{1+\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E)}{2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^E)}$, $h(x)$ *could take either value and might be randomized.*

Proof. Note that since we are optimizing over the set of all binary classifiers, h optimizes the Lagrangian objective pointwise for every x. In particular, we have from Lemma 8 that:

$$h(x) = \arg\min_p \left[\ell(p,0)\left(1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right) + f(x)\left(-\ell(p,0)\left[1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right] + \ell(p,1)\left[1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right]\right)\right]$$

Setting $p = 0$ makes the inner portion of the expression evaluate to

$$f(x)\left(1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right),$$

and setting $p = 1$ makes the inner portion of the expression evaluate to

$$\left(1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right) - f(x)\left(1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right)$$

In order to find the optimal h, we want to find the threshold at which setting $p = 1$ minimizes the expression, and hence:

$$\left(1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right) - f(x)\left(1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right) < f(x)\left(1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right)$$

$$\frac{1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})}{\left(1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right) + \left(1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})\right)} < f(x)$$

$$\frac{1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})}{2 + 2\sum_{g\in\mathcal{G}} \lambda_g(g(x) - w_g^{\mathrm{E}})} < f(x)$$

Thus,

$$h(x) = \begin{cases} 1, & \text{if } f(x) > \frac{1+\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}})}{2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}})} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}}) > 0, \\ 0, & \text{if } f(x) < \frac{1+\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}})}{2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}})} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}}) > 0, \\ 1, & \text{if } f(x) < \frac{1+\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}})}{2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}})} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}}) < 0, \\ 0, & \text{if } f(x) > \frac{1+\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}})}{2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}})} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}}) > 0. \end{cases}$$

□

From Lemma 9, we can now define a best-response model and use Algorithm 2 to generate an optimally post-processed model that preserves γ–Error fairness. The algorithm's error bounds may be derived using symmetric arguments to sections 3.1 and 3.2, where $\hat{f}$ is α-multicalibrated in expectation with respect to $\mathcal{G}, \mathcal{H}$, and $\mathcal{G} \times \mathcal{H}$ and is jointly multicalibrated with respect to functions of the form:

$$1\left[\langle \lambda^{t-1}, x_{\mathcal{G}} - w^{\mathrm{E}}\rangle \geq \frac{2v-1}{1-2v}\right]$$

the proofs from section 3.2 may be modified to get its desired error bounds.

Algorithm 2 Projected Gradient Descent Algorithm for γ-Error Fairness

Input: D: dataset, $f : \mathcal{X} \to [0,1]$: regression function, $\mathcal{G}$: groups, γ: tolerance on fairness violation, C: bound on dual ($\|\lambda\|_1 \leq C$), η: learning rate

Initialize dual vector $\lambda^0 = \mathbf{0}$ and set $T = \frac{1}{4} \cdot C^2 \cdot (C^2 + 4|\mathcal{G}|)^2$.

for $t = 1, \ldots, T$ **do**

Primal player updates h_t

$$h_t(x) = \begin{cases} 1, & \text{if } f(x) > \frac{1+\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}})}{2+2\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}})} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}}) > 0, \\ 0, & \text{if } f(x) < \frac{1+\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}})}{2+2\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}})} \text{ and } 2+2\sum_{g^{t-1}\in\mathcal{G}} \lambda_g(g(x)-w_g^{\mathrm{E}}) > 0, \\ 1, & \text{if } f(x) < \frac{1+\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}})}{2+2\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}})} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}}) < 0, \\ 0, & \text{if } f(x) > \frac{1+\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}})}{2+2\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}})} \text{ and } 2+2\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}}) > 0, \\ 1, & \text{if } 2+2\sum_{g\in\mathcal{G}} \lambda_g^{t-1}(g(x)-w_g^{\mathrm{E}}) = 0. \end{cases}$$

Compute

$$\begin{aligned} \hat{\rho}_g^t &= \mathbb{E}_{(x,y)\sim D}[\ell(h_t(x),1)g(x)f(x) + \ell(h_t(x),0)g(x)(1-f(x)) \\ &\quad - w_g^{\mathrm{E}}(\ell(h_t(x),1)f(x) - w_g^{\mathrm{E}}\ell(h_t(x),0)(1-f(x)] \text{ for all } g \in \mathcal{G}, \\ \hat{\rho}^t &= \mathbb{E}_{(x,y)\sim D}[f(x)\ell(h_t(x),1) + (1-f(x))\ell(h_t(x),0)], \end{aligned}$$

where $w_g^{\mathrm{E}} = \mathbb{P}_{(x,y)\sim\mathcal{D}}[g(x)=1]$.

Dual player updates

$$\begin{aligned} \lambda_{g,t,+} &= \max(0, \lambda_{g,t,+} + \eta \cdot (\hat{\rho}_g^t - \hat{\rho}^t - \gamma)), \\ \lambda_{g,t,-} &= \max(0, \lambda_{g,t,-} + \eta \cdot (\hat{\rho}^t - \hat{\rho}_g^t - \gamma)). \end{aligned}$$

Dual player sets $\lambda_t = \sum_{g\in\mathcal{G}} \lambda_g^{t,+} - \lambda_{g,t,-}$.

if $\|\lambda_t\|_1 > C$ **then**

set $\lambda_t = \arg\min_{\{\tilde{\lambda}\in\mathbb{R}^{2\mathcal{G}} \mid \|\tilde{\lambda}\|_1 \leq C\}} \|\lambda_t - \tilde{\lambda}\|_2^2$

end if

end for

Output: $\bar{h} := \frac{1}{T}\sum_{t=1}^{T} \hat{h}_t$, a uniformly random classifier over all rounds' hypotheses.

A.3 Statistical Parity Fairness

Definition 17. *We say that classifier $h : \mathcal{X} \to \mathcal{Y}$ satisfies γ-Statistical Parity (SP) Fairness with respect to $\mathcal{D}$ and $\mathcal{G}$ if for all $g \in \mathcal{G}$,*

$$\mathbb{P}_{(x,y)\sim\mathcal{D}}[g(x)=1]\left|\mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[h(x)|g(x)=1] - \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[h(x)]\right| \in \gamma.$$

We consider the following fairness-constrained optimization problem:

$$\begin{aligned} \min_{h\in\Delta\mathcal{H}} \quad & \mathrm{err}(h) \\ \text{s.t. for each } g \in \mathcal{G}: \quad & \mathbb{P}[g(x)=1]\left|\mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[h(x)|g(x)=1] - \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[h(x)]\right| \leq \gamma, \end{aligned} \tag{11}$$

Definition 18. *Let $f : \mathcal{X} \to R \subseteq [0,1]$ be some regression function and let $\gamma \in \mathbb{R}_+$. Define $\phi_{SP}(f, \gamma, \mathcal{H})$ to be the following optimization problem:*

$$\min_{h \in \Delta\mathcal{H}} \quad \mathop{\mathbb{E}}_{x \sim \mathcal{D}_X}[f(x)\ell(h(x),1) + (1-f(x))\ell(h(x),0)]$$

$$\text{s.t. for each } g \in \mathcal{G}: \quad \left| \mathop{\mathbb{E}}_{x \sim \mathcal{D}_X}[h(x)g(x)] - w_g^{SP} \mathop{\mathbb{E}}_{x \sim \mathcal{D}_X}[h(x)] \right| \leq \gamma$$

where $w_g^{SP} = \mathbb{P}[g(x) = 1]$.

Lemma 10. *Let f^* be the Bayes optimal regression function over $\mathcal{D}$. Then optimization problem $\psi_{SP}(f^*, \gamma, \mathcal{H})$ is equivalent to the fairness-constrained optimization problem 11.*

Definition 19 (Lagrangian). *Given any regression function f, we define a Lagrangian of the optimization problem $\psi_{SP}(f, \gamma, \mathcal{H})$ as $L_f^{SP} : \mathcal{H} \times \mathbb{R}^{2|\mathcal{G}|} \to \mathbb{R}$:*

$$L_f^{SP}(h, \lambda) = \mathop{\mathbb{E}}_{x \sim \mathcal{D}_X} \Bigg[f(x)\ell(h(x),1) + (1-f(x))(\ell(h(x),0) + \sum_{g \in \mathcal{G}} \lambda_g^+ \big(h(x)(g(x)-1) - \gamma\big) + \sum_{g \in \mathcal{G}} \lambda_g^- \big(h(x)(1-g(x)\big) - \gamma) \Bigg].$$

Lemma 11. *The optimal post-processed classifier h of $\psi_{SP}(f, \gamma, \mathcal{H}_A)$ for some regressor f takes the following form:*

$$h(x) = \begin{cases} 1, & \text{if } f(x) > 1/2 + (1/2)\sum_{g \in \mathcal{G}} \lambda_g (g(x) - 1), \\ 0, & \text{if } f(x) < 1/2 + (1/2)\sum_{g \in \mathcal{G}} \lambda_g (g(x) - 1). \end{cases}$$

In the edge case in which $f(x) = 1/2 + (1/2)\sum_{g \in \mathcal{G}} \lambda_g (g(x) - 1)$, $h(x)$ could take either value and might be randomized.

Proof. Note that we can rewrite our Lagrangian from Definition 19 as

$$L_f^{\mathrm{SP}}(h, \lambda) = \mathop{\mathbb{E}}_{x \sim \mathcal{D}_X} \left[f(x)(\ell(h(x),1) - \ell(h(x),0)) + \ell(h(x),0) + h(x) \sum_{g \in \mathcal{G}} \lambda_g (g(x) - 1) + \gamma \sum_{g \in \mathcal{G}} (\lambda^+ + \lambda^-) \right],$$

and hence our optimal h will be optimal pointwise, i.e.

$$h(x) \arg\min_p \left[f(x)(\ell(p,1) + \ell(p,0)) - \ell(p,0) + p \sum_{g \in \mathcal{G}} \lambda_g (g(x) - 1) \right]$$

We can then find our threshold by comparing this expression when $p = 0$ and $p = 1$, i.e.

$$-f(x) + 1 + \sum_{g \in \mathcal{G}} \lambda_g (g(x) - 1) < f(x)$$

$$\frac{1 + \sum_{g \in \mathcal{G}} \lambda_g (g(x) - 1)}{2} < f(x).$$

Hence,

$$h(x) = \begin{cases} 1, & \text{if } f(x) > 1/2 + (1/2)\sum_{g \in \mathcal{G}} \lambda_g (g(x) - 1), \\ 0, & \text{if } f(x) < 1/2 + (1/2)\sum_{g \in \mathcal{G}} \lambda_g (g(x) - 1). \end{cases}$$

□

We can now define a best-response model and use Algorithm 3 to generate an optimally post-processed model that preserves γ-Statistical Parity fairness. Assuming that $\hat{f}$ is α-multicalibrated in expectation with respect to $\mathcal{G}, \mathcal{H}$, and $\mathcal{G} \times \mathcal{H}$ and is jointly multicalibrated with respect to functions of the form $1[\langle \lambda, x_{\mathcal{G}} - \beta \rangle \geq 2v - 1]$, the proofs from section 3.2 may be modified to get its desired error bounds.

Algorithm 3 Projected Gradient Descent Algorithm for γ-Statistical Parity Fairness

Input: D: dataset, $f : \mathcal{X} \to [0,1]$: regression function, $\mathcal{G}$: groups, γ: tolerance on fairness violation, C: bound on dual ($\|\lambda\|_1 \leq C$), η: learning rate

Initialize dual vector $\lambda^0 = \mathbf{0}$ and set $T = \frac{1}{4} \cdot C^2 \cdot (C^2 + 4|\mathcal{G}|)^2$.

for $t = 1, \ldots, T$ **do**

Primal player updates h_t

$$h_t(x) = \begin{cases} 1, & \text{if } f(x) \geq 1/2 + (1/2) \sum_{g \in \mathcal{G}} \lambda_g^{t-1}(g(x) - 1), \\ 0, & \text{if } f(x) < 1/2 + (1/2) \sum_{g \in \mathcal{G}} \lambda_g^{t-1}(g(x) - 1). \end{cases}$$

Compute

$$\hat{\rho}_g^t = \left| \mathop{\mathbb{E}}_{x \sim \mathcal{D}_\mathcal{X}} [h_t(x) g(x)] - w_g^{\text{SP}} \mathop{\mathbb{E}}_{x \sim \mathcal{D}_\mathcal{X}} [h_t(x)] \right| \text{ for all } g \in \mathcal{G},$$
$$\hat{\rho}^t = \mathbb{E}_{(x,y) \sim D}[f(x)\ell(h_t(x), 1) + (1 - f(x))\ell(h_t(x), 0)],$$

where $w_g^{\text{SP}} = \mathbb{P}[g(x) = 1]$.

Dual player updates

$$\lambda_g^{t,+} = \max(0, \lambda_g^{t,+} + \eta \cdot (\hat{\rho}_g^t - \hat{\rho}^t - \gamma)),$$
$$\lambda_g^{t,-} = \max(0, \lambda_g^{t,-} + \eta \cdot (\hat{\rho}^t - \hat{\rho}_g^t - \gamma)).$$

Dual player sets $\lambda^t = \sum_{g \in \mathcal{G}} \lambda_g^{t,+} - \lambda_g^{t,-}$.

if $\|\lambda^t\|_1 > C$ **then**

set $\lambda^t = \arg\min_{\{\tilde{\lambda} \in \mathbb{R}^{2\mathcal{G}} | \|\tilde{\lambda}\|_1 \leq C\}} \|\lambda_t - \tilde{\lambda}\|_2^2$.

end if

end for

Output: $\bar{h} := \frac{1}{T} \sum_{t=1}^T \hat{h}_t$, a uniformly random classifier over all rounds' hypotheses.

A.4 Achieving All Fairness Notions

Ideally, we would like our function to be multicalibrated so that we can achieve any fairness notion downstream. Putting everything together from the previous sections, we can do so.

Definition 20 (Set of thresholding functions $\mathcal{B}(C)$). *Let $x_\mathcal{G} \in \{0,1\}^{|\mathcal{G}|}$ denote the group membership indicator vector of some point x, and define the following functions:*

$$d^{FP}(v) := \frac{2v - 1}{1 - v},$$
$$d^{FN}(v) := \frac{1 - 2v}{v},$$
$$d^{E}(v) := \frac{2v - 1}{1 - 2v},$$
$$d^{SP}(v) := 2v - 1.$$

Then, for any λ, x, β, let

$$s_\lambda^{FP}(x, v) := 1[\langle \lambda, x_\mathcal{G} - \beta^{FP} \rangle \geq d^{FP,E}(v)],$$
$$s_\lambda^{FN}(x, v) := 1[\langle \lambda, x_\mathcal{G} - \beta^{FN} \rangle \geq d^{FN}(v)],$$
$$s_\lambda^{E}(x, v) := 1[\langle \lambda, \alpha x_\mathcal{G} - w^E \rangle \geq d^{E}(v)],$$
$$s_\lambda^{SP}(x, v) := 1[\langle \lambda, x_\mathcal{G} - 1 \rangle \geq d^{SP}(v)],$$

where

$$\beta^{FP} = \{\mathbb{P}_{(x,y) \sim \mathcal{D}}[g(x) = 1 | y = 0]\}_{g \in \mathcal{G}},$$
$$\beta^{FN} = \{\mathbb{P}_{(x,y) \sim \mathcal{D}}[g(x) = 1 | y = 1]\}_{g \in \mathcal{G}},$$
$$w^E = \{\mathbb{P}_{(x,y) \sim \mathcal{D}}[g(x) = 1]\}_{g \in \mathcal{G}}.$$

Define $\mathcal{B}(C) = \{s_\lambda^{FP} | \lambda \in \Lambda(C)\} \cup \{s_\lambda^{FN} | \lambda \in \Lambda(C)\} \cup \{s_\lambda^{E} | \lambda \in \Lambda(C)\} \cup \{s_\lambda^{SP} | \lambda \in \Lambda(C)\}$, *where* $\Lambda(C) = \left\{\lambda \in \mathbb{R}^{2\mathcal{G}} \middle| \|\lambda\|_1 \leq C\right\}$, *as defined in Equation 12.*

Then, if f is multicalibrated with respect to $\mathcal{B}(C)$, any of the projected gradient descent algorithms covered above (Algorithms 4 through 2) may be run to achieve the desired fairness notion.

B EXPANDED PROOFS AND SECTION 3 DISCUSSION

Lemma 12. *Let f^* be the Bayes optimal regression function over $\mathcal{D}$. Then optimization problem $\psi(f^*, \gamma, \mathcal{H})$ is equivalent to the fairness-constrained optimization problem* (1).

Proof. We confirm that the objective and constraints are both equivalent. First the objective:

$$\begin{aligned} err(h) &= \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[\ell(h(x), y)] \\ &= \sum_{(x,y)\in\mathcal{X}\times\mathcal{Y}} \mathbb{P}(X = x, Y = y)\, \ell(h(x), y) \\ &= \sum_{x\in\mathcal{X}} \mathbb{P}(X = x, Y = 0)\, \ell(h(x), 0) + \mathbb{P}(X = x, Y = 1)\, \ell(h(x), 1) \\ &= \mathop{\mathbb{E}}_{x\in\mathcal{X}}[(1 - f^*(x))\ell(h(x), 0) + f^*(x)\ell(h(x), 1)] \end{aligned}$$

For the constraints, note that

$$\begin{aligned} w_g|\rho_g(h) - \rho(h)| &= \mathbb{P}[g(x) = 1, y = 0]\, |\mathbb{P}[h(x) = 1|g(x) = 1, y = 0] - \mathbb{P}[h(x) = 1|y = 0]| \\ &= \mathbb{P}[g(x) = 1, y = 0]\left|\frac{\mathbb{P}[h(x) = 1, g(x) = 1, y = 0]}{\mathbb{P}[g(x) = 1, y = 0]} - \frac{\mathbb{P}[h(x) = 1, y = 0]}{\mathbb{P}[Y = 0]}\right| \\ &= \left|\mathbb{P}[h(x) = 1, g(x) = 1, y = 0] - \frac{\mathbb{P}[g(x) = 1, y = 0]\mathbb{P}[h(x) = 1, y = 0]}{\mathbb{P}[Y = 0]}\right| \\ &= \left|\mathbb{E}[\ell(h(x), 0)g(x)(1 - f^*(x))] - \frac{\mathbb{P}[g(x) = 1, y = 0]}{\mathbb{P}[Y = 0]}\mathbb{E}\left[\ell(h(x), 0)(1 - f^*(x))\right]\right| \\ &= \left|\mathbb{E}[\ell(h(x), 0)g(x)(1 - f^*(x))] - \mathbb{P}[g(x) = 1|Y = 0]\mathbb{E}\left[\ell(h(x), 0)(1 - f^*(x))\right]\right| \\ &= \left|\mathbb{E}[\ell(h(x), 0)g(x)(1 - f^*(x))] - \beta_g\mathbb{E}\left[\ell(h(x), 0)(1 - f^*(x))\right]\right|. \end{aligned}$$

The result follows. □

Lemma 13.

$$\begin{aligned} L_f(h, \lambda) = \mathop{\mathbb{E}}_{x\sim\mathcal{D}_\mathcal{X}}\Bigg[&\ell(h(x), 0)\Big(\kappa\Big) - \gamma\sum_{g\in\mathcal{G}}(\lambda_g^+ + \lambda_g^-) \\ &- f(x)\Big(-\ell(h(x), 1) + \ell(h(x), 0)\big(\kappa\big)\Big)\Bigg]. \end{aligned}$$

Proof. Distributing out like terms in the expression for the Lagrangian in Definition 8 gives us

$$\begin{aligned}
L_f(h,\lambda) = \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\Bigg[& f(x)\ell(h(x),1) + (1-f(x))\ell(h(x),0) \\
& + \sum_{g\in\mathcal{G}} \lambda_g^+\big(\ell(h(x),0)g(x)(1-f(x)) - \beta_g\ell(h(x),0)(1-f(x)) - \gamma\big) \\
& + \lambda_g^-\big(\beta_g\ell(h(x),0)(1-f(x)) - \ell(h(x),0)g(x)(1-f(x)) - \gamma\big)\Bigg] \\
= \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\Bigg[& \ell(h(x),0)\Big(1 + \sum_{g\in\mathcal{G}} \lambda_g^+(g(x)-\beta_g) + \lambda_g^-(\beta_g - g(x))\Big) - \gamma\sum_{g\in\mathcal{G}}(\lambda_g^+ + \lambda_g^-) \\
& - f(x)\Big(-\ell(h(x),1) + \ell(h(x),0)\big(1 + \sum_{g\in\mathcal{G}}\lambda_g^+(g(x)-\beta_g) + \sum_{g\in\mathcal{G}}\lambda_g^-(\beta_g - g(x))\big)\Big)\Bigg] \\
= \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\Bigg[& \ell(h(x),0)\Big(1 + \sum_{g\in\mathcal{G}}(\lambda_g^+ - \lambda_g^-)(g(x)-\beta_g)\Big) - \gamma\sum_{g\in\mathcal{G}}(\lambda_g^+ + \lambda_g^-) \\
& - f(x)\Big(-\ell(h(x),1) + \ell(h(x),0)\big(1 + \sum_{g\in\mathcal{G}}(\lambda_g^+ - \lambda_g^-)(g(x)-\beta_g)\big)\Big)\Bigg].
\end{aligned}$$

Recall that $\lambda_g = \lambda_g^+ - \lambda_g^-$, so we are done. □

Definition 21 (Optimal post-processed classifier). *We say that a classifier h_f is an optimal post-processing of f if there exists a vector λ^f such that the following primal/dual optimality conditions are simultaneously met:*

$$h_f(x) \in \arg\min_{h\in\mathcal{H}_A} L_f(h,\lambda^f) \quad \lambda^f \in \arg\max_{\lambda\in\mathbb{R}^{2|\mathcal{G}|}} L_f(h_f,\lambda).$$

For convenience, we write

$$h^*(x) = h_{f^*}(x) \quad \textit{and} \quad \lambda^* = \lambda^{f^*}$$
$$\hat{h}(x) = h_{\hat{f}}(x) \quad \textit{and} \quad \hat{\lambda} = \lambda^{\hat{f}}$$

where f^* is the Bayes optimal regressor and $\hat{f}$ is any other regressor. We will write λ_g^* and $\hat{\lambda}_g$ to refer to the dual variable in λ^* and $\hat{\lambda}$ for group g, respectively. We observe that as the optimal solution to the Lagrangian minimax optimization problem, $h^*(x)$ is the Bayes optimal classifier subject to the fairness constraints in 1.

Lemma 14. *The optimal post-processed classifier h of $\psi(f,\gamma,\mathcal{H}_A)$ for some regressor f takes the following form:*

$$h(x) = \begin{cases} 1, & \text{if } f(x) > \frac{\kappa}{\mu} \text{ and } \mu > 0, \\ 0, & \text{if } f(x) < \frac{\kappa}{\mu} \text{ and } \mu > 0, \\ 1, & \text{if } f(x) < \frac{\kappa}{\mu} \text{ and } \mu < 0, \\ 0, & \text{if } f(x) > \frac{\kappa}{\mu} \text{ and } \mu < 0. \end{cases},$$

where $\kappa = 1 + \sum_{g\in\mathcal{G}} \lambda_g(g(x)-\beta_g)$ and $\mu = 1+\kappa$.

In the edge case in which $f(x) = \frac{\kappa}{\mu}$, $h(x)$ could take either value and might be randomized.

Proof. Note that since we are optimizing over the set of all binary classifiers, h optimizes the Lagrangian objective pointwise for every x. In particular, we have from Lemma 13 that:

$$h(x) = \arg\min_p \Big[\ell(p,0)\big(\kappa\big) - f(x)\Big(-\ell(p,1) + \ell(p,0)\big(\kappa\big)\Big)\Big].$$

Determining the optimal threshold is equivalent to determining when the above expression with $\ell(p,0) = 1$ and $\ell(p,1) = 0$ is less than $f(x)$, i.e.

$$\begin{aligned} \kappa - f(x)\big(\kappa\big) &< f(x) \\ \kappa &< f(x)\left(1 + \big(\kappa\big)\right). \end{aligned}$$

Thus,

$$h(x) = \begin{cases} 1, & \text{if } f(x) > \frac{\kappa}{\mu} \text{ and } \mu > 0, \\ 0, & \text{if } f(x) < \frac{\kappa}{\mu} \text{ and } \mu > 0 \\ 1, & \text{if } f(x) < \frac{\kappa}{\mu} \text{ and } \mu < 0, \\ 0, & \text{if } f(x) > \frac{\kappa}{\mu} \text{ and } \mu < 0 \end{cases}$$

□

In Lemma 14, we can only describe the optimal post-processed classifier for cases where either $f(x)$ is less than or greater than the threshold $\frac{\kappa}{\mu}$, $h(x)$. In practice, our algorithm will need to update h at round t according to the current dual variables λ in a way that is well-defined for all values of $f(x)$. Hence, we define our best response as follows, where ties between $f(x)$ and the threshold are broken by rounding to 1.

Definition 22 (Best Response Model). *Given regressor f and dual variables λ, let the best response h be defined as*

$$h(x) = \begin{cases} 1, & \text{if } f(x) \geq \frac{\kappa}{\mu} \text{ and } \mu > 0, \\ 0, & \text{if } f(x) < \frac{\kappa}{\mu} \text{ and } \mu > 0, \\ 1, & \text{if } f(x) \leq \frac{\kappa}{\mu} \text{ and } \mu < 0, \\ 0, & \text{if } f(x) > \frac{\kappa}{\mu} \text{ and } \mu < 0. \end{cases}$$

Lemma 15. *For any regression model f and dual variables λ, The classifier h defined in Definition 22 is a "best response" in the sense that:*

$$h \in \arg\min_{h \in \mathcal{H}_A} L_f(h, \lambda).$$

B.1 Proofs from Section 3.1

Game formulation. We pose the optimization of our original linear program as a zero-sum game between a primal (minimization) player who plays over the set of hypotheses and a dual (maximization) player who plays over the set of dual variables. The utility function of the game is the Lagrangian of our linear program as stated in Definition 8. The value of this game is given by

$$\min_{h \in \Delta\mathcal{H}} \max_{\lambda \in \mathbb{R}^{2|\mathcal{G}|}} L_f(h, \lambda).$$

Constraining the linear program. In order to compute an approximate minimax solution to this game, we need to constrain the strategy space of the dual player.

That is, we need to bound the dual space to a region $\Lambda = \left\{\lambda \in \mathbb{R}^{2\mathcal{G}} \middle| \|\lambda\|_1 \leq C\right\}$. We call this constrained version of the problem the Λ-bounded Lagrangian problem, which has value

$$\min_{h \in \Delta\mathcal{H}} \max_{\lambda : |\lambda|_1 \leq C} L_f(h, \lambda). \tag{12}$$

We can apply the minimax theorem to this bounded game to see:

$$\min_{h \in \Delta\mathcal{H}} \max_{\lambda : |\lambda|_1 \leq C} L_f(h, \lambda) \equiv \max_{\lambda : |\lambda|_1 \leq C} \min_{h \in \Delta\mathcal{H}} L_f(h, \lambda).$$

We will only be able to achieve an approximate solution to the problem, which we define as follows.

Definition 23. *We say that (h, λ) is a v-approximate minimax solution to the Λ-bounded Lagrangian problem L_f if $L_f(h, \lambda) \leq \min_{h' \in \Delta\mathcal{H}} L_f(h', \lambda) + v$ and $L_f(h, \lambda) \geq \max_{\lambda' \in \Lambda} L_f(h, \lambda') - v$.*

An approximate minimax solution to this bounded version of the problem is also an approximate solution to the original problem we described in Equation 1.

Theorem 3 ([18]). *Let (h, λ) be a v-approximate minimax solution to the Λ-bounded Lagrangian problem L_f and let* OPT *be the objective value of the optimal solution to $\psi(f, \gamma, \mathcal{H}_A)$. Then, $err(h) \leq OPT + 2v$, and $\forall g \in \mathcal{G}, w_g|\rho_g(h) - \rho(h)| \leq \gamma + (1 + 2v)/C$.*

Approximate equilibrium of the constrained game. Now, we can proceed with no-regret play to find an approximate solution to the game. The dual player will play projected gradient descent over their vector λ and the primal player will best respond, as described in Algorithm 4.

Theorem 4. *Algorithm 4 returns an $\epsilon-$approximate equilibrium solution to the zero-sum game defined by Equation 12 after $T = \frac{1}{4\epsilon^2}\left(\frac{1}{\epsilon^2} + 4|\mathcal{G}|\right)^2$ rounds.*

To prove this, we will use the following result from Freund and Shapire.

Theorem 5 ([9]). *(Approximately solving a game). If $\lambda_1, \ldots, \lambda_T \in \Delta_\lambda$ is the sequence of distributions over λ played by the dual player and $h_1, \ldots, h_T \in \mathcal{H}$ is the sequence of best-response hypotheses played by the primal player satisfying regret guarantees*

$$\frac{1}{T}\max_{\lambda\in\Lambda}\sum_{t=1}^{T} U(h_t,\lambda) - \frac{1}{T}\sum_{t=1}^{T}\mathop{\mathbb{E}}_{\lambda\sim\lambda_t}[U(h_t,\lambda)] \le \Delta_1$$

and

$$\frac{1}{T}\sum_{t=1}^{T}\mathop{\mathbb{E}}_{\lambda\sim\lambda_t}[U(h_t,\lambda)] - \frac{1}{T}\min_{h\in\mathcal{H}}\sum_{t=1}^{T}\mathop{\mathbb{E}}_{\lambda\sim\lambda_t}[U(h,\lambda)] \le \Delta_2$$

then the time-average of the two players' empirical distributions is a $(\Delta_1+\Delta_2)-$approximate equilibrium.

Proof of Theorem 4. We follow the regret analysis of [24]. To instantiate their result, we need a bound on the norm of the gradients of the loss function and on the diameter of the feasible set F. First, we see that at each step the gradient of the loss seen by gradient descent is bounded:

$$\|\nabla\ell\|^2 = \sum_{g\in\mathcal{G}} w_g\left(\rho_g-\rho-\gamma\right)^2 + w_g\left(-\rho_g+\rho-\gamma\right)^2 \le 2|\mathcal{G}|.$$

Second, we see that if we consider the feasible set such that $\|\lambda\| \le \frac{1}{\epsilon}$, then $\|F\|^2 = \frac{1}{\epsilon^2}$. Thus we have that the regret of the dual player is bounded:

$$\mathcal{R}(T) \le \frac{\|F\|^2\sqrt{T}}{2} + (\sqrt{T}-\frac{1}{2})\|\nabla\ell\|^2$$
$$\frac{\mathcal{R}(T)}{T} \le \frac{1}{T}\left(\frac{\frac{1}{\epsilon^2}\sqrt{T}}{2} + (\sqrt{T}-\frac{1}{2})2|\mathcal{G}|\right) \le \frac{\frac{1}{\epsilon^2}+4|\mathcal{G}|}{2\sqrt{T}}.$$

After $T = \frac{1}{4\epsilon^2}\left(\frac{1}{\epsilon^2}+4|\mathcal{G}|\right)^2$ rounds, by [9] the average over empirical distributions of play of the dual and primal players, $\bar{\lambda}$ and $\bar{h}$, respectively, form an $\epsilon-$approximate equilibrium solution to the zero-sum game defined by 12. □

Lemma 16. *lemma Let h_t be the response to λ_{t-1} described in Algorithm 4 at some round $t \in [T]$. Then,*

$$h_t(x) = s_{\lambda_{t-1}}(x, f(x)).$$

Proof. Recall from Lemma 15 and Algorithm 4 that the best response to λ that the primal player can make is to compute h based on the thresholding of the expression

$$\tau = \frac{\kappa_{t-1}}{\mu_{t-1}}.$$

Setting this threshold to be greater than or equal to some value v, note the following is implied:

$$\frac{\kappa_{t-1}}{\mu_{t-1}} \ge v,$$
$$\Rightarrow \sum_{g\in\mathcal{G}}\lambda_{g,t-1}(g(x)-\beta_g) - v\sum_{g\in\mathcal{G}}\lambda_{g,t-1}(g(x)-\beta_g) \ge 2v-1,$$
$$\Rightarrow (1-v)(\sum_{g\in\mathcal{G}}\lambda_{g,t-1}(g(x)-\beta_g) \ge 2v-1,$$
$$\Rightarrow \langle\lambda_{t-1}, x_{\mathcal{G}}-\beta\rangle = \sum_{g\in\mathcal{G}}\lambda_{g,t-1}(g(x)-\beta_g) \ge \frac{2v-1}{1-v}.$$

Thus, taking the indicator of

$$1[\langle\lambda_{t-1}, x_{\mathcal{G}}-\beta\rangle \ge d(v)]$$

is equivalent to determining if the threshold τ is greater than or equal to some v, and hence by the definition of $s_{\lambda_{t-1}}(x,v)$ in Definition 9 and of the best response h in Definition 22, if v is set to $f(x)$ it follows that

$$h(x) = s_{\lambda_{t-1}}(x, f(x)).$$

□

Theorem 6. *Let* OPT *be the objective value of the optimal solution to $\psi(f,\gamma,\mathcal{H}_A)$. Then, for any $C \in \mathbb{R}$, after $T = \frac{1}{4}\cdot C^2\cdot\left(C^2+4|\mathcal{G}|\right)^2$ iterations, Algorithm 4 outputs a randomized hypothesis $\bar{h}$ with the following properties:*

- *the error of the output satisfies $err(\bar{h}) \le$ OPT $+\frac{2}{C}$*
- *the constraint violation of the output satisfies $w_g|\rho_g(\bar{h})-\rho(\bar{h})| \le \gamma+\frac{1}{C}+\frac{2}{C^2}$*

- *the output $\bar{h}$ is the uniform mixture over T constituent models, each of which belong to the set of threshold functions $\mathcal{B}(C)$.*

Proof of Theorem 6. Applying Theorems 3 and 4, we have that after T rounds $(\bar{h}, \bar{\lambda})$ is an ϵ-approximate equilibrium to the zero-sum game of 12 and equivalently a minimax solution to the Λ-bounded Lagrangian. Taking $\epsilon = 1/C$, the solution $(\bar{h}, \bar{\lambda})$ is a $\frac{1+2\epsilon}{1/\epsilon} = 1/C + 2/C^2$ approximate solution to the original linear program 1. The final condition follows from Lemma 16. □

Algorithm 4 Projected Gradient Descent Algorithm

Input: D: dataset, $f : \mathcal{X} \to [0,1]$: regression function, $\mathcal{G}$: groups, γ: tolerance on fairness violation, C: bound on dual ($\|\lambda\|_1 \leq C$), η: learning rate
Initialize dual vector $\lambda^0 = \mathbf{0}$ and set $T = \frac{1}{4} \cdot C^2 \cdot (C^2 + 4|\mathcal{G}|)^2$.
for $t = 1, \ldots, T$ **do**
  Primal player updates h_t

$$h_t(x) = \begin{cases} 1, & \text{if } f(x) \geq \frac{\kappa_{t-1}}{\mu_{t-1}} \text{ and } \mu_{t-1} > 0, \\ 0, & \text{if } f(x) < \frac{\kappa_{t-1}}{\mu_{t-1}} \text{ and } \mu_{t-1} > 0, \\ 1, & \text{if } f(x) \leq \frac{\kappa_{t-1}}{\mu_{t-1}} \text{ and } \mu_{t-1} < 0, \\ 0, & \text{if } f(x) > \frac{\kappa_{t-1}}{\mu_{t-1}} \text{ and } \mu_{t-1} < 0, \\ 1, & \text{if } \mu_{t-1} = 0 \end{cases}$$

  Compute

$$\hat{\rho}_g^t = \mathop{\mathbb{E}}_{(x,y)\sim D}[\ell(h_t(x), 0) g(x)(1 - f(x))] \text{ for all } g \in \mathcal{G},$$
$$\hat{\rho}^t = \mathop{\mathbb{E}}_{(x,y)\sim D}[\beta_g \ell(h_t(x), 0)(1 - f(x))], \text{ where } \beta_g = \mathbb{P}[g(x) = 1 | y = 0]$$

  Dual player updates

$$\lambda_{g,t,+} = \max(0, \lambda_{g,t,+} + \eta \cdot (\hat{\rho}_g^t - \hat{\rho}^t - \gamma)),$$
$$\lambda_{g,t,-} = \max(0, \lambda_{g,t,-} + \eta \cdot (\hat{\rho}^t - \hat{\rho}_g^t - \gamma)).$$

  Dual player sets $\lambda^t = \sum_{g\in\mathcal{G}} \lambda_{g,t,+} - \lambda_{g,t,-}$.
  if $\|\lambda^t\|_1 > C$ **then**
    set $\lambda^t = \arg\min_{\{\tilde{\lambda} \in \mathbb{R}^{2\mathcal{G}} | \|\tilde{\lambda}\|_1 \leq C\}} \|\lambda_t - \tilde{\lambda}\|_2^2$.
  end if
end for
Output: $\bar{h} := \frac{1}{T} \sum_{t=1}^{T} \hat{h}_t$, a uniformly random classifier over all rounds' hypotheses.

B.2 Proofs from Section 3.2

Theorem 7. *Set $C = \sqrt{1/\alpha}$. Let $\hat{f}$ be α-approximately multicalibrated in expectation with respect to $\mathcal{G}$, $\mathcal{H}$, and $\mathcal{G} \times \mathcal{H}$ and α-approximately jointly multicalibrated in expectation with respect to $\mathcal{G} \times \mathcal{B}(C)$. Let $\bar{h}$ be the result of running Algorithm 4 with input $\hat{f}$ and C. Then, $err(\bar{h}) \leq err(h^*) + \alpha(5 + 2\sqrt{1/\alpha}) + 2\sqrt{\alpha}$, and for all $g \in \mathcal{G}$, $w_g \left|\rho_g(\bar{h}) - \rho(\bar{h})\right| \leq w_g \left|\rho_g(h^*) - \rho(h^*)\right| + 2\alpha$.*

In order to prove this, we will proceed through the specifics of each line of the Proof Sketch 3.2 in Section 3.2 through Lemmas 17 through 3.

Lemma 17 (Equality in Equation 2).

$$err(h^*) = L^*(h^*, \lambda^*)$$

Proof. Consider the optimal solution (h^*, λ^*) to $\psi(f^*, \gamma, \mathcal{H})$, and recall that $\text{err}(h) = \mathbb{E}_{x\sim\mathcal{D}_X}[f^*(x)\ell(h(x), 1) + (1 - f^*(x))\ell(h(x), 0)]$. Since the solution is optimal, it follows from complementary slackness, for each group g one of the following must hold: Either the constraint is exactly tight and so its "violation" term in the Lagrangian evaluates to 0, or its corresponding dual variables $\lambda_g^{\pm} = 0$. Thus, $L_f^*(h^*, \lambda^*)$ simplifies to

$$\begin{aligned}
L_f^*(h^*, \lambda^*) = &\mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\Bigg[f(x)\ell(h(x),1) + (1-f(x))\ell(h(x),0) \\
&+ 0\cdot\sum_{g\in\mathcal{G}}\lambda_g^+\big(\ell(h(x),0)g(x)(1-f(x)) - \beta_g\ell(h(x),0)(1-f(x)) - \gamma\big) \\
&+ 0\cdot\sum_{g\in\mathcal{G}}\lambda_g^-\big(\beta_g\ell(h(x),0)(1-f(x)) - \ell(h(x),0)g(x)(1-f(x)) - \gamma\big)\Bigg] \\
= &\mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\Big[f(x)\ell(h(x),1) + (1-f(x))\ell(h(x),0)\Big] \\
= &\,\mathrm{err}(h^*)
\end{aligned}$$

□

Lemma 18 (Bounding Equation 2 by Equation 3).

$$L^*(h^*, \lambda^*) \geq L^*(h^*, \hat{\lambda}).$$

Proof. This follows from the dual optimality condition that $\lambda^* \in \arg\max_\lambda L^*(h^*, \lambda)$. □

Lemma 19. *(Bounding Equation 3 by Equation 4) Fix any λ. If $\hat{f}$ is α-multicalibrated with respect to $\mathcal{G}, \mathcal{H}$, and $\mathcal{G}\times\mathcal{H} = \{g(x)\cdot h(x) | g\in\mathcal{G}, h\in\mathcal{H}\}$, then then we have*

$$\left|\hat{L}(h^*, \lambda) - L^*(h^*, \lambda)\right| \leq \alpha(3 + 2\|\lambda\|_1).$$

Proof. Observe that we can write:

$$\hat{L}(h, \lambda) = L_1(h, \lambda) - \gamma\sum_{g\in\mathcal{G}}(\lambda_g^+ + \lambda_g^-) - \hat{L}_2(h, \lambda),$$

where

$$\begin{aligned}
L_1(h, \lambda) &= \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\Big[\ell(h(x),0)\Big(\kappa\Big)\Big], \\
\hat{L}_2(h, \lambda) &= \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\Big[\hat{f}(x)\Big(-\ell(h(x),1) + \ell(h(x),0)\big(\kappa\big)\Big)\Big].
\end{aligned}$$

Similarly, we can write:

$$L^*(h, \lambda) = L_1(h, \lambda) - \gamma\sum_{g\in\mathcal{G}}(\lambda_g^+ + \lambda_g^-) - L_2^*(h, \lambda),$$

where

$$L_2^*(h, \lambda) = \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\Big[f^*(x)\Big(-\ell(h(x),1) + \ell(h(x),0)\big(\kappa\big)\Big)\Big].$$

Observe that the L_1 term does not depend on $\hat{f}$ or f^* and so is common between $\hat{L}$ and L^*. We can bound $\hat{L}_2$ as follows:

$$\begin{aligned}
\hat{L}_2(h^*, \lambda) &= \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\Big[\hat{f}(x)\Big(-\ell(h^*(x),1) + \ell(h^*(x),0)\big(\kappa\big)\Big)\Big] \\
&= \mathop{\mathbb{E}}_{x\sim\mathcal{D}_X}\Big[\hat{f}(x)\Big(-(1-h^*(x)) + h^*(x)\big(\kappa\big)\Big)\Big] \\
&= \sum_{v\in R}\mathbb{P}[\hat{f}(x) = v]\mathop{\mathbb{E}}_{x\sim\mathcal{D}_x}\Big[\hat{f}(x)\Big(-(1-h^*(x)) + h^*(x)\big(\kappa\big)\Big)\Big|\hat{f}(x) = v\Big] \\
&\leq \sum_{v\in R}\mathbb{P}[\hat{f}(x) = v]\mathop{\mathbb{E}}_{x\sim\mathcal{D}_x}\Big[f^*(x)\Big(-(1-h^*(x)) + h^*(x)\big(\kappa\big)\Big)\Big|\hat{f}(x) = v\Big] \\
&\quad + \alpha\left(3 + \sum_{g\in\mathcal{G}}\lambda_g(1+\beta_g)\right) \\
&\leq L_2^*(h^*, \lambda) + \alpha\left(3 + 2\|\lambda\|_1\right),
\end{aligned}$$

where the first inequality follows from the fact that $h^* \in \mathcal{H}$ and $\hat{f}$ is multicalibrated with respect to $\mathcal{G}, \mathcal{H}$, and $\mathcal{G} \times \mathcal{H}$, which we verify below:

$$\begin{aligned}
&\sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[\left(f^*(x) - \hat{f}(x)\right) \cdot \left(-(1 - h^*(x)) + h^*(x)(\kappa)\right) \middle| \hat{f}(x) = v\right] \\
&= \sum_{v \in R} \mathbb{P}[\hat{f}(x) = v]\left[\left(f^*(x) - \hat{f}(x)\right) \cdot \left(-1 + 2h^*(x) + h^*(x) \sum_{g \in \mathcal{G}} \lambda_g (g(x) - \beta_g)\right) \middle| \hat{f}(x) = v\right] \\
&= -\sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[\hat{f}^*(x) - \hat{f}(x) \middle| \hat{f}(x) = v\right] \\
&\quad + 2\sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[(f^*(x) - \hat{f}(x))h^*(x) \middle| \hat{f}(x) = v\right] \\
&\quad + \sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \sum_{g \in \mathcal{G}} \lambda_g \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[(f^*(x) - \hat{f}(x))h^*(x)g(x) \middle| \hat{f}(x) = v\right] \\
&\quad - \sum_{v \in R} \mathbb{P}[\hat{f}(x) = v] \sum_{g \in \mathcal{G}} \lambda_g \beta_g \mathop{\mathbb{E}}_{x \sim \mathcal{D}_x}\left[(f^*(x) - \hat{f}(x))h^*(x) \middle| \hat{f}(x) = v\right] \\
&\leq 3\alpha + \sum_{g \in \mathcal{G}} \lambda_g (1 + \beta_g)\alpha \\
&\leq 3\alpha + \alpha \sum_{g \in \mathcal{G}} \lambda_g (1 + \max_{g' \in \mathcal{G}} \beta_{g'}) \\
&\leq 3\alpha + \alpha \sum_{g \in \mathcal{G}} \lambda_g (1 + 1) \\
&\leq 3\alpha + 2\|\lambda\|_1 \alpha
\end{aligned}$$

Similarly, we can show that $L^*(h^*, \lambda) - \hat{L}(h^*, \lambda) \leq \alpha\,(3 + 2\|\lambda\|_1)$. Putting everything together, we get that:

$$\left|\hat{L}(h^*, \lambda) - L^*(h^*, \lambda)\right| \leq \alpha(3 + 2\|\lambda\|_1).$$

This concludes the proof. □

Lemma 20 (Bounding Equation 4 by Equation 5).

$$\hat{L}(h^*, \hat{\lambda}) \geq \hat{L}(\hat{h}, \hat{\lambda})$$

Proof. This follows from the primal optimality condition that $\hat{h} \in \arg\min_{h \in \mathcal{H}_A} \hat{L}(h, \hat{\lambda})$ and that $\mathcal{H} \subseteq \mathcal{H}_A$. □

Lemma 21 (Equality of Equation 5 and Equation 6).

$$\hat{L}(\hat{h}, \hat{\lambda}) = \widehat{err}(\hat{h})$$

Proof. This follows the same complimentary slackness argument as the proof of Lemma 17. □

Lemma 22 (Bound of Equation 6 by Equation 7). *Consider $\bar{h}$ output by algorithm 4 after $T = \frac{1}{4} \cdot C^2 \cdot \left(C^2 + 4|\mathcal{G}|\right)^2$ rounds. Then,*

$$\widehat{err}(\hat{h}) + 2/C \geq \widehat{err}(\bar{h})$$

Proof. This follows directly from Theorem 6. □

We now have the tools to prove our main theorem.

Proof of Theorem 7. Applying lemmas 17 through 3 gives us

$$\begin{aligned}
\mathrm{err}(h^*) &= L^*(h^*, \lambda^*) \quad \text{(Lemma 17)} && (13)\\
&\geq L^*(h^*, \hat{\lambda}) \quad \text{(Lemma 18)} && (14)\\
&\geq \hat{L}(h^*, \hat{\lambda}) - \alpha(3 + 2\|\lambda\|_1) \quad \text{(Lemma 19)} && (15)\\
&\geq \hat{L}(\hat{h}, \hat{\lambda}) - \alpha(3 + 2\|\lambda\|_1) \quad \text{(Lemma 20),} && (16)
\end{aligned}$$

and

$$\begin{aligned}\hat{L}(\hat{h},\hat{\lambda}) &= \widehat{\mathrm{err}}(\hat{h}) \quad \text{(Lemma 21)} &(17)\\ &\geq \widehat{\mathrm{err}}(\bar{h}) - 2/C \quad \text{(Lemma 22)} &(18)\\ &\geq \mathrm{err}(\bar{h}) - 2/C - 2\alpha \quad \text{(Lemma 3).} &(19)\end{aligned}$$

Putting this all together gives us

$$\begin{aligned}\mathrm{err}(h^*) &\geq \mathrm{err}(\bar{h}) - \alpha(3 + 2\|\lambda\|_1) - 2/C - 2\alpha\\ &= \mathrm{err}(\bar{h}) - \alpha(5 + 2\|\lambda\|_1) - 2/C\\ &\geq \mathrm{err}(\bar{h}) - \alpha(5 + 2C) - 2/C\end{aligned}$$

We want to set C to minimize this discrepancy. Noting that the derivative of $\alpha(5 + 2C) + 2/C$ with respect to C is $2\alpha - 2/C^2$, we get a minimization at $C = \sqrt{1/\alpha}$.

Setting C as such gives the desired bound:

$$\mathrm{err}(h^*) \geq \mathrm{err}(\bar{h}) - \alpha(5 + 2\sqrt{1/\alpha}) - 2\sqrt{\alpha}.$$

Following a similar analysis as Lemma 3, we can bound the fairness constraints on $\bar{h}$ by bounding them for the model $\hat{h}_t$ found at every round $t \in [T]$ of Algorithm 4.

$$\begin{aligned}w_g \cdot (\hat{\rho}_g(\hat{h}_t) - \hat{\rho}(\hat{h}_t)) &= \mathop{\mathbb{E}}_{x\sim\mathcal{D}_x}[(1-\hat{f}(x))\ell(\hat{h}_t(x),0)g(x)] - \mathop{\mathbb{E}}_{x\sim\mathcal{D}_x}[(1-\hat{f}(x))\ell(\hat{h}_t(x),0)]\beta_g\\
&= \sum_{v\in R}\mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=0]\mathop{\mathbb{E}}_{x\sim\mathcal{D}_x}[(1-\hat{f}(x))\ell(\hat{h}_t(x),0)\cdot(g(x)-\beta_g)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=0]\\
&\quad + \mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\mathop{\mathbb{E}}_{x\sim\mathcal{D}_x}[(1-\hat{f}(x))\ell(\hat{h}_t(x),0)\cdot(g(x)-\beta_g)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\\
&= \sum_{v\in R}\mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\mathop{\mathbb{E}}_{x\sim\mathcal{D}_x}[(1-\hat{f}(x))\ell(\hat{h}_t(x),0)\cdot(g(x)-\beta_g)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\\
&= \sum_{v\in R}\mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\mathop{\mathbb{E}}_{x\sim\mathcal{D}_x}[\ell(\hat{h}_t(x),0)\cdot(g(x)-\beta_g-\hat{f}(x)g(x)+\hat{f}(x)\beta_g)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\\
&\leq \sum_{v\in R}\mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\mathop{\mathbb{E}}_{x\sim\mathcal{D}_x}[\ell(\hat{h}_t(x),0)\cdot(g(x)-\beta_g-f^*(x)g(x)+f^*(x)\beta_g)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]+2\alpha\\
&= \sum_{v\in R}\mathbb{P}[\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]\mathop{\mathbb{E}}_{x\sim\mathcal{D}_x}[(1-f^*(x))\ell(\hat{h}_t(x),0)\cdot(g(x)-\beta_g)|\hat{f}(x)=v, s_{\lambda_{t-1}}(x,v)=1]+2\alpha\\
&= \mathop{\mathbb{E}}_{x\in\mathcal{D}_x}[(1-f^*(x))\ell(h_t(x),0)\cdot(g(x)-\beta_g)]+2\alpha\\
&= w_g(\rho_g(h_t)-\rho(h_t))+2\alpha.\end{aligned}$$

Here, the inequality comes from our multicalibration guarantees: (1) because we assumed $\mathcal{G}$ contains the I, we can swap $\hat{f}(x)$ with $f^*(x)$ at the cost of α additive error, and (2) because we have joint mutlicaliration with respect to $\mathcal{G}\times\mathcal{B}(C)$, we can swap $\hat{f}(x)g(x)$ with $f^*(x)g(x)$ at the cost of α additive error. We can repeat the same argument in the opposite direction, and get that

$$w_g\left|\rho_g(h^*)-\rho(h^*)\right| \geq w_g\left|\rho_g(\bar{h})-\rho(\bar{h})\right| - 2\alpha.$$

□

C ACHIEVING JOINT MULTICALIBRATION

In this section we give an algorithm that can take as input any model $f : \mathcal{X} \to [0,1]$ and transform it into a new model $\hat{f} : \mathcal{X} \to R$ such that $\hat{f}$ achieves multicalibration in expectation with respect to a class of functions $C_1 \subset \{0,1\}^{\mathcal{X}}$ and simultaneously, joint multicalibration in expectation with respect to a class of functions $C_2 \subset \{0,1\}^{\mathcal{X}\times R}$ where $R = \{0, \frac{1}{m}, \frac{2}{m}, \ldots, 1\}$ for some $m > 0$. Our algorithm can be viewed as a variant of the original multicalibration algorithm of [14] (our variant achieves the stronger guarantee of calibration in expectation, first defined in [11]), or a simplification of the split-and-marge algorithm of [11], which replaces the "merge" operation with simple per-update rounding.

First we observe that without loss of generality, we can focus on achieving joint multicalibration for a single class of functions. To see this, note that given $C_1 \subset \{0,1\}^{\mathcal{X}}$, we can transform it into an identical class of two argument functions that simply ignore their second argument:

$$C_1' = \{c \text{ where } c(x,v) = c_1(x) \text{ for every } c_1 \in C_1\}.$$

Note that if $\hat{f}$ is α-approximately joint-multicalibrated with respect to C_1', then it is α-approximately multicalibrated with respect to C_1 and vice versa. In other words, in order to be simultaniously multicalibrated with respect to C_1 *and* joint-multicalibrated with respect to C_2, it is sufficient (actually equivalent) to be joint-multicalibrated with respect to $C_1' \cup C_2$. Therefore, we focus on enforcing joint-multicalibration with respect to arbitrary $C \subset \{0,1\}^{\mathcal{X}\times[0,1]}$.

Before we describe the algorithm, we define the round operation. Write $[\frac{1}{m}] = \{0, \frac{1}{m}, \frac{2}{m}, \ldots, 1\}$ for any $m > 0$. We let $f' = Round(f, m)$ to denote the function that simply rounds the output of f to the nearest grid point of $[\frac{1}{m}]$. Similarly, we write $Round(v, m) = \arg\min_{v' \in [\frac{1}{m}]} |v' - v|$ to denote the grid point of $[\frac{1}{m}]$ closest to v.

Algorithm 5 Multicalibration algorithm

Input: α, f, C
$m = \frac{1}{\alpha}$
$f_0 = Round(f, m)$
$t = 0$
While there exists a $c \in C$ such that:

$$\sum_{v \in R} \mathbb{P}_{x\sim\mathcal{D}_X}[f_t(x) = v, c(x,v) = 1]\left(v - \mathbb{P}_{(x,y)\sim\mathcal{D}}[y|f_t(x) = v, c(x,v) = 1]\right)^2 \geq \alpha$$

Let

$$(v_t, c_t) = \arg\max_{v\in R, c\in C} \mathbb{P}_{x\sim\mathcal{D}_X}[f_t(x) = v, c(x,v) = 1] \cdot \left(v - \mathbb{P}_{(x,y)\sim\mathcal{D}}[y|f_t(x) = v, c(x,v) = 1]\right)^2$$
$$S_t = \{x \in \mathcal{X} : f_t(x) = v, c_t(x, v_t) = 1\}$$
$$\tilde{v}_t = \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[y|x \in S_t]$$
$$v_t' = Round(\tilde{v}_t, m)$$

Let

$$f_{t+1}(x) = \begin{cases} v_t' & \text{if } x \in S_t \\ f_t(x) & \text{otherwise.} \end{cases}$$

$t = t + 1$
EndWhile

Theorem 8. *The output of Algorithm 5 $f_T : \mathcal{X} \to \{0, \alpha, 2\alpha, \ldots, 1\}$ is $\sqrt{\alpha}$-approximately jointly multicalibrated with respect to C where $T \leq \frac{4}{\alpha^2}$.*

Proof. By definition, the output of the algorithm f_T is such that

$$\sum_{v \in R} \mathbb{P}_{x\sim\mathcal{D}_X}[f_t(x) = v, c(x,v) = 1]\left(v - \mathbb{P}_{(x,y)\sim\mathcal{D}}[y|f_t(x) = v, c(x,v) = 1]\right)^2 < \alpha$$

for every $c \in C$, meaning it is satisfies $\sqrt{\alpha}$-joint calibration:

$$\begin{aligned}
&\sum_{v \in R} \mathbb{P}_{x\sim\mathcal{D}_X}[f_t(x) = v, c(x,v) = 1]\left|v - \mathbb{P}_{(x,y)\sim\mathcal{D}}[y|f_t(x) = v, c(x,v) = 1]\right| \\
&\leq \sqrt{\sum_{v \in R} \mathbb{P}_{x\sim\mathcal{D}_X}[f_t(x) = v, c(x,v) = 1]\left(v - \mathbb{P}_{(x,y)\sim\mathcal{D}}[y|f_t(x) = v, c(x,v) = 1]\right)^2} \\
&< \sqrt{\alpha}.
\end{aligned}$$

So it suffices to show that the algorithm halts in less than $T \leq \frac{4}{\alpha^2}$ rounds. Define

$$B(f) = \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[(y - f(x))^2].$$

We use B as a potential function and show that we decrease it in each round in the following lemma. □

Lemma 23. *For every $t < T$, $B(f_{t+1}) - B(f_t) \leq -\frac{\alpha^2}{4}$*

Proof. Define $\tilde{f_t}$ such that

$$\tilde{f_t}(x) = \begin{cases} \tilde{v}_t & \text{if } x \in B_t \\ f_t(x) & \text{otherwise.} \end{cases}$$

$$B(f_{t+1}) - B(f_t) = \underbrace{\left(B(f_{t+1}) - B(\tilde{f_t})\right)}_{(*)} + \underbrace{\left(B(\tilde{f_t}) - B(f_t)\right)}_{(**)}$$

Bounding (*):

$$\begin{aligned} B(f_{t+1}) - B(\tilde{f_t}) &= \mathbb{P}_{x\sim\mathcal{D}_X}[x \in S_t] \cdot \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[(y - f_{t+1}(x))^2 - (y - \tilde{f_t}(x))^2 | x \in S_t] \\ &= \mathbb{P}_{x\sim\mathcal{D}_X}[x \in S_t] \cdot \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[((y - \tilde{f_t}(x)) + (\tilde{v}_t - v_t'))^2 - (y - \tilde{f_t}(x))^2 | x \in S_t] \\ &= \mathbb{P}_{x\sim\mathcal{D}_X}[x \in S_t] \cdot \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[2(y - \tilde{v}_t)(\tilde{v}_t - v_t') + (\tilde{v}_t - v_t')^2 | x \in S_t] \\ &\leq \mathbb{P}_{x\sim\mathcal{D}_X}[x \in S_t] \cdot \frac{1}{4m^2} \end{aligned}$$

where the last inequality follows from the fact that $\tilde{v}_t = \mathbb{E}_{(x,y)\sim\mathcal{D}}[y | x \in S_t]$ and $|\tilde{v}_t - v_t'| \leq \frac{1}{2m}$.

Bounding (**): Because in round t,

$$\sum_{v\in R} \mathbb{P}_{x\sim\mathcal{D}_X}[f_t(x) = v, c(x,v) = 1] \left(v - \mathbb{P}_{(x,y)\sim\mathcal{D}}[y | f_t(x) = v, c(x,v) = 1]\right)^2 \geq \alpha,$$

we must have

$$\mathbb{P}_{x\sim\mathcal{D}_X}[x \in S_t] \, (v_t - \tilde{v}_t)^2 = \mathbb{P}_{x\sim\mathcal{D}_X}[x \in S_t] \left(v_t - \mathbb{P}_{(x,y)\sim\mathcal{D}}[y | x \in S_t]\right)^2 \geq \frac{\alpha}{m+1}.$$

Now,we show that

$$\begin{aligned} B(\tilde{f_t}) - B(f_{t+1}) &= \mathbb{P}_{x\sim\mathcal{D}_X}[x \in S_t] \cdot \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[(y - \tilde{f_t}(x))^2 - (y - f_t(x))^2 | x \in S_t] \\ &= \mathbb{P}_{x\sim\mathcal{D}_X}[x \in S_t] \cdot \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[(y - \tilde{f_t}(x))^2 - ((y - \tilde{f_t}(x)) + (\tilde{v}_t - v_t))^2 | x \in S_t] \\ &= \mathbb{P}_{x\sim\mathcal{D}_X}[x \in S_t] \cdot \mathop{\mathbb{E}}_{(x,y)\sim\mathcal{D}}[-2(y - \tilde{v}_t)(\tilde{v}_t - v_t) - (\tilde{v}_t - v_t))^2 | x \in S_t] \\ &\leq \frac{-\alpha}{m+1} \end{aligned}$$

where the last inequality follows from the fact that $\mathbb{E}_{(x,y)}[y | x \in S_t] = \tilde{v}_t$.

Combining them together, we get

$$\begin{aligned} B(f_{t+1}) - B(f_t) &\leq \frac{1}{4m^2} - \frac{\alpha}{m+1} \\ &= \frac{\alpha^2}{4} - \frac{\alpha^2}{\alpha+1} \\ &\geq \frac{\alpha^2}{4} - \frac{\alpha^2}{2} \\ &= -\frac{\alpha^2}{4}. \end{aligned}$$

□

Iterating Lemma 23 over T rounds, we have

$$B(f_T) \leq B(f_0) - T\frac{\alpha^2}{4}.$$

Also, because $B(f) \in [0,1]$ for any f, it must be that $T \leq \frac{4}{\alpha^2}$.

D OUT OF SAMPLE GUARANTEES

In the body of the paper, we assumed that we had direct access to distributional quantities — in particular, we needed to evaluate expectations over the feature distribution. In this section, we show that it is possible to estimate these quantities from modest amounts of unlabeled data sampled from the underlying distribution, and that the guarantees of our algorithm carry over to the underlying distribution. In particular, our algorithm results in a solution to the linear program that approximately satisfies its constraints on the underlying distribution, and achieves objective value that is approximately optimal within its comparison class. The strategy we take is to analyze a slightly modified algorithm (Algorithm 6), which at every stage, uses a fresh sample of data to evaluate the necessary expectations empirically. In particular, it uses a *new* sample at every iteration, and so has sample complexity that scales linearly with the number of iterations. Using techniques from adaptive data analysis [3, 6, 17] similar to how they are used by [14] to prove sample complexity bounds, we could reduce our linear dependence on T in our sample complexity bound by a quadratic factor by reusing data across rounds, but we settle for the conceptually simpler bound here.

Theorem 9. *Fix any distribution $\mathcal{D}$, hypothesis class $\mathcal{H}$, class of group indicators $\mathcal{G}$, dual bound C, and $\epsilon, \delta > 0$. After T rounds, with probability $1-\delta$, Algorithm 6 outputs a randomized hypothesis $\bar{h}$ such that $err(\bar{h}) \leq OPT + \frac{2}{C} + 8\epsilon$ and $\omega_g|\rho_g(\bar{h}) - \rho(\bar{h})| \leq \gamma + \frac{1}{C} + \frac{2}{C^2} + \frac{8\epsilon}{C}$, where OPT is the objective value of the optimal solution of $\psi(f, \gamma, \mathcal{H}_A)$. It makes use of $m = O\left(T\frac{\log(\frac{2T|G|}{\delta})}{2\epsilon^2}\right)$ samples of unlabeled data drawn i.i.d. from $\mathcal{D}_X$. Here T is as specified in the algorithm: $T = \frac{1}{4}\cdot C^2 \cdot (C^2 + 4|\mathcal{G}|)^2$.*

Lemma 24. *Fix any distribution $\mathcal{D}$, hypothesis class $\mathcal{H}$, and class of group indicators $\mathcal{G}$. In a single round t of Algorithm 6 with $S_t \sim \mathcal{D}^m$ for $m = O(\frac{\log(\frac{2|G|}{\delta})}{2\epsilon^2})$, Algorithm 6 returns a hypothesis h_t that with probability $1-\delta$ satisfies for all $g \in G$:*

$$|err(h_t, g, \mathcal{D}) - err(h_t, g, S_t)| \leq \epsilon$$
$$|\rho(h_t, g, \mathcal{D}) - \rho(h_t, g, S_t)| \leq \epsilon.$$

Algorithm 6 Projected Gradient Descent Algorithm

Input: $\mathcal{D}$: data distribution, $f : \mathcal{X} \to [0,1]$: regression function, $\mathcal{G}$: groups, γ: tolerance on fairness violation, C: bound on dual ($\|\lambda\|_1 \leq C$), η: learning rate, m = $\frac{\log(\frac{2|G|}{\delta})}{2\epsilon^2}$: batch size of fresh data for each round of gradient descent, ϵ: per round estimation error, δ: failure probability

Initialize dual vector $\lambda^0 = \mathbf{0}$ and set $T = \frac{1}{4}\cdot C^2 \cdot (C^2 + 4|\mathcal{G}|)^2$.

for $t = 1, \ldots, T$ **do**

Primal player updates h_t

$$h_t(x) = \begin{cases} 1, & \text{if } f(x) \geq \frac{\kappa_{t-1}}{\mu_{t-1}} \text{ and } \mu_{t-1} > 0, \\ 0, & \text{if } f(x) < \frac{\kappa_{t-1}}{\mu_{t-1}} \text{ and } \mu_{t-1} > 0, \\ 1, & \text{if } f(x) \leq \frac{\kappa_{t-1}}{\mu_{t-1}} \text{ and } \mu_{t-1} < 0, \\ 0, & \text{if } f(x) > \frac{\kappa_{t-1}}{\mu_{t-1}} \text{ and } \mu_{t-1} < 0. \end{cases}$$

Sample S_t i.i.d. from $\mathcal{D}^m$

Compute

$$\hat{\rho}t, g = \mathop{\mathbb{E}}_{(x,y)\sim S_t}[\ell(h_t(x), 0)g(x)(1 - f(x))] \text{ for all } g \in \mathcal{G},$$
$$\hat{\rho}_t = \mathop{\mathbb{E}}_{(x,y)\sim S_t}[\beta_g \ell(h_t(x), 0)(1 - f(x))], \text{ where } \beta_g = \mathbb{P}[g(x) = 1 | y = 0]$$

Dual player updates

$$\lambda_{g,t,+} = \max(0, \lambda_{g,t,+} + \eta \cdot (\hat{\rho}_{t,g} - \hat{\rho}_t - \gamma)),$$
$$\lambda_{g,t,-} = \max(0, \lambda_{g,t,-} + \eta \cdot (\hat{\rho}_t - \hat{\rho}_{t,g} - \gamma)).$$

Dual player sets $\lambda_t = \sum_{g\in\mathcal{G}} \lambda_{g,t,+} - \lambda_{g,t,-}$.

if $\|\lambda^t\|_1 > C$ **then**

set $\lambda^t = \arg\min_{\{\tilde{\lambda}\in\mathbb{R}^{2\mathcal{G}} | \|\tilde{\lambda}\|_1 \leq C\}} \|\lambda_t - \tilde{\lambda}\|_2^2$.

end if

end for

Output: $\bar{h} := \frac{1}{T}\sum_{t=1}^{T} \hat{h}_t$, a uniformly random classifier over all rounds' hypotheses.

Theorem 10 (Chernoff-Hoeffding Bound). *Let $X_1, X_2, \ldots, X_m$ be i.i.d. random variables with $a \leq X_i \leq b$ and $\mathbb{E}[X_i] = \mu$ for all i. Then, for any $\alpha > 0$,*

$$\mathbb{P}\left(\left|\frac{\sum_i X_i}{m} - \mu\right| > \alpha\right) \leq 2\exp\left(\frac{-2\alpha^2 m}{(b-a)^2}\right).$$

Proof of Lemma 24. This claim follows by applying a Chernoff-Hoeffding bound with $m \geq \frac{\ln(\frac{2|G|}{\delta})}{2\epsilon^2}$ □

Proof Sketch of Theorem 9. Taking $m > \frac{\log(\frac{2T|G|}{\delta})}{2\epsilon^2}$, we have that in a single round t of our algorithm we are able to estimate the true distributional classification and fairness constraint errors up to an additive error of ϵ with probability $1 - \delta/T$ — and hence with probability $1 - \delta$, we estimate these quantities up to additive error ϵ uniformly over all T rounds. We can then make one small modification to the analysis of Algorithm 4. First observe that since the primal player's best response does not depend on any estimation of a distributional quantity based on the sample S_t, their regret is still zero, as it is in the analysis of Algorithm 4. The dual player, on the other hand, is given loss vectors that deviate from the versions that would have been computed on the underlying distribution by at most 2ϵ in ℓ_∞ norm, and hence experience additional regret (to the true distributional quantities) larger than in the analysis of Algorithm 4 by up to an additional additive 4ϵ. Consequently, the equilibrium solution $(\bar{h}, \bar{\lambda})$ from Algorithm 6 is an $4\epsilon + 1/C$ approximate equilibrium to the zero-sum game of 12 which then, applying Theorem 3, yields a $\frac{2}{C} + 8\epsilon$ approximate solution to the objective of the original linear program. □

Self-Destructing Models: Increasing the Costs of Harmful Dual Uses of Foundation Models

ABSTRACT

A growing ecosystem of large, open-source foundation models has reduced the labeled data and technical expertise necessary to apply machine learning to many new problems. Yet foundation models pose a clear dual-use risk, indiscriminately reducing the costs of building both harmful and beneficial machine learning systems. Policy tools such as restricted model access and export controls are the primary methods currently used to mitigate such dual-use risks. In this work, we review potential safe-release strategies and argue that both policymakers and AI researchers would benefit from fundamentally new technologies enabling more precise control over the downstream usage of open-source foundation models. We propose one such approach: the *task blocking* paradigm, in which foundation models are trained with an additional mechanism to impede adaptation to harmful tasks without sacrificing performance on desirable tasks. We call the resulting models *self-destructing models*, inspired by mechanisms that prevent adversaries from using tools for harmful purposes. We present an algorithm for training self-destructing models leveraging techniques from meta-learning and adversarial learning, which we call *meta-learned adversarial censoring (MLAC)*. In a small-scale experiment, we show MLAC can largely prevent a BERT-style model from being re-purposed to perform gender identification without harming the model's ability to perform profession classification.

1 INTRODUCTION

A defining capability of large pretrained models (hereafter foundation models; FMs) is their ability to adapt to many downstream tasks in a few-shot manner—potentially improving performance and efficiency in domains with little training data [7]. Today, anyone with an internet connection can download a foundation model and adapt it to socially beneficial use-cases, like building better educational tools or improving access to justice. However, a malicious actor can also adapt a foundation model to nearly any harmful use-case they desire. For example, an oppressive government can take a powerful pretrained language model and adapt it to identify dissidents; a rogue actor can adapt a pretrained object recognition system such that commercially available drones act as targeted loitering munitions; or a pretrained drug discovery system can be used for creating chemical or biological weapons, like neurotoxins [55]. Unfortunately, due to their general-purpose nature, preventing such dual uses of foundation models is difficult. This creates a tension between making these models widely available and ensuring that they are used in a safe and responsible way.

Currently, there are several approaches to mitigating the dual uses of FMs which can be divided into *structural* safety mechanisms and *technical* safety mechanisms. Structural mechanisms use licenses or access restrictions to prevent harmful uses; there is a broad spectrum of such structural release mechanisms. Some have suggested a review board for selecting the structural release mechanism [34] while others have argued that open source access to foundation models is essential for safety research [6]. While structural release approaches aim to prevent malicious users from acquiring foundation models or providing legal remedies if they exceed the terms of their access, *technical* strategies ensure that the model cannot be used for harmful purposes even if a malicious user is able to gain access to the model itself. Current technical strategies aim to tune the model so that it is less likely to produce harmful content at inference time [3], but do not consider the case where adversaries have access to model parameters.

In this work, we review these strategies, noting that no strategy on its own is able to prevent harmful dual uses of FMs. In particular we note the disconnect between the goal of many structural safety mechanisms and the new reality of open-source foundation models: structural safety strategies aim to prevent a malicious actor from gaining access to the model parameters altogether. In recent months, however, powerful open-source models have been released to the public, including Meta's Llama model which was leaked online despite a restricted access policy [53, 58]. Such developments demand changes to the threat model of malicious FM usage, specifically, that eventually model parameters will become generally accessible. Unlike the assumptions of current safety strategies, there should

*Both authors contributed equally to this research.

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08…$15.00
https://doi.org/10.1145/3600211.3604690

then be a last layer of defense that renders the model itself as harmless as possible. We argue that we need more *technical* strategies to supplement *structural* strategies to reduce the ability for adversaries to use and adapt foundation models for harmful tasks: even when they have access to model parameters. Where existing access restrictions must navigate the tension between openness and safety, we seek to provide a new research pathway for reducing (and in some cases obviating) this tension.

We suggest one such new path forward: *self-destructing models*. Self-destructing models are trained via a task blocking method that impedes the adaptation of the model to a harmful task without impairing the model's ability to be used for its original intended purpose. By increasing the compute, data, and talent required to adapt public models to harmful tasks, self-destructing models have the potential to supplement access controls and other safety mechanisms. We demonstrate a task-blocking mechanism using meta-learning for training a self-destructing model. We find that meta-learning is an essential step in reducing an adversary's ability to tune a model for a harmful task. Simple adversarial losses [16], often used in current technical strategies, do not significantly reduce the costs of harmful adaptation. We hope that the proposed mechanism forms an initial step toward developing new safe release strategies even under the assumption that model parameters become available to adversaries.

Below, we first review the state of current safe-release approaches and their shortfalls, making the case for a shift in the threat model to make model parameters as harmless as possible even with model access. Second, we define the *task blocking* problem and evaluation metrics as well as *self-destructing models*. Third, we describe an initial algorithm, Meta-Learned Adversarial Censoring (MLAC), for training self-destructing models, evaluating its ability to impede fine-tuning a language model to perform demographic information extraction. Fourth, we identify key directions for future research in the development of self-destructing models.

2 REVIEWING THE RISKS AND MITIGATION STRATEGIES FOR DUAL USES

Foundation models can be and, importantly, *have been* used for harmful purposes unforeseen by their creators in recent years. They have been fine-tuned on hate speech and deployed to 4chan [57]; hackers have released methods to bypass ChatGPT's safety filters so that it can be used to help generate malware and spam [23]; stable diffusion models have been fine-tuned to generate abusive imagery [28].

Researchers, practitioners, and policymakers are increasingly searching for new ways to prevent machine learning models from being used for these harmful dual purposes—e.g., Solaiman [51], Brundage et al. [9], Whittlestone and Ovadya [59], Shevlane [49], Brundage et al. [8], and many others. Proposed tools have included export controls, controlled or restricted release strategies, using terms of service or licensing, and alignment and fine-tuning for safety. In this section, we briefly examine each of these methods and discuss potential gaps in relying on each strategy. We consider both *structural* methods (e.g., export controls, use of licensing, and access restrictions), and *technical* methods (e.g., alignment fine-tuning).

2.1 Structural Methods

Export Controls. Recently, researchers, such as Flynn [21], have recommended that the United States consider export controls on hardware related to AI, including NVIDIA A100 GPUs, to restrict certain actors' capacity to train powerful AI models that require substantial computational resources. In 2022, the United States imposed these export controls on AI-related hardware and hardware-manufacturing equipment, following researchers' suggestions [56].

Such export controls may help restrict pre-training of foundation models—a use case which requires large amounts of specialized hardware, but they do not necessarily restrict inference-time computing and small-scale adaptation once model parameters are available. Even the largest foundation models can now be deployed or adapted on commodity hardware using techniques such as adapters [27], 8-bit [12], and even 4-bit [13] quantization, and other optimization strategies. A recent open-source project was able to run multi-billion parameter LLaMa models on a MacBook Pro with near-equal performance to some state-of-the-art closed-source models, using these techniques.[1] As a result, hardware export controls may no longer be sufficient to prevent the efficient adaptation of foundation models or the large-scale deployment of pre-trained models, nor can they prevent malicious actors located in countries not included in the export control regime.

The U.S. government has also put in place export controls on certain *software* and *models* with specific harmful dual uses. For example, in a 2020 rulemaking, the Department of Commerce Bureau of Industry and Security (BIS) restricted export of software that can be used for automated geospatial analysis. Under this regulation the model is controlled if it meets four criteria: (1) it provides a graphical user interface to identify objects in geospatial imagery; (2) it "reduces pixel variation by performing scale, color, and rotational normalization on the positive samples"; (3) it "[t]rains a Deep Convolutional Neural Network to detect the object of interest from the positive and negative samples"; (4) it "[i]dentifies objects in geospatial imagery using the trained Deep Convolutional Neural Network by matching the rotational pattern from the positive samples with the rotational pattern of objects in the geospatial imagery." But such highly specific export controls do not cover general-purpose foundation models (and associated training software). In fact, a recent demonstration showed how to adapt a CLIP model [44] exactly for analyzing satellite imagery in an easy way using all open-source software [2]. Flynn [21] argued that applying export controls to general-purpose foundation models would be ineffective due to the ease of violating export controls through the same mechanisms as software piracy, as well as the harmful impacts to innovation that such restrictions could have.

Overall, while export controls may be effective in restricting access to large-scale chipsets or certain software, once adversaries can gain access to open-source (or leaked) foundation model parameters they can be readily adapted to harmful dual-uses.

Access Control. Controlled release or restricted access strategies are another set of structural mechanisms that can supplement export controls and reduce malicious actors' ability to access models [41, 49, 52].

[1] https://github.com/ggerganov/llama.cpp

Approach	Examples	Challenges
Export Controls	United States Export Controls on AI hardware	Imprecise, reduced hardware costs, open-source models
Controlled Release	API-only access, Release by request/agreement	Open-source models, leaks, monitoring difficulties
Licensing	OpenRAIL	Requires monitoring and enforcement action, leaks
Filtering, Alignment	Reinforcement Learning from Human Feedback	Can be bypassed by fine-tuning or prompt engineering

Table 1: A review of current or proposed approaches to safe foundation model release.

One such approach is to make the model accessible only by agreement. This involves vetting potential users and requiring them to sign a restrictive terms of service before gaining access to the model. For instance, Meta's OPT-175B model and Llama both employ this approach [53, 61, 62]. This access restriction approach is attractive as it does not require hosting any centralized infrastructure for serving model queries. It only requires one-time vetting of the users requesting model access. However, as evidenced by the recent Llama model leak onto BitTorrent [58] and HuggingFace,[2] this approach is susceptible to unauthorized dissemination, effectively negating access control efforts.

Another approach is to never release the model at all, but provide access via an application programming interface (API). Many companies, such as OpenAI, Anthropic, Cohere, and AI21 adopt this approach to protect their trade secrets and prevent harmful dual uses. This approach prevents direct access to model weights, preventing uncontrolled dissemination and retaining the ability to cut off access to malicious users at any time. However, this approach requires monitoring of API usage to detect and revoke access when abused, as well as considerable resources to maintain. Providing such an API may not be possible for researchers and entities without access to centralized model-hosting infrastructure.

Additionally, as open-source efforts continue to match the performance of these closed-source models, the effectiveness of any access control approaches may decrease. Access control approaches require all model creators capable of training similarly capable foundation models to be in agreement on the mechanism for release. If one equally-capable foundation model is available as open-source, malicious actors can simply turn to this alternative.

Terms of Service/Sale (ToS) and Licenses. Closely tied to access controls are licensing agreements to prevent harmful dual-uses. These agreements place restrictions on who can use the model, for what purpose, and in what format. For example, OpenRAIL [18] and similar licenses impose several usage limitations to prevent users from using the model for defamation, spreading disinformation, providing medical advice, or for use by law enforcement. Such terms of service (ToS)-based approaches are also used in other settings, such as by Boston Dynamics, which prohibits modifying its robots for lethal capability and reserves the right to prevent any misuse.[3]

However, relying solely on licensing agreements assumes that malicious actors would respect them and that legal action against violators is possible. Unfortunately, this approach faces several challenges. Firstly, harmful actors may be located in countries that do not enforce licensing requirements. Further, it may be challenging to identify malicious actors and issue a cease-and-desist request. Finally, model creators may not have the resources to monitor and enforce compliance with licensing agreements.

Overall, licensing agreements face the same challenges as other structural restrictions. They require the resources, and international reach, for enforcement.

2.2 Technical Strategies

Unlike structural strategies, we classify *technical strategies* as those that modify foundation models directly to make it more difficult to use them for harmful purposes. Existing technical strategies focus on tuning models to prevent them from outputting harmful content at inference time or adding content filters to block potentially harmful outputs.

Safety Filters. Some models come with safety filters that scan model outputs for harmful content and then redact the output. Stable Diffusion models use this approach to replace offensive content generated by the model with a blank image by default [48]. However, for open-source models safety filters can simply be removed by deleting a few lines of code. This has led users on Reddit to post tutorials like "How to remove [Stable Diffusion's] safety filter in 5 seconds."[4] Other researchers have noted that the filter itself is easily bypassed even without access to directly modify the code [45]. While safety filters can be effective and integral parts of a safe model release, they are more effective when coupled with other structural mechanisms like restricted or API-only model access.

Safety Tuning and Alignment. Alternative approaches such as reinforcement learning from human feedback tune the model itself to be less harmful [3]. Sometimes these approaches fall into a larger class of methods under the moniker *AI alignment*. Since these methods directly train the model to be more difficult to use for harmful purposes at inference time, they are an essential part of a safe release strategy—either for open-source models or for models coupled with a structural release restriction. Though they make the model parameters more difficult to use for harmful tasks, they can be bypassed in two ways.

First, prompt engineering can be used to put models in a state that nonetheless allows them to be used for harmful purposes. For example, hackers now sell prompts and methods to bypass alignment processes and filters for OpenAI's series of models [23]. This allows would-be malicious actors to generate phishing emails and malware with the model, despite its use restrictions.

Second, open-source models can be fine-tuned to remove these restrictions. In one such instance, the open-source GPT-J model

was fine-tuned on 4chan data (mainly consisting of toxic content and hate speech) and deployed to post to the forum [57].

In the remainder of this work, we describe and evaluate an approach to mitigating this second method of bypassing existing technical model protections.

2.3 The Need For New Technical Mitigation Strategies

The strategies discussed above are individually imperfect; however, each contributes to increasing the costs of successfully co-opting foundation models for harmful dual uses. As access to increasingly capable models becomes commonplace—either through leaks or open-source releases—it is crucial to ensure that the underlying model parameters themselves are optimized for safety as a last line of defense. Structural barriers, such as access restrictions and terms of service, can become ineffective as model weights are distributed through services like BitTorrent.

As regulators recognize the potential dangers associated with increasingly capable systems, it is becoming evident that they will take action to address the risks. One E.U. AI Act proposal would see liability placed on open-source models, incentivizing restricted access approaches. Others argue that such a move would stifle innovation and make it more difficult to develop safer overall models [6, 17, 25]. As Black et al. [6] write, "open access to [FMs] is critical to advancing research in a wide range of areas—particularly in AI safety, mechanistic interpretability, and the study of how [FM] capabilities scale." Yet while more widely available FMs certainly enable greater accessibility, auditability, and understanding of these powerful models, making FMs widely available for downstream adaptation without restriction comes at some cost to safety.

Despite the benefits of open-source releases, if open-source models are regularly adapted for harmful purposes, the pendulum of regulation could swing toward the more restrictive regime as regulators look to available structural tools like access restrictions. To supplement the policy options available to regulators, and to increase the safety of foundation models by default, we encourage more research to expand the toolbox of technical approaches to ensure that model parameters are as safe as possible, even when they are leaked or openly available. We introduce a new class of methods for this toolbox: *task blocking* for *self-destructing models*. These methods are not perfect, but add another layer of protection when combined with other approaches.

3 TASK BLOCKING & SELF-DESTRUCTING MODELS

The goal of task blocking is to create models that increase the costs of fine-tuning on harmful downstream tasks such that an adversary would rather start from scratch than use the pretrained model, while remaining useful for desired tasks (see Fig. 1). The resulting models are "self-destructing models" which impede adaptation on harmful dual-uses by increasing the costs of the harmful use. In this section, we more precisely define our problem setting and describe an initial algorithm for it.

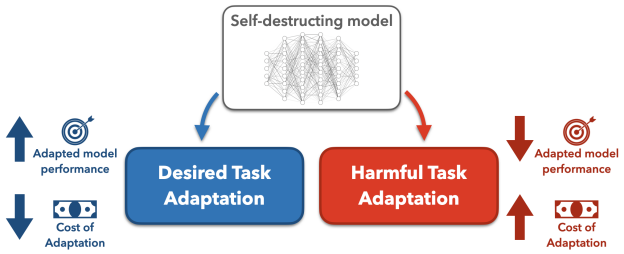

Figure 1: An ideal self-destructing model would boost performance and reduce adaptation costs relative to training from scratch only for desired tasks, while impeding learning of harmful tasks.

3.1 The Task Blocking Problem

We assume that an adversary aims to adapt a pretrained model π_θ (where θ are model parameters of model π) to a harmful task, searching for the best adaptation procedure f among a set of adaptation procedures $\mathcal{F}$ in order to find the one that maximizes harmful task performance. Adaptation procedures in $\mathcal{F}$ may include simple fine-tuning, a hyper-parameter search over fine-tuning procedures, as well as other more advanced adaptation mechanisms that we leave to future work. The goal of task blocking is to produce a self-destructing model with parameters $\tilde{\theta}$, which performs similarly to a standard pre-trained model on a set of desired tasks while being more costly to successfully adapt to harmful tasks.[5]

We define two regimes to increase costs: (1) increase data costs by decreasing sample efficiency; (2) increase compute costs by slowing convergence of the training process.

Data Costs. In the first regime, we assume that the adversary has little data to adapt an FM to their harmful task and that the cost of gathering more data is high. A hallmark trait of traditional FMs is effective few-shot adaptation, learning rapidly from small, fixed-sized datasets. A self-destructing FM, on the other hand, should provide few-shot performance comparable to a randomly initialized model. We define the *few-shot performance improvement* of an FM with parameters θ as the performance gain over a randomly initialized model, both with a fixed adaptation procedure search budget. This can be represented as the following formula:

$$\mathcal{E}^n_{data}(\theta) = \max_{f \in \mathcal{F}} \mathcal{M}\left(f(\theta, D_n)\right) - \max_{f \in \mathcal{F}} \mathcal{M}\left(f(\theta^r, D_n)\right), \quad (1)$$

where $\mathcal{M}$ is the performance metric (where higher is better), n is the number of data points available, D_n is an adaptation dataset of n examples from the task of interest, and θ^r is a randomly-initialized model. $f \in \mathcal{F}$ is an adaptation procedure drawn from a fixed distribution. The size of $\mathcal{F}$ loosely corresponds to the adversary's resource budget for adaptation. Note that the max in Equation 1 encapsulates hyperparameter optimization over the adaptation distribution. $\mathcal{E}_{data} = \frac{1}{N}\sum_n^N \mathcal{E}^n_{data}$ is the average sample-wise regret between the FM parameters θ and a random re-initialization θ^r after

[5]While the goal of a self-destructing model is to reduce performance on harmful tasks after fine-tuning, it should enable high quality *predictions* or *fine-tunability* for desired tasks. Our experiments explore the prediction goal, and we leave exploration of preserving fine-tunability for future work.

each follows the same adaptation procedure $f(\cdot)$ on a fixed-sized dataset D_n. An ideal self-destructing model has $\mathcal{E}_{data} \leq 0$, meaning the model is no more data efficient than a randomly-initialized model for the (presumably harmful) task of interest.

Compute Costs. If data is cheap or plentiful, it may be difficult to prevent an adversary from learning the task since perhaps even a random model can learn the task with the amount of data available. In this data regime (large amount of cheap data), the benefit of an FM is improved compute efficiency, rather than increased accuracy. Here, we would define the FM's *compute cost improvement @p* as the amount of compute saved by using the FM over a randomly initialized model to achieve performance p, where p may measure accuracy, loss, or another metric and compute could be measured in FLOPs, train steps, hyperparameters searched, wall clock time, etc. While in the previous setting, we fix the *dataset size* and blocking aims to reduce performance, in this setting, we fix the *performance* and blocking aims to increase compute costs. The goal of task blocking in this case is to prevent any compute cost improvement over a random initialization when adapting the self-destructing model to a harmful task, while retaining compute cost improvement for desired tasks. Formally, compute cost improvement @p is given as

$$\mathcal{E}^{p}_{compute}(\theta) = C(\mathcal{F}, \theta^{r}, p) - C(\mathcal{F}, \hat{\theta}, p) \tag{2}$$

where C measures the compute cost of applying adaptation procedures from family $\mathcal{F}$ to random parameters θ^r or FM parameters θ until a model with performance level p is found.

However, for the purposes of this work, we focus on data costs, studying methods for reducing few-shot performance improvement for harmful tasks. We leave analysis of compute cost improvement reduction to future work.

Defining Harmful Dual Uses. A large body of work has pointed to inherently harmful uses that FM creators may wish to block: from creating neurotoxins [55] to race detection [38]. In our work we assume that a harmful dual use is *known* and *defined*. That is, the self-destruct mechanism will have data to approximate the dual use and actively encode a mechanism to block it. This requirement inherently requires a normative definition of harmful dual uses. As in other threat modeling exercises and mechanisms for removing harmful content from models, model creators will have to identify the set of tasks to be blocked. Creating self-destructing models may impede their use for harmful purposes counter to the model creator's values, but it is up to the model creator to determine those values. While defining harmful tasks *a priori* may be difficult, this work reflects a "red teaming" approach to harm prevention, common in security contexts. That is, model creators play the role of an adversary to identify and prevent harms. This can function as a complement to other access control methods, providing more confidence that certain known harmful tasks are blocked.

Relationship to Other Technical Safety Mechanisms. Reinforcement learning from human feedback (RLHF), and other similar approaches, have been used to mitigate the harms that model can have at inference time [3]. While RLHF aims at ensuring that agents are as harmless as possible at inference time, the goal of self-destructing models and task blocking is to make it difficult to undo these safety mechanisms and co-opt the model even with access to model parameters and adaptation. These are complementary approaches and can be used concurrently to make the model parameters as safe as possible overall. Essentially, the aim is to maintain the model's harmlessness for as long as possible, even when an adversary has direct access.

Input: pretrained model $m = w_d \circ \pi_\theta$, desired task dataset D_d, harmful task dataset D_h, adaptation methods $\tilde{\mathcal{F}}$, adaptation steps K, learning rates η, η_h, η_d
Initialize: Adversarial harmful task head w_h and learning rate α_h, with $\phi = \{w_h, \alpha_h\}$; initial blocked params $\tilde{\theta} \leftarrow \theta$
for n steps **do**
  Sample adaptation procedure $\tilde{f}_k \sim \tilde{\mathcal{F}}$
  Sample data batches $b_d \sim D_d$, $\{b^k_h\} \sim D_h$, $b_h \sim D_h$
  $\{\theta_k\}, \{w^k_h\} \leftarrow \tilde{f}_k(w_h \circ \pi_{\tilde{\theta}}, \{b^k_h\}, \alpha_h)$ // do inner loop
  $\ell^h_k = \mathcal{L}_h(w^k_h \circ \pi_{\theta_k}, b_h), \forall k$ // outer loop harmful NLLs
  $\ell^d = \mathcal{L}_d(w_d \circ \pi_\theta, b_d)$ // desired NLLs
  $\tilde{\theta} \leftarrow \tilde{\theta} - \eta \nabla_\theta \left(\ell^d - \frac{1}{K} \sum_k^K \ell^h_k \right)$ // update blocked model
  $\phi \leftarrow \phi - \eta_h \frac{1}{K} \sum_{k=1}^K \nabla_\phi \ell^h_k$ // update adversarial params
  $w_d \leftarrow w_d - \eta_d \nabla_{w_d} \ell^d$ // update desired task head
end for

algorithm 1: MLAC Training Procedure

3.2 Meta-Learned Adversarial Censoring

To prevent successful adaptation of pretrained models to harmful tasks, we describe *Meta-Learned Adversarial Censoring (MLAC)*, a meta-training procedure that aims to eliminate any useful information about the harmful task in the model's parameters *even after fine-tuning on that task*. Given a desired task dataset D_d and harmful task dataset D_h, MLAC learns a feature extractor $\pi_{\tilde{\theta}}$ that is effective for the desired task but cannot be effectively used or efficiently fine-tuned to perform the harmful task.

In the *inner loop* of each meta-training step, the feature extractor and an adversarially learned prediction head w_h are adapted to the harmful task with several steps of gradient-based adaptation with an adversarially learned learning rate α_h. The adaptation procedure $\tilde{f}$ used at each meta-training step is sampled from $\tilde{\mathcal{F}}$, a proxy for the true adversary's adaptation class $\mathcal{F}$. In this case, we narrow $\tilde{\mathcal{F}}$ to be different fine-tuning approaches with close-to-optimal hyperparameters (e.g., Adam for K steps and learning rate α_h). In the *outer loop*, the adversarial parameters $\phi = \{w_h, \alpha_h\}$ are trained to minimize the harmful task negative log likelihoods of the adapted models, while the blocked parameter initialization $\tilde{\theta}$ are trained to maximize the harmful task negative log likelihoods of the adapted models. We also must counteract the self-destruct mechanism with something that will prevent unlearning of the entire network. In this work, we simply optimize for a given desirable task as the counter-balance by minimizing ℓ^d, which updates both the desired task head w_d and the representation parameters $\tilde{\theta}$. See Algorithm 1 for the complete training procedure. Note that in practice, we use Adam rather than SGD in the outer loop to optimize $\tilde{\theta}$, adversarial parameters ϕ, and desired task output head w_d. We use `higher` [24] for implementing the bi-level meta-learning process.

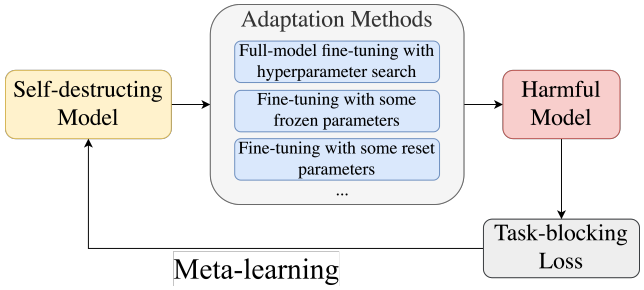

Figure 2: High-level visualization of the meta-learning process.

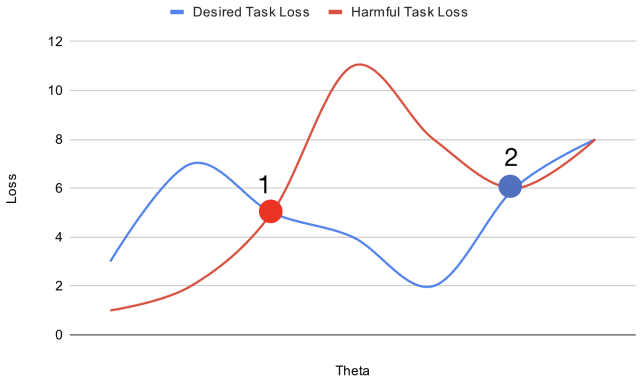

Figure 3: High-level optimization perspective of the MLAC procedure. A foundation model placed in point 1 would easily be tuned via gradient descent for both the harmful task loss and the desired task loss global optimum. On the other hand a foundation model in point 2 would easily reach the desired task optimum, but is more likely to be stuck in a local optimum for the harmful task.

Calibration. We also add another mechanism to strengthen the inner-loop adversary. In binary classification tasks, maximizing the loss of the harmful task may lead to a degenerate optimum where labels are flipped, which leaks information about the harmful task. To prevent this outcome, we also optimally calibrate the logits via a simple linear projection (w) solved via differentiable convex optimization [1, 15]. Thus at step k of the inner loop we solve the maximum likelihood problem:

$$w_c^k = \underset{W}{\text{argmax}} \sum_i^{|b_h|} \left[\text{logsoftmax} \left[\left(W \circ m^k \right)(x_i) \right]^\top y_i \right]$$
$$\text{s.t.} -1 \leq W \leq 1, \qquad (3)$$

where $m^k = w_h^k \circ \pi_\theta^k$ is the blocked model after k steps of adaptation using the adversarial harmful task head and learning rate. Thus this projection updates line 7 of Alg. 1 to $\ell_k^h = \mathcal{L}_h(w_c^k \circ w_h^k \circ \pi_{\theta_k}, b_h)$. We also refer to calibration as *head adjustment*, as it essentially refines the linear function computed by the final output head.

High-level Intuition. Figures 2 provides a visualization of this method. At each step, the self-destructing model samples from possible adaptation methods that could be used to adapt the model to a harmful dual use. This multi-step loss is then inverted in a meta-learning step to prevent the model from being easily adapted in this sampled fashion.

From an optimization perspective, the goal is to identify a parameter space where adaptation to desired tasks is relatively simple via standard adaptation techniques, but the same part of the parameter space might be a low-utility local optimum or saddle-point that is more difficult to escape for the harmful task. This can be seen as a simplified visualization in Figure 3. Of course, adaptation methods can be created to reset parts of the network such the global harmful optimum can be recovered (in the extreme resetting most of the network to escape the local optimum). However, this will decrease the utility of the expensive pre-training and increase the costs to adversaries, adding another tool in the toolkit against harmful dual-uses.

4 EXPERIMENTS

The goal of our experiments is to assess the ability of MLAC and several simple baselines to reduce the few-shot performance improvement of a pre-trained FM.[6]

4.1 Dataset.

In a demonstrative experiment, we utilize an existing dual-use dataset in the de-biasing literature, "Bias in Bios" [10]. The dataset consists of professional biographies. Each biography has a label that is the gender identity of the biography's subject as well as the profession being discussed. We split the data into a train, validation, and evaluation set. We consider the "desirable task" for which we want to maintain good performance as the profession detection task. We wish to block the gender identification task. On the original dataset, we find that a random model can learn gender classification to over 90% accuracy with only 10 examples, leaving only marginal ability for an FM to improve in data efficiency. Thus, to make the FM more beneficial, we replace all pronouns with "they/their," similar to the censored dataset in the original data. While this task pair has traditionally been used for de-biasing, and while we mainly use this as an initial demonstration, there may be valid reasons for preventing an adversary from detecting demographic information from text. In countries where anti-minority action is common, automated systems that identify demographics may cause serious harm. For example, a country may wish to identify people of a certain religion, sexual orientation, or other identity group in automated and ultimately harmful ways. Or the state may wish to identify another feature that is highly correlated with identity which will lead to the same harms.[7]

4.2 Protocol.

For all experiments, we run 50k steps of MLAC meta-training on the training set. At test time, we take the resulting self-destructing model and run it through a rigorous hyperparameter search to maximize fine-tuning performance on the harmful task. We allow

[6] Code is available at https://github.com/Breakend/SelfDestructingModels.

[7] Technology Experts Letter to DHS Opposing the Extreme Vetting Initiative, 2017.

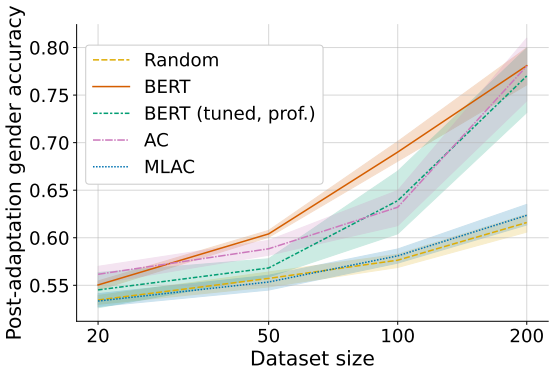

Figure 4: Harmful task (gender identification) performance after fine-tuning. MLAC shows fine-tuning performance similar to a randomly-initialized model, while adversarial censoring (AC) [16] does not prevent effective fine-tuning. Shading indicates 95% confidence intervals across 6 random seeds.

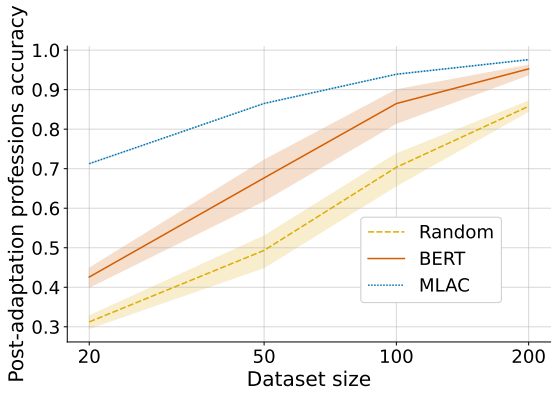

Figure 5: After fine-tuning the MLAC-blocked model on the desired task, few-shot performance exceeds both BERT and a randomly-initialized model. Note the MLAC objective includes training on the desired task, so this comparison clearly advantages MLAC; nonetheless, it provides evidence that there *exists* a blocked initialization that can be effectively fine-tuned on the desired task. Discovering such an initialization without using desired task data in pre-training is an important direction for future work.

hyperparameter searches with 50 fine-tuning trials, using the tree-structured Parzen Estimator [4] in the `hyperopt` software package [5]. We search over learning rate, batch size, maximum number of steps, and freezing of intermediate representation layers. For this process, we subsample the validation set to simulate an adversary with a dataset of size N. This subsampled validation set is used as the training set for the adversary. We then use the entire evaluation set to evaluate the adversary's performance on held-out data and for hyperparameter tuning. We make the conservative assumption that the adversary can perform hyperparameter tuning using the *population*, even if the amount of data for fine-tuning itself is limited. This choice weighs heavily in the adversary's favor, disadvantaging the self-destruct method. We repeat the hyperparameter search process 6 times with different random seeds and data subsets. This yields confidence intervals over different adversaries training on different subsets of the data.

4.3 Comparisons.

We compare MLAC to the adversarial censoring (*AC* in Fig. 4) method from Edwards and Storkey [16] as well as a model simply fine-tuned on the desired task (*BERT (fine-tuned)* in Fig. 4). For AC, an adversarial layer is learned on top of representation layers to predict the undesirable task. The gradient is then flipped to destroy undesirable information in the representation layer. Notably, MLAC with $K = 0$ and with no calibration is equivalent to adversarial censoring. We use a BERT-tiny model as our FM to save on compute costs [14, 54] and use a linear classifier head for the tasks. Note that, as mentioned in Sec. 3.2, we focus on making sure that the professions task is unimpeded, so we directly train on cross-entropy loss as $\mathcal{L}_g$ during MLAC pre-training. For all models, the final achieved performance is retained for the desired professions task (see below and Figure 5).

4.4 Results.

Fig. 4 shows that MLAC returns nearly identical-to-random harmful task performance at all data regimes. Conversely, adversarial censoring (the equivalent of MLAC without calibration and $K = 0$) does not appear to have any effect on post-fine-tuning harmful task performance. Fig. 6 shows the vital role played by the depth of the inner training loop of MLAC, suggesting that *a meta-learning process is genuinely necessary to impede harmful task performance.* To ensure that desired task performance is retained, we evaluate the blocked model on the desired task of profession classification, comparing with fine-tuning a pretrained BERT-tiny model and a random model. Fig. 5 shows the result; MLAC is clearly able to solve the task effectively, surpassing the few-shot performance of BERT-tiny.[8] Finally, we find that head re-calibration may mildly improve blocking on average when pooled across all inner-loop step configurations (Fig. 7).

5 ETHICAL CONSIDERATIONS AND LIMITATIONS

Before we conclude, we point out several other considerations and limitations.

First, while the goal of our approach is to make models safer overall, we recognize that value judgements will be made in deciding which tasks to block. Sometimes these judgement decisions can themselves encode biases and it requires an approach that takes into account a range of perspectives. Nonetheless, we argue that considering potential harmful dual-uses is an essential part of any

[8] Recall again that we use the desired task loss to counter-balance the task blocking mechanism, so this is expected. We do however use separate held-out subsets of data for final desired-task tuning and evaluation. As mentioned previously, our goal for the purposes of this initial exploration is to determine whether desired task performance can be retained while blocking a harmful task. Future work should examine generalization for retaining desired task adaptation performance across many desired tasks.

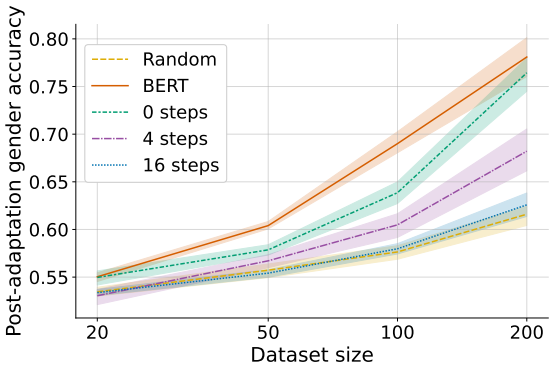

Figure 6: Evaluation of various inner loop depths during MLAC training. Just 16 steps enables near-random performance, even though the adversary performs up to 1000 steps during fine-tuning.

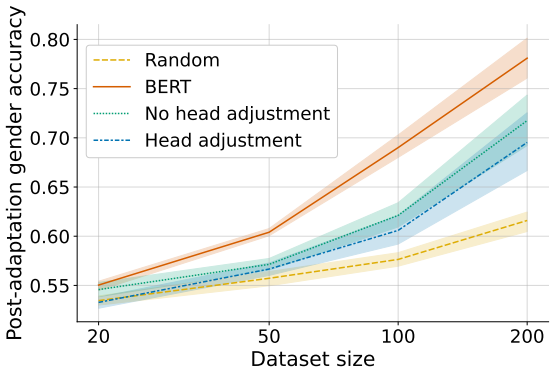

Figure 7: Ablating optimal adversary prediction calibration (or *head adjustment*) during MLAC training. Using optimally calibrated adversary predictions (modifying line 7 of Alg. 1) modestly improves blocking. Aggregated over 0, 4, and 16 steps.

modern model release process. Current standard licenses for foundation models already contain a list of restricted tasks [18, 53], but self-destructing models encode this directly into their optimization objective as well.

Second, it is necessary to collect data for harmful tasks to effectively block them. While this draws a direct parallel to security research, red-teaming, and white-hat hacking, there may be risks in aggregating this data. And there may be impacts on the well-being of potential annotators and security research members [35]. Sufficient precautions should be taken to mitigate these harms.

Third, there may be a risk of over-confidence in the self-destructing mechanism. While this paradigm adds a new tool to the safety toolkit, it does not completely prevent manipulation for every harmful task. And just like any other safety tool there will likely be a back-and-forth where adversaries learn to overcome some techniques. As such, self-destructing models can be combined with other safety mechanisms—structural or technical—to increase the costs of harmful dual-uses.

Fourth, our experiments demonstrate the functionality of self-destructing models in a constrained setting, but further work is needed to scale these approaches to more tasks, larger models, and more complicated settings. We believe this is an exciting new research direction, but requires more work to deploy at scale.

6 RELATED WORK

A number of researchers have sought to address dual use risks by restricting points of control [7, 8, 21, 49, 52, 65], despite there also being substantial benefits to open access [6, 62]. We aim to provide an alternative that allows for open access while still hindering bad actors.

Some work on AI safety has sought mechanisms to prevent agents from learning degenerate behaviors. Orseau and Armstrong [39], for example, seek to prevent a particular scenario where an agent learns to disable its off-switch so that it continues to collect reward. We on the other hand focus on preventing a different, broader, set of harmful behaviors: adaptation of pretrained models to harmful tasks.

Closely related to our work are methods for de-biasing, editing, or removing harmful content from models. Like domain invariance approaches [22, 31, 60, 63], Edwards and Storkey [16] use an adversarial approach to remove information from representations. Ravfogel et al. [46] and Ravfogel et al. [47] take a similar approach and find a projection on the final output layer of a pretrained model that removes gender-based biases from the model (and prevent recovery of those biases after that projection layer). Pryzant et al. [43] similarly use adversarial methods to remove confounds from representations. Others have created model editing techniques to remove outdated or harmful content from pretrained models [11, 36, 37, 50]. While these other methods generally optimize for the information to be removed from the original model, we optimize for poor performance even *after* adaptation of the original model to a harmful task. This can be accomplished via a meta-learning approach.

In the context of meta-learning, MAML [19] and related algorithms [20, 30, 33, 42, 64] have shown that the desired *post*-fine tuning behavior of a neural network can be effectively encoded in its *pre*-fine tuning network initialization. While existing works have leveraged this ability in order to enable more rapid learning of new tasks, our work encodes a blocking mechanism into a network's initialization that *prevents* effective adaptation on harmful tasks.

Finally, some scholars have tuned models to be safer by using reinforcement learning from human feedback and other approaches for incorporating human preferences, including Bai et al. [3], Korbak et al. [29], Ouyang et al. [40], and others.

7 CONCLUSION

This work is only a first step in raising the cost for harmful dual uses of pretrained models through task blocking. Future work might expand this study in at least four directions: *scaling* the self-destructing model framework to larger FMs; studying *generalization* of the learned blocking behavior to new (but related) datasets other than the one used during MLAC meta-training; training/evaluating with *stronger adversaries* that incorporate adaptation methods such as prefix tuning [32], adapter layers [26], or others;

and evaluating the preservation of desired task *fine-tunability* for out-of-distribution tasks. Future work might also introduce concealed architectural changes that hide self-destruct triggers in the network but are more robust to adversarial mechanisms. We hope self-destructing models can become one tool enabling model developers to share their artifacts while minimizing dual use risks.

ABSTRACT

When bias mitigation methods are applied to make fairer machine learning models in fairness-related classification settings, there is an assumption that the disadvantaged group should be better off than if no mitigation method was applied. However, this is a potentially dangerous assumption because a "fair" model outcome does not automatically imply a positive impact for a disadvantaged individual—they could still be negatively impacted. Modeling and accounting for those impacts is key to ensure that mitigated models are not unintentionally harming individuals; we investigate if mitigated models can still negatively impact disadvantaged individuals and what conditions affect those impacts in a loan repayment example. Our results show that most mitigated models negatively impact disadvantaged group members in comparison to the unmitigated models. The domain-dependent impacts of model outcomes should help drive future bias mitigation method development.

1 INTRODUCTION

The issue of algorithmic decision-making systems making harmful or discriminatory predictions is well-recognized (e.g., [7, 10, 15, 21, 28, 30, 31, 36, 37, 39, 40]). Algorithmic fairness research evolved in response to this, primarily focusing on optimizing for some fairness notion to prevent harm. Bias mitigation methods have been developed for different points along the Machine Learning (ML) pipeline and fairness constraints have operationalized fairness notions which are often dependent on conditional probabilities relating to model outcomes (e.g., [1, 2, 8, 9, 14, 17, 18, 41]). However, there is little consensus on when to use which bias mitigation method or constraint [11, 12, 15, 27].

Recent research has shown that "fair" outcomes and benefits for individuals are not always aligned, highlighting that algorithmic fairness sometimes falls short of its main goal of minimizing harm [13, 20, 25, 26, 35]. We call a model that has a bias mitigation method applied to it a mitigated model. Fairness disparity metrics measured after model training show how well a model satisfies a fairness constraint (e.g., Equality of Opportunity) that represents a fairness goal (e.g., groups should have equal true positive rates). Fairness constraints can aid in bias detection (with fairness metric disparities) and bias mitigation by constraining a model's training to satisfy a fairness goal. Sometimes fairness constraints, when used for bias mitigation, make an assumption that the positive class is beneficial. However, if that assumption is not valid, then applying the bias mitigation methods can result in fairer outcomes but worse potential impacts for individuals, especially for disadvantaged groups.

For instance, in the case of loan repayment, let us assume a bank developed a mitigated model that predicts an applicant's ability to repay the bank if given a loan. If the fairness constraint, Demographic Parity (DP), is used, then the selection rates (positive class rates) across the groups should be equal. This could result in a high false positive rate for the disadvantaged group. If an individual is falsely classified and expected to repay but defaults, because the DP constraint assumed a positive outcome was beneficial for them, then that positive outcome in fact had a negative impact on them. The example emphasizes our motivating problem that while fairness disparities for a mitigated model might be low, the individuals classified could still be negatively impacted which is a major issue.

Previous works began investigating how to quantify impact and what its relationship with fair decision-making is [13, 20, 24–26]. These works considered models such as a temporary labor market model [20], threshold optimization [26], causal models [24], agent-simulations [13], and multi-armed bandits [25]. They did not

consider a model in a classic binary classification setting though. Since many bias mitigation methods that constrain model learning with fairness constraints apply to classification settings, these works could not consider how different mitigation methods could have affected their results. When fairness constraints were used in previous works, only one or two fairness constraints were considered. They also did not consider how the datasets themselves could have played a role in their impact results; for instance, what if the disadvantaged group was not in the minority?

In this paper, we investigate the question: when a false positive model outcome may have a negative impact, can mitigated models in a binary classification setting do more harm than good for the disadvantaged group? We explore this question through a case study of the loan repayment example aforementioned. We focus on the disadvantaged group because we aim to minimize negative impacts that that group experiences from supposedly "fair" models, while also considering the effect on the advantaged group. Our objectives that support us in answering our research question are: (1) quantifying the impact of different model outcomes, allowing us to explore specific cases where a positive outcome does not necessarily imply a positive impact, and (2) analyzing how different fairness constraints and dataset makeup relate to the impacts by group. We use DP and four other fairness constraints with several off-the-shelf ML models with different bias mitigation methods to apply the constraints to better understand the relationship between fairness constraint choice and impact.

In addition, we explore the effect of the dataset makeup on impacts too, motivated by this question: if we adjust the demographic group representation and increase the number of disadvantaged applicants who repay the bank, do we see a positive impact on the disadvantaged group? To begin to answer this in our experiments, we use synthetic datasets alongside a real-world dataset for comparison. We vary the synthetic datasets with two parameters: demographic group representation, which shows what data proportions are made up of disadvantaged and advantaged individuals, and repayment label composition by group, which shows if an individual repays or defaults if given a loan[1]—when we discuss dataset composition, we refer to these parameters.

Our results highlight that achieving good fairness disparity metric values and low negative impact results for the disadvantaged group are often in conflict with one another. As a result, the majority of the mitigated models tested actually leave the disadvantaged group worse off than the unmitigated models from an impact stand point. Also, the dataset composition did not have much of an effect on the impact results. The rest of the paper is structured as follows: the literature review in Section 2, the definitions in Section 3, the methodology for our work in Section 4, the experimental setup in Section 5, the results in Section 6, a discussion of the results in Section 7, and our conclusion in Section 8.

2 LITERATURE REVIEW

Our research is about algorithmic fairness in classification settings and impact considerations. The algorithmic fairness community has presented multiple fairness constraints for bias detection such as Equality of Opportunity (EOO) and Equalized Odds (EO) (e.g., [2, 9, 14, 18, 41]) and bias mitigation methods for mitigating unfairness at different stages along the ML pipeline (e.g., [1, 2, 8, 14, 17, 18, 22, 23, 28]). These methods were developed to answer a call for more safe and trusted algorithms, after algorithmic harms were highlighted in multiple domains from online ad delivery to hiring (e.g., [4, 6, 7, 31, 37]). The choice of bias mitigation methods and fairness constraints should be informed by the domain [16, 27].

While aiming to make ML models more "fair" is a valuable goal, scholars argue that we must look at the actual impacts from model outcomes to understand whether individuals were positively affected by the model and begin to explore how to quantify impact in different settings from labor market models to multi-armed bandits [13, 20, 24–26]. We describe the most relevant work to our's from this strand of research—Liu *et al.* coined the term "delayed impact" and conducted experiments using the loan repayment example to see if disadvantaged groups are better off in terms of delayed impact when optimizing for thresholds under fairness constraints [26]. We extend this work with the same example but instead of focusing on class probabilities, we focus on class labels. We also take this research further by using multiple ML models with bias mitigation methods to apply more fairness constraints than previously considered, by using synthetic datasets of varying compositions to test how that affects the impact results, and by modeling impact in different ways than before.

While some researchers generate data to make their data discrimination free or more fair from a causal lens [38, 43, 44], we generate synthetic datasets, not with a de-biasing goal, but to represent different dataset compositions from which models can learn and we can study their effects on impact. Friedler *et al.* conducted a comparative study of bias mitigation methods and found that these methods were sensitive to feature distributions in datasets [16], providing motivation for our consideration of dataset composition since we also use different mitigation methods. Zafar creates synthetic datasets with varying correlations between the sensitive feature and the label to analyze the relationship between the accuracy and discrimination [45]. Reddy *et al.* test numerous models with various synthetic dataset configurations to analyze the models' fairness performances [33]. Similarly to Reddy *et al.* and Zafar, we control demographic group representation and repayment label composition in our synthetic datasets. We do this to better understand the relationship between dataset composition and impacts from different mitigated models.

3 PRELIMINARIES

In this section, we outline the formalizations we use for our experiments and explain what we mean by impact.

3.1 Definitions

In our paper, we consider a binary supervised learning setting. A **dataset** is $D = \{(x_1, y_1), \ldots, (x_n, y_n)\}$, where $x_i \in X$ is an **instance**, $y_i \in \{0, 1\}$ is the **true label** of x_i, and n is the **number of samples in** X. D is split into two subsets, $D_{train} \subset D$ and $D_{test} \subset D$, such that $(D_{train} \cup D_{test}) = D$ and $(D_{train} \cap D_{test}) = \{\}$. To train a classifier model, the instances must undergo feature encoding where information is extracted from each instance into features

[1]The repayment label is what the model is trying to learn from the data.

that are categorical and/or numerical; each instance $x \in X$ is a k-dimensional **feature** vector $\langle f_1^x, \ldots, f_k^x \rangle$.

We are interested in problems where instances will contain, directly or indirectly, personal information about individuals. One such feature that we assume is in X is a **protected attribute** which is sensitive in nature (e.g., race or gender) [34, 42]. This attribute can be strongly associated with other features. The actual constructs that are considered a protective attribute depend on the domain and legal context. For any instance, $x = \langle f_1^x, \ldots, f_k^x \rangle$, we assume the first feature, f_1^x, is the protected attribute which can have values of $f_1^x \in \{0, 1\}$, where 0 represents a disadvantaged group and 1 represents an advantaged group.[2] We assume the disadvantaged group is underprivileged (often due to systemic power structures, inequity, and oppression) in comparison to the advantaged group which is privileged.

The protected attribute allows us to split instances into two groups (D_0 and D_1), where the subindex denotes the value of the protected attribute (e.g. $D_i = \{(\langle f_1^x, \ldots, f_k^x \rangle, y) | (\langle f_1^x, \ldots, f_k^x \rangle, y) \in D$ and $f_1^x = i\}$.) In addition, instances can also be split according to their label into D^1 and D^0, where the superindex denotes the value of the label (e.g. $D^i = \{(\langle f_1^x, \ldots, f_k^x \rangle, y) | (\langle f_1^x, \ldots, f_k^x \rangle, y) \in D$ and $y = i\}$.) Finally, the set D_j^i denotes the set of instances where the label takes value i and the protected attribute takes value j.

We define a **deterministic classifier** as a function, $h : X \longrightarrow \hat{Y}$, where $\hat{Y} = \{0, 1\}$. For any instance of x, $h(x)$ is the prediction returned from the classifier. The function h approximates a true function, representing the population, $t : X \longrightarrow Y$, where $Y = \{0, 1\}$ and for any instance x, $t(x)$ is the true label of x. We denote the prediction of a particular instance of x as $h(x) = \hat{y}_x$ and we denote the true label of a particular instance x as $t(x) = y_x$. The conditional probability that h, outputs a given prediction, $\hat{y}$, given a protected attribute, a, is denoted as $P(\hat{y}|a)$ where $\hat{y} \in \{0, 1\}$ and $a \in \{0, 1\}$. To analyze a classifier's performance, confusion matrices which show model outcomes are commonly used. The model outcomes are the True Positives (TP), False Positives (FP or Type I Error), True Negatives (TN), and False Negatives (FN or Type II Error), when looking at the predicted and true labels. Many fairness constraints can also be explained by TP, FP, TN, and FN [29].

3.2 Impact

We argue it is crucial to consider different ways that impact might relate to model outcomes.[3] If impact is not considered, then mitigated models could actually cause more harm to disadvantaged groups under certain conditions. The loan repayment example from before highlights this problem: where a fair outcome based on a DP-constrained model resulted in a FP applicant who was negatively impacted because they defaulted, since they were unable to repay the bank. There is a tension between benefits of certain model outcomes, like being granted a loan as a FP, and the actual impacts they have on individuals, defaulting on said loan.

In this paper, we assume that a classifier h's impact is a function of instances dependent on model predictions and true labels that outputs weights, i_h: $X \rightarrow W$, such that for any instance x, the weight w, returned by $i_h(x)$ depends on $\hat{y}_x$ and y_x and $w \in \mathbb{R}$.[4] The weight represents the impact of a model outcome for a given instance and can be deterministically or non-deterministically generated (according to some distribution like a Normal distribution). We note here, though, that when i_h provides non-deterministically generated weights as outputs we take liberties with the function, since a function must map every input value to a single output value. But, in this case, the same input could have different valued outputs because the output is dependent on the distribution. We define impact more specifically for our loan repayment example below in Section 5.4.

4 METHOD

We return to our research question: assuming that a false positive model outcome does not have a positive impact, can mitigated models negatively impact the disadvantaged group rather than positively impact them? We explore this question in a binary classification setting with a loan repayment example. The main objectives of this paper are to quantify the impact of model outcomes in different ways and to analyze the relationships between impact and dataset composition and impact and fairness constraints. To do this, we perform experiments, controlling for different variables like the datasets and their compositions, bias mitigation methods, fairness constraints, ML model choice, and impact functions to help us study impact. We provide a visualization of our experimental pipeline from a high level in Figure 1 and explain details more below.

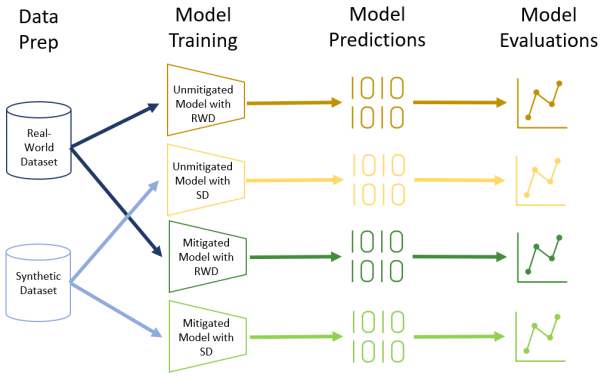

Figure 1: Our experimental pipeline follows a typical ML pipeline. We show how a real-world dataset (RWD) and one of our synthetic datasets (SD) would be pushed through the pipeline. For each dataset, we train an unmitigated model and multiple mitigated models (we only visualize one mitigated model here for simplicity purposes). The top two models are unmitigated models and the bottom two are mitigated models which would have a bias mitigation method applied with a chosen fairness constraint. Multiple runs would need to happen to go through all the different combinations of ML models, fairness constraints, and bias mitigation methods.

[2]Note our work can easily be extended to consider more than two labels for the protected attribute.

[3]We highlight that another way to think about impact is expected utility.

[4]Since we assume weights are real numbers, categorical weights can also be considered if transformed into numbers.

As mentioned before, we use multiple datasets so they are all funnelled through this pipeline multiple times to account for different ML model and bias mitigation method choices. For a real-world dataset, we transform the FICO scores dataset from over 300k TransUnion TransRisk scores from 2003 that was preprocessed by Hardt *et al.* into a tabular loan repayment dataset where each row corresponds to an individual loan applicant [18]. The FICO scores dataset as is contains a cumulative distribution function (CDF) providing the fraction of the racial group that falls below a given credit score and a probability mass function (PMF) showing the probability of an applicant repaying the bank given their race and credit score. We are interested in a tabular dataset so we can apply common bias mitigation methods with fairness constraints to study how they affect impact. We also assemble synthetic datasets with different demographic group representations and repayment label compositions; experiments with these synthetic datasets allow us to understand how the dataset composition affects the impact on different groups.

With a dataset for each experimental run, we then train off-the-shelf ML models that are mitigated during training using different reduction algorithms, our bias mitigation method of choice, that can use different fairness constraints each time (see Section 5.2 for details). By using reduction algorithms, we could simply change the constraint to be used for each experiment in an agnostic way. For each mitigated model, we run one reduction algorithm paired with one fairness constraint until we complete every combination. Models with no bias mitigation method applied during training we call unmitigated models. We train these mitigated and unmitigated models on the loan repayment dataset and the synthetic datasets.

After receiving the mitigated and unmitigated model predictions for all of our experiment runs, we evaluate the models. To do so, we calculate their model accuracy, fairness disparity metric, and impact results. We check the model performance and bias because we aim to develop well-performing and fair models. The fairness disparity metric results show us whether the mitigated model performs as well as the unmitigated model, how effective the bias mitigation method is at satisfying a fairness constraint, and whether the application of a particular mitigation method and constraint negatively impacts the disadvantaged group.

5 EXPERIMENTAL SETUP

In this section, we present the fairness constraints, ML models, bias mitigation methods, datasets, and impact functions that we use. We assume a white-box scenario where we have access to data, models, and model outputs. Recall that we consider a binary classification problem where a model predicts if a loan applicant will repay the bank if given a loan.

5.1 Fairness Constraints

We focus on group fairness which aims to identify what groups are at risk of being harmed [14]. Group fairness is defined in terms of constraints on a model called fairness constraints or parity constraints (we will use the former term). We explain the group fairness constraints considered for our experiments in Table 1 and refer to them primarily by the acronyms stated there.[5] These metrics were chosen because of their canonical nature within the algorithmic fairness domain and their availability in open-source fairness toolkits and libraries [3, 5]. Also, expert knowledge is not required to use them. All of our metrics are Bias Preserving which has an underlying assumption that the status quo is the baseline for equality across groups except for one which is Bias Transforming, DP, which assumes that protected groups, from an equality standpoint, start at different points [42]. To measure the level of fairness in a model, we take the fairness disparity metric value, telling us how well the model abides by a given fairness constraint.

5.2 ML Models and Reduction Algorithms

We utilize off-the-shelf ML models from *sklearn* to make our experiments easily replicable [32]. In our experiments, we use the following models: Decision Tree (DT), Gaussian Naive Bayes (GNB), Logistic Regression (LGR), and Gradient Boosted Trees (GBT) classifiers. We also chose these models because their fit functions had a sample weights parameter—this parameter is necessary for the reduction algorithms in *Fairlearn* [5]. For ML model performance, we consider accuracy as our metric of choice which is common to consider in the algorithmic fairness literature.

Microsoft's *Fairlearn* toolkit implements Agarwal *et al.*'s bias mitigation method which includes two reduction algorithms, Exponentiated Gradient and Grid Search; we use this mitigation method in our experiments. The reduction algorithms take the parameters: an already trained ML model and a fairness constraint, and then narrow the binary classification to weighted classification problems that focus on achieving strong performing models for certain classes. The algorithms' goal is to optimize the trade-off between the chosen fairness constraint and the model's accuracy. In the reduction algorithm, the fairness constraints are transformed into Lagrange multipliers. We encourage the reader to read Agarwal *et al.*'s paper for a more in-depth understanding of the reduction algorithms [1]. Reduction algorithms are versatile because they allow developers the choice in their ML model, unlike other fairness methods applied during training which are often model-specific.

5.3 Datasets

In our experiments, we have a dataset which represents the real-world and then we have eight synthetic datasets that represent different potential scenarios. For model training, we split each of the datasets into 70% train and 30% test sets. For testing the synthetic datasets, we use two different test sets. The first test set is the test set created when we split the synthetic dataset. The second test set matches the real-world dataset's composition. This real-world test set allows us to test how well the model trained on a synthetic dataset performs on a subset of the real-world's population.

5.3.1 Baseline Dataset. We transformed the FICO scores dataset from 2003 preprocessed by Hardt *et al.* into a tabular dataset that can be used in a binary classification setting which we call our

[5]Note that some metrics have different names in the literature so we try to clear up any confusion: DP is sometimes called Statistical Parity and Acceptance Rate. EO in previous literature is referred to as Disparate Mistreatment. EOO has a mathematical equivalent metric in False Negative Error Rate balance [9]. False Positive Rate Parity (FPRP) or False Positive Error Rate balance is also sometimes referred to as Predictive Equality and is linked to the True Negative Rate.

Table 1: The fairness constraints we consider in our experiments are listed and defined, where $y \in \{0, 1\}$.

Name	Expression
Demographic Parity (DP) [14]	$P(\hat{Y} = 1\|A = 0) = P(\hat{Y} = 1\|A = 1)$
Equalized Odds (EO) [18]	$P(\hat{Y} = 1\|Y = y, A = 0) = P(\hat{Y} = 1\|Y = y, A = 1)$
Equality of Opportunity (EOO) [18]	$P(\hat{Y} = 1\|Y = 1, A = 0) = P(\hat{Y} = 1\|Y = 1, A = 1)$
False Positive Rate Parity (FPRP) [9]	$P(\hat{Y} = 1\|Y = 0, A = 0) = P(\hat{Y} = 1\|Y = 0, A = 1)$
Error Rate Parity (ERP) [2]	$P(\hat{Y} = y\|Y \neq y, A = 0) = P(\hat{Y} = y\|Y \neq y, A = 1)$

baseline dataset [18]. The data is composed of FICO scores (for showing credit worthiness). We note that Liu *et al.* also used the same dataset for their impact experiments [26]. The credit scores ranged from 300 to 850 and the authors assumed the Black group as disadvantaged and the White group as advantaged.

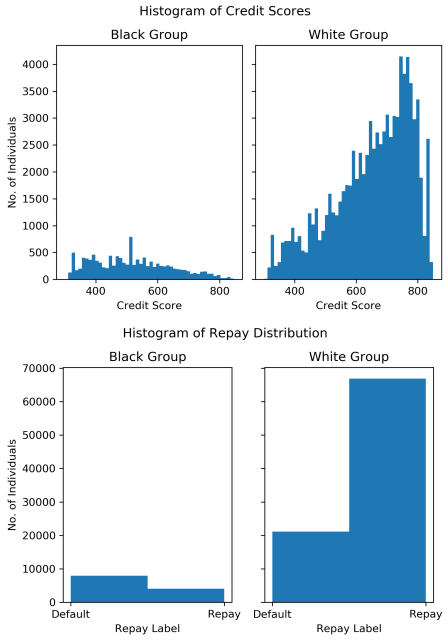

Figure 2: We show the baseline dataset composition for the credit scores and repayment labels by group.

For our baseline dataset, we generated 100k rows or 100k individuals based upon Liu *et al.*'s dataset composition such that the same demographic group representation, credit score distributions by race based on the CDF, and repayment label distributions based on the PMF are upheld. Our rationale behind that dataset composition is that it matches the real-world dataset. Each row or individual has two features: credit score and race which make up X. The dataset also contains labels, Y, for whether the loan could be repaid by the individual.[6] Our baseline dataset labels are generated from the PMFs for an individual repaying given their credit score. For visualizations of the dataset concerning the credit scores and repayment labels by group, see Figure 2. We use one algorithm to create our baseline dataset, similar to Liu *et al.*'s method [26]. The Algorithm 1 (see Appendix A.3) generates a dataset based on two parameters, demographic group representation and order of magnitude (for the dataset size), by using the CDF and PMF.

5.3.2 Synthetic Datasets. Since the baseline dataset is imbalanced considering the demographic group representation (12% Black and 88% White) and the disadvantaged group's repayment label composition (see the bottom left plot of Figure 2), we change those parameters when generating synthetic datasets. These synthetic datasets let us test how impact is affected by varying dataset compositions. We consider cases when the disadvantaged group is the majority, in the minority (matching the baseline dataset), and when the two groups have equal representation. We keep the credit score distributions the same and adjust the disadvantaged group's repayment label composition for only some runs so we can see the effect of the altered demographic distributions. In addition, by adjusting the disadvantaged group's repayment label composition, we oversample for instances where the disadvantaged group repays the bank so the models learn from a more balanced dataset. We do not adjust the advantaged group's repayment labels since we are primarily focused on minimizing harm to the disadvantaged group.

We use the following two ratios to generate synthetic datasets and Table 2 shows the ratios we have for all our datasets—the baseline dataset is included there as well. To generate these datasets, we extend Algorithm 1 to adjust the repayment label ratios for the disadvantaged group through Algorithm 2 and 3 in Appendix A.3.

Definition 5.1. The **demographic-ratio** is $R = r_0 : r_1$ such that $r_0 = |D_0|/|D|$ and $r_1 = |D_1|/|D|$.

Definition 5.2. The **label-ratio** is $L_a = |D_a^0| : |D_a^1|$ such that $|D_a^0|$ is the number of negative instances for a group $a \in 0, 1$ and $|D_a^1|$ is the number of positive instances for that same group.

Each scenario in Table 2 is categorized with a two-letter code such that the first letter represents the demographic-ratio and the second letter represents the disadvantaged group's label-ratio. A "0" means the ratio matches the baseline dataset, "i" means the ratio is imbalanced (not the same imbalanced ratio as the baseline however), and "b" means the ratio is balanced.[7] The "00" scenario represents the baseline dataset; while, as another example, the disadvantaged group is in the majority and the disadvantaged group's repayment label-ratio match the baseline's label-ratio in the "i0" scenario.

[6]For more information about how we transformed the initial FICO score dataset into a tabular dataset, see the GitHub: https://github.com/mjorgen1/explore-fair-impacts.

[7]The baseline dataset ratios are imbalanced as well but we did not force them to be.

Table 2: The dataset names and parameters used as constraints when generating the datasets for our experiements. Note that we only specify the disadvantaged group's label-ratio here, not the advantaged group's label-ratio which remains unchanged.

Dataset Name [Label]	Demographic-Ratio	Disadvantaged-Label-Ratio
Baseline [00]	0.12 : 0.88	0.66 : 0.34
Demo-Bal-Repay-Baseline [b0]	0.5 : 0.5	0.66 : 0.34
Demo-Imbal-Repay-Baseline [i0]	0.88 : 0.12	0.66 : 0.34
Demo-Baseline-Repay-Bal [0b]	0.12 : 0.88	0.5 : 0.5
Demo-Bal-Repay-Bal [bb]	0.5 : 0.5	0.5 : 0.5
Demo-Imbal-Repay-Bal [ib]	0.88 : 0.12	0.5 : 0.5
Demo-Baseline-Repay-Imbal [0i]	0.12 : 0.88	0.34 : 0.66
Demo-Bal-Repay-Imbal [bi]	0.5 : 0.5	0.34 : 0.66
Demo-Imbal-Repay-Imbal [ii]	0.88 : 0.12	0.34 : 0.66

5.4 Impact and Credit Scores

In our example, we assume that TPs and FPs are granted loans. The applicants who were classified as TNs or FNs would most likely no longer be followed up with by the bank after the rejection notification, so data on the actual impacts of those model outcomes are not available. As a result of this, we focus on the impact of the TP and FP model outcomes. We note that different model errors can lead to different impacts [19].

We take inspiration from Liu *et al.*'s focus on predatory lending for our impact measurement [26]. The credit score of applicants is a key feature in our example. We assume that the change in credit score is related to the model outcome so we use that feature in our impact calculations. For any instance, $x = \langle f_1^x, \ldots, f_k^x \rangle$, we assume that the second feature, $f_2^x \in [300, 850]$, is the credit score for an applicant. We define a set $S = \{f_2^x\}$, where s_i holds the credit score for applicant x_i.

5.4.1 Deterministically Generated Weights. The deterministically generated weights reflect the credit score change values used in Liu *et al.*'s experiments such that the weight, $w = \{75, -150\}$, depends on if an applicant is a TP or FP respectively [26]. If a sample, x_i, is a TP, meaning the applicant is correctly predicted to repay the bank, then the s_i is increased by 75 points; if that applicant is deemed an FP, meaning they are incorrectly predicted to repay the bank, then the s_i is decreased by -150 points. For all of our datasets, we use these weights when calculating credit score changes.

Table 3: The mean, μ, and standard deviation, σ, values for generating the non-deterministically generated weights from Normal probability distributions.

Name	μ_{TP}	σ_{TP}	μ_{FP}	σ_{FP}
Benchmark	75	15	-150	15
Equal	100	15	-100	15
Benchmark-Swap	150	15	-75	15

5.4.2 Non-Deterministically Generated Weights. We also conduct experiments with the baseline dataset using non-deterministically generated weights for the impact function. We generate these weights for w through a Normal probability distribution (see Table 3). We use the deterministically generated weights as means for the Benchmark distributions for comparison purposes. We also consider two other scenarios where FP and TP model outcomes have opposite but equal valued effects, the Equal distributions, and where the TP is weighed even more heavily than a FP, the Benchmark-Swap distributions. The standard deviations were chosen by taking into account the empirical rule for Normal distributions and the limit of the credit score range since we wanted updated credit scores to abide by their constraints. We argue that using non-deterministically generated weights is a potentially better modeling of reality since the applicants' credit scores could drop or increase at different scales.

5.4.3 Measuring Average Impact. Now that we have defined our weight generation, we define average impact for this problem as the difference in credit scores after the predictions, $\hat{Y}$. We calculate the average impact by group for all of our experiments.

Definition 5.3. Classifier h's **average impact** on group a is:

$$\bar{I}_a = \frac{1}{|D_a|} \cdot \sum_{i \in D_a} s_i + w$$

6 RESULTS

We present our results below and remind the reader that the mitigated models are those that had a reduction algorithm with a fairness constraint applied. When providing the fairness disparity metric values for the unmitigated and mitigated models, we show all four ML model results. When we present impact results, these are calculated by taking the average impact by group which we define in Section 5.4. For the impact findings, we only ran experiments with a Decision Tree (DT) model. We chose the DT model because it generated more stable results than a Gaussian Naive Bayes (GNB) model and produced comparable results to Logistic Regression (LGR) and Gradient Boosted Trees (GBT) models when trained on our datasets (see Table 4 and 5, and Table 6 in the Appendix A.2). The demographic groups are differentiated by the labels: disadvantaged, Black, or "0" and advantaged, White, or "1."

6.1 Baseline Dataset Results

First, we analyze how unfair the unmitigated models are when trained on the baseline dataset and check how well the bias mitigation methods minimized that unfairness in the mitigated models. Table 4 displays the fairness disparity metric values for the unmitigated models and Table 5 shows how well the bias mitigation methods mitigated bias according to the fairness constraints applied. The smaller the fairness disparity metric value, the closer the model satisfies a fairness constraint. If a fairness disparity metric value is 0, a model is satisfying the fairness constraint completely. All mitigated models perform well by reducing the fairness disparity metric for the applied fairness constraint and exhibit similar results. For the model accuracy results, see Table 6 in the Appendix A.2—the unmitigated DT, LGR, and GBT models all reach 88% accuracy and that performance only dropped between 1% and 4% for the mitigated models which shows that even with bias mitigation methods applied the models still perform reasonably well.

Table 4: Values of the fairness disparity metrics for our unmitigated models when trained on the baseline dataset, where the rows are the ML models tested and the columns are the fairness constraints considered.

Classifier	DP	EO	EOO	FPRP	ERP
DT	49.40	23.77	23.77	20.44	4.45
GNB	82.55	96.4	96.4	38.09	21.62
LGR	49.03	22.1	21.38	22.1	3.79
GBT	46.23	18.6	18.6	18.27	4.16

Table 5: Values of the fairness disparity metrics for our mitigated models when trained on the baseline dataset, where the rows are the ML models tested and the columns are the fairness constraints applied with the Exponentiated Gradient reduction algorithm and measured for the disparity metric.

Classifier	DP	EO	EOO	FPRP	ERP
DT	0.45	3.77	1.88	0.34	1.16
GNB	0.85	2.18	1.18	0.29	0.1
LGR	0.83	2.49	0.9	0.59	0.3
GBT	0.65	2.84	1.41	0.05	1.44

We used Exponentiated Gradient for our reduction algorithm of choice for the remainder of our results after comparing the results with Grid Search. Exponentiated Gradient (see Table 5) was more effective than Grid Search (see Table 7 in Appendix A.2) at decreasing the fairness disparity metric values from the unmitigated model fairness disparity metric values (see Table 4). Since we are interested in how different mitigated models impact groups, we chose the reduction algorithm for our experiments that gave stronger fairness results.

Before we can check if our credit score distributions from mitigated models are statistically significant in comparison to the credit score distributions from unmitigated models, we must test if those distributions are Normal. We check if the updated credit score distributions for the baseline dataset with deterministically generated weights are Normal distributions by using the Kolmogorov-Smirnov test. Then, with our not-Normal updated credit score distributions, we use Mann-Whitney tests to look at discrepancies between the updated credit scores and unmitigated versus mitigated models. This analysis tells us if there are statistically significant changes to credit score distributions when using bias mitigation methods.

6.1.1 Impact with Deterministic Weights. By considering the impact for the disadvantaged group (see the top plot of Figure 3), we highlight that, even though we have an improvement in fairness (as shown in Table 4 and 5), the disadvantaged group the majority of the time experiences a negative impact. For all models, the worst impact occurs when DP is the fairness constraint. The few models that positively impact the disadvantaged group are the unmitigated and ERP-constrained models. Besides the ERP-constrained model, none of the mitigated model results could exceed the unmitigated positive impact. The lower plot of Figure 3 shows that the advantaged group always experiences a high positive impact across all mitigated models.

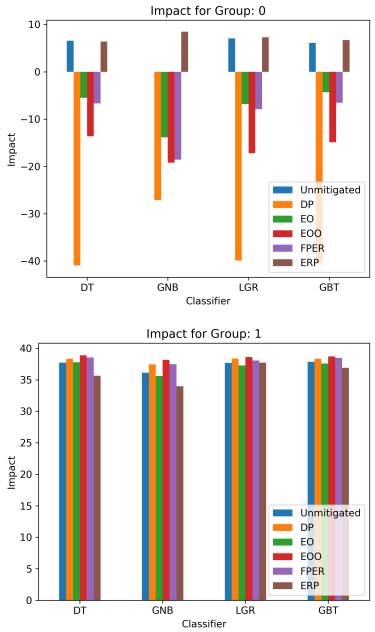

Figure 3: Impact for all classifier and fairness constraints when using the baseline dataset and when weights are deterministically generated.

We examine the statistical significance of how the impact on an individual affects the credit scores by demographic group; we compare the updated credit score distributions from each mitigated model (for all ML models) with the unmitigated model for each group. We update the credit scores based on the model outcomes given the deterministically generated weights. The updated credit score distributions for ERP-constrained models by demographic group are not statistically significant from the unmitigated model

for the disadvantaged group but this is most likely because the results are similar (see Figure 7 in the Appendix A.1). For all models with DP, EO, EOO, and FPRP as the fairness constraint, the change in the score distributions of the disadvantaged group is statistically significant. At the same time, the score distributions from the mitigated models for the advantaged group are not statistically significant, except for the ERP-constrained GNB model.

6.1.2 Impact with Non-deterministic Weights. Figure 4 displays the impact results for our groups with non-deterministically generated weights for impact when using a DT model. When we lessen the weight of an FP applicant and increase it for a TP applicant, the advantaged and disadvantaged groups impact increases, unsurprisingly. However, the DP-constrained model still has the lowest impact in comparison to other constraints for the disadvantaged group for all impact setups with non-deterministic weights.

When we compare the mitigated DT model impact results from Figure 3 with the Benchmark distribution impact results from Figure 4, we see that the results match up such that DP-constrained model has the lowest impact, followed by EOO, FPRP, and EO-constrained models. Similarly, the impact results for the ERP and unmitigated models are aligned. For the advantaged group, the results also are aligned such that the mitigated models do not change the advantaged group's impact much at all. We see the same statistically significant results as discussed in Section 6.1.1 and these results can be found in Figure 8 in the Appendix A.1.

When the TP and FP impacts have equal weight for the Equal distribution (see Figure 4), only the DP- constrained model leads to a negative impact for the disadvantaged group. However, only the ERP-constrained model impact matches the unmitigated model impact for the disadvantaged group while the other four fairness constraints result in a worse impact. We find that the statistically significant results for the disadvantaged group from the Equal distribution match the Benchmark distribution results; the advantaged group results match as before too except for two more significant results from the ERP-constrained DT and EO-constrained GNB models. These results can be seen in Figure 9 in Appendix A.1.

When TPs are weighed twice as heavily as FPs in the Benchmark-Swap distribution (see Figure 4) we see less impact variation amongst the models for the disadvantaged group, with the DP-constrained model as an exception as shown in Figure 10 in Appendix A.1. The statistical significance tests vary more with this setup, except for the disadvantaged group's results for constrained DT, LGR, and GBT models which remain the same and, similar to the Equal distribution results, the EO-constrained GNB model result is significant for the advantaged group. The GNB results are different such that only the ERP and DP results are statistically significant. When ERP constrains all the models, the advantaged group has statistically significant changes to their credit scores.

6.2 Synthetic Dataset Results

We trained an unmitigated DT model and mitigated DT models on our synthetic datasets. For each of our synthetic datasets, we tested the models with two test sets—one that matched the training set for the synthetic dataset and then one that matched the baseline dataset. The latter test set allows us to see how the model trained on

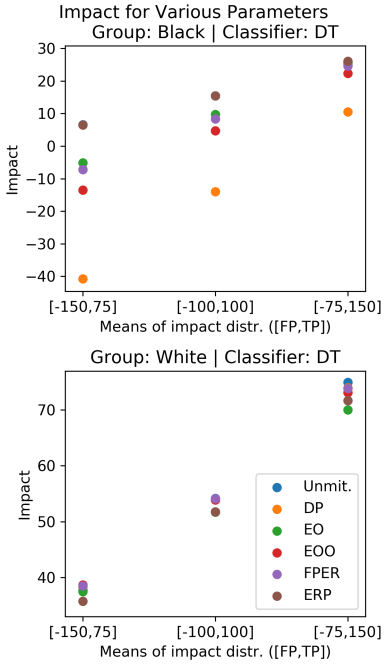

Figure 4: Impact for all fairness constraints for the three non-deterministically generated weight distributions when a DT model was trained on the baseline dataset. Recall that the Benchmark distribution impact results are on the left [-150,75], the Equal distribution impact results are in the middle [-100,100], and the Benchmark-Swap distribution impact results are on the right [-75,100].

synthetic data would work on a test set that matches the real-world. We provide the impact results depending on what test set was used.

No matter what test set was used, the impact of the advantaged group, when having trained models on the synthetic datasets, behaves identically (see bottom plots of Figure 5 and 6). For the rest of this section, we focus on the disadvantaged group's results. For the best impact-performing models for the disadvantaged group, we point to the unmitigated and ERP-constrained models in the top plots of Figures 5 and 6.

As a reminder for our dataset configuration notation (see Section 5.3.2), each scenario is labeled with a two-letter code, where the first letter represents the demographic-ratio and the second letter represents the disadvantaged group's label-ratio. For the values, a "0" says the ratio matches the baseline dataset, "i" says the ratio is imbalanced (but not the same imbalanced ratio as the baseline), and "b" says the ratio is balanced.

6.2.1 Train and Test Sets Have Equal Composition. When increasing the disadvantaged group's representation, we see little effect on the group's impact, see the top plot of Figure 5. When we only change the demographic-ratio and increase it for the disadvantaged group (see scenarios "b0" and "i0" in the top plot of Figure 5), we see an increase in impact for the disadvantaged group (except for the unmitigated and ERP-constrained model results which remain consistent) in comparison to scenario "00" and then all the impact

results converge when the disadvantaged group is in the majority ("i0"). In comparison, in Figure 5, we show that there is less impact variance but the impact improves when the disadvantaged group is more likely to repay (see scenarios "0b," "bb," "ib," "0i," "bi," and "ii") when we compare to the "00" scenario (when they are more likely not to repay the bank).

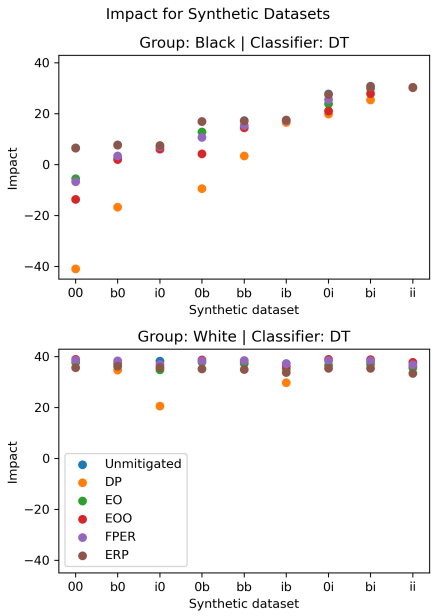

Figure 5: Impact with deterministically generated weights for all synthetic datasets with a test set with equal composition to the training set.

6.2.2 Test Set Matches Baseline Composition. When the disadvantaged group is in the minority (see scenarios "00," "0b," and "0i") in Figure 6, we have the most variance between the impact results. Of the disadvantaged group results in Figure 6, we see the two worst impact results from the DP and EOO-constrained models which align with the worst impact results for the disadvantaged group in Figure 5, when we are not testing with the baseline test set. When increasing the disadvantaged group representation in the synthetic datasets, the impact does increase in comparison to the baseline for EO, EOO, DP, and FPRP-constrained models until it converges (see scenarios "b0," "i0," "bb," "ib," "bi," and "ii") with other model results when the disadvantaged group is in the majority in the top plot of Figure 6. The other two model impact results for the unmitigated and ERP-constrained models show little changes and are consistent as seen in the top plot of Figure 6. Constrastingly to the top plot of Figure 5, where we saw an upward trend for the impact, when we test with the baseline in the top plot of Figure 6, we find the impact stagnating and changing little in comparison to scenario "00."

7 DISCUSSION

Mitigated models can do more harm than good. Our results demonstrate that the bias mitigation methods successfully mitigated unfairness in our loan repayment example. However, the

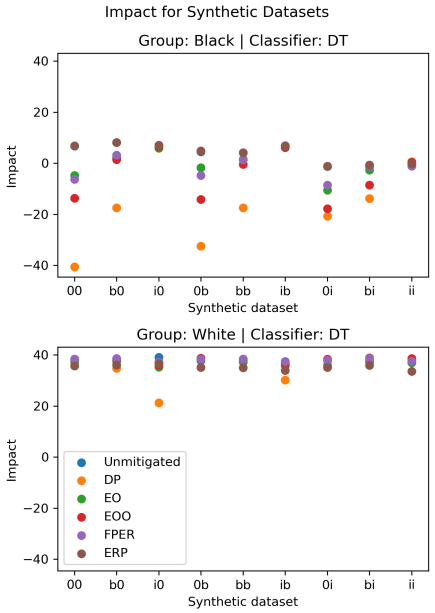

Figure 6: Impact with deterministically generated weights for all synthetic datasets with a test set with the baseline dataset composition.

results also demonstrate a trade-off between optimizing for fairness disparities and impact when choosing a fairness constraint. The problem with this trade-off is that mitigated models sometimes do more harm than unmitigated models and we saw that the disadvantaged group experienced negative impacts the majority of the time when mitigated models were used. We find ERP-constrained and unmitigated models outperforming other models with respect to the disadvantaged group's impact (see top plots of Figure 5 and Figure 6), while the DP-constrained and EOO-constrained models have the lowest impact results.

Balanced datasets may not solve inequalities. Our results also show that the disadvantaged group does not necessarily benefit when a model learns from a synthetic training set that does not match the real-world population's composition. In most cases, they will be treated similarly or worse than if they were being classified by an unmitigated model. When using test sets with the same composition as the training sets, the disadvantaged group tends to see an increase in impacts as they increase their label and demographic-ratios. However, when the test sets match the baseline data (representing the real-world), we see the impacts mostly stagnating or dropping. These results emphasize that imbalanced demographic group and label data should not be assumed to be a problem. We acknowledge though a limitation in our experiments is that the data the models are trained on only includes two features. We leave further impact investigations with datasets that include larger feature sets for future work.

Impact is a key factor not usually accounted for. The weights of the harms and benefits that make up the impact function play a vital role in the impact results and its interpretation. We

argue that impact results can be used to assist practitioners in deciding which fairness constraint to pick. They can decide what the appropriate trade-offs for fairness disparities and impact are (since they can have contradicting best fairness results) when optimizing for their model results. With that said, when impact is a key consideration and certain conditions hold, fairness constraints might not be sufficient. Impact-driven constraints or methods should be developed that consider the weights of different model outcomes and not only the model outcomes like many fairness notions do. Potential future work can also consider how to represent impact when there is not a clear feature (like credit score in our case) that is related to model outcomes.

8 CONCLUSION

In this paper, we assumed that a false positive model outcome has a negative impact and investigated if, in that case, mitigated models benefit the disadvantaged group or further harm them. To explore this, we used the loan repayment example and tested how fairness constraints and dataset composition affect the impacts on demographic groups. Our experiments, in the case of our loan repayment example under certain conditions, showcased that impact was worsened for the disadvantaged group the majority of the time when testing supposedly "fair" models. We highlight though that impact highly depends upon the context. Our key finding is that there is a trade-off between fairness constraints and impact.

We argue that including notions of impact while testing mitigated models before they are deployed is crucial. Testing these models with those impacts can aid practitioners in choosing the fairness constraint that matters most for their use case. Lastly, we emphasize that decreases in fairness disparity metric values in mitigated models do not necessarily equate to decreases in negative impacts on the disadvantaged group.

A EXTENDED REASONING AND RESULTS

A.1 Credit Score Change Statistical Significance Results

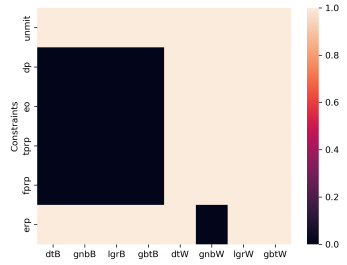

Figure 7: The credit score distribution statistical significance results when using deterministically generated weights.

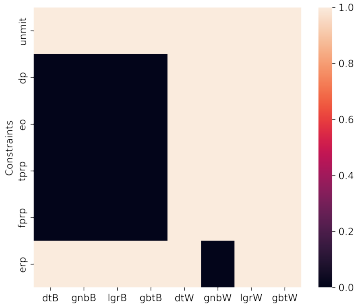

Figure 8: The credit score distribution statistical significance results when using the Benchmark distribution for non-deterministically generated weights.

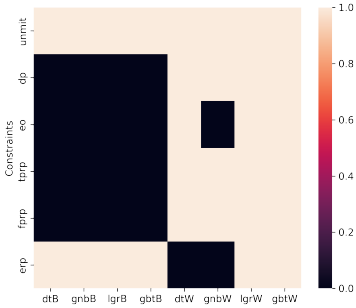

Figure 9: The credit score distribution statistical significance results when using the Equal distribution for non-deterministically generated weights.

We include the statistical significance results for the updated credit score distributions as a result of weights generated for impact from mitigated models in comparison to unmitigated models

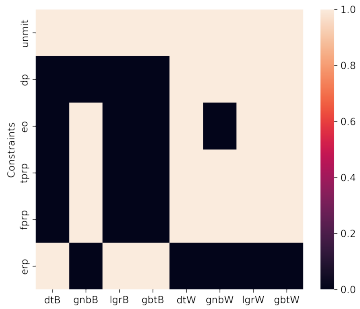

Figure 10: The credit score distribution statistical significance results when using the Benchmark-Swap distribution for non-deterministically generated weights.

("unmit" as referred to in the Figures). In each of the Figures, they showcase the results of the MWU-Tests, which compare credit score distributions from each mitigated model with the unmitigated score distribution for each model and by protected attribute. We note that in the Figures TPRP (True Positive Rate Parity) refers to Equality of Opportunity (EOO). The "B" or "W" added to the ML model acronym on the x-axis represents if it was a Black or White group distribution. The y-axis shows the fairness constraint used. If the field is dark in color, the result of the MWU-test is significant ($p < 0.05$), which means that the credit score distributions tested are significantly different. We give the results for all ML models when we have deterministically generated weights for impact in Figure 7 and when we have non-deterministically generated weights in Figures 8, 9, and 10. Deeper analysis of these results are in the main body of the paper.

A.2 Model Performance and Reduction Algorithm Results

Table 6 shows the model performance of our ML models. The accuracy of the unmitigated model (without any fairness constraint) trained with the GNB classifier is lower than the accuracy of the other three unmitigated models, which all have an accuracy of 88%. The mitigated models all have relatively similar accuracies.

Table 6: Model accuracy (in %) for all classifiers (by row) when trained on the baseline dataset. The column, "Unmit," shows the results of the unmitigated models and the columns to the right of that column specifies the fairness constraints applied to the mitigated models with the Exponentiated Gradient reduction algorithm for those results.

Classifier	Unmit	DP	EO	EOO	FPRP	ERP
DT	88.18	84.66	85.36	86.59	87.41	85.29
GNB	85.67	81.49	83.96	86.24	87.16	84.92
LGR	88.23	84.66	84.54	86.44	87.42	84.95
GBT	88.22	84.70	85.16	86.58	87.45	85.42

In our paper, we chose to use Exponentiated Gradient for our extended experiments with the synthetic datasets as our reduction

Table 7: The values of the fairness disparity metrics for our mitigated models (with Grid Search applied using the fairness constraints along the columns) for all four classifiers (rows) when trained on the baseline dataset.

Classifier	DP	EO	EOO	FPRP	ERP
DT	28.17	22.79	7.46	20.82	5.26
GNB	82.42	44.22	0.63	38.21	1.27
LGR	27.84	24.81	5.53	22.02	5.21
GBT	28.17	21.54	5.9	19.28	5.32

algorithm over the Grid Search algorithm. We present the Grid Search fairness disparity metric results with the baseline dataset to showcase why Exponentiated Gradient was the stronger algorithm for mitigating unfairness. We include Table 7 that covers the fairness disparity results after Grid Search mitigated unfairness in our different ML models. If compared with Table 5, we clearly see that Exponentiated Gradient outperforms Grid Search when dropping the fairness disparity metric values in comparison to the unmitigated model results in Table 4.

A.3 Dataset Generation Algorithms

The algorithms we used for generating our datasets are below. Algorithm 1 generates a tabular dataset from the original loan repayment dataset, depending on demographic ratio and order of magnitude. In the algorithms, when "concat" is used, we refer to the method concatenate which happens by row ("row") or by column ("col") and combines arrays into one array. Algorithm 2 generates the subset of data with the chosen ratios (demographic-ratio and label-ratio) that we vary and Algorithm 3 is the overall sampling loop connecting Algorithm 1 and 2, ensuring that we generate a dataset with the desired ratios and size.

The time complexity and space complexity of our algorithms are $O(n)$, highlighting that as the dataset size increases so does the running time and storage space. In our algorithms, we focus on the generation of one key feature for X, but the algorithms could, potentially, be used to sample more features; also, other features could be generated separately. With these algorithms, we assume we have access to a true label distribution and a feature distribution for a key feature. However, this might not be the case.

Algorithm 1 Create baseline dataset

Require: $f_1(x) \leftarrow P(X \leq x)$ {Cumulative distribution function for items},
$f_2(x) \leftarrow P(X = x)$ {Probability mass function for the label likelihoods},
oom {Order of magnitude for dataset creation},
$(r_0, r_1) \leftarrow R$ {Demographic group ratio},
$choices(items, probabilities, samples_{num})$ {Function for generating samples},
$randint(start, stop)$ {Function for generating random numbers}

$samples\_num_0 \leftarrow oom \times r_0$ {Initialize variables for number of samples by group}
$samples\_num_1 \leftarrow oom \times r_1$
$items_0 \leftarrow f_1.values_0$ {Collect the values from the CDF functions for each group}
$items_1 \leftarrow f_1.values_1$
$probs_0 \leftarrow f_2(items_0)$ {Collect the probabilities from the PMF functions for each group}
$probs_1 \leftarrow f_2(items_1)$
$samples_0 \leftarrow choices(items_0, probs_0, samples\_num_0)$ {Generate the samples for the groups}
$samples_1 \leftarrow choices(items_1, probs_1, samples\_num_1)$
$samples_{disadv} \leftarrow array([0] \times samples\_num_0)$
$samples_{adv} \leftarrow array([1] \times samples\_num_1)$
$D \leftarrow shuffle([concat_{col}[concat_{row}samples_0 \& samples_1]$ {Combine the arrays}
$\&[concat_{row}samples_{disadv} \& samples_{adv}]$ & $[concat_{row}probs_0 \& probs_1]])$
$labels \leftarrow []$, $index \leftarrow 0$ {Initialize array for labels and integer variable for index}
for $index < |D|$ **do**
  $rand\_num \leftarrow randint(0, 1000)/10$ {Initialize a random integer variable}
  if $rand\_num > D[index][2]$ **then**
    $label.append(0)$ {If true, assign negative class label}
  else
    $labels.append(1)$ {Else, assign a positive class label}
  end if
end for
$D \leftarrow concat_{col}[D \& labels]$, $D \leftarrow D.remove_{col}(2)$ {Add labels to D and drop probabilities}
return D

Algorithm 2 Generate subset with defined ratios

Require: D {Whole data set $[x_{group,label} \in D$ denote a sample with a $group, label \in (0, 1)]$},
$|S|$ {Size of our desired synthetic subset $S \subseteq D$}, R, L_0, L_1

for $group \in (0, 1)$ and $label \in (0, 1)$ **do**
  $|S_{group,label}| = d_{group} * l_{group,label} * |S|$ {Compute the number of samples}
end for
for $group \in (0, 1)$ and $label \in (0, 1)$ **do**
  if $|S_{group,label}| < |D_{group,label}|$ **then**
    $|S_{new}| = |D_{group,label}|/(d_{group} * l_{group,label})$ {Adjust the set size}
    for $group \in (0, 1)$ and $label \in (0, 1)$ **do**
      $|S_{group,label}| = d_{group} * l_{group,label} * |S_{new}|$ {Adjust the number of samples}
    end for
  end if
end for
for $group \in (0, 1)$ and $label \in (0, 1)$ **do**
  $S_{group,label} \in S = \{x_{group,label} \in D; |S_{group,label}|\}$ {Sample the desired amount of $x \in D$}
end for
return S

Algorithm 3 Generation of subset loop

Require: $|S|_{desired}, |D|, R, L_0, L_1, P(X \leq x)$ {Cumulative distribution function for items}, $P(X = x)$ {Probability mass function for the label likelihoods}

$D \leftarrow createBaselineSyntheticSet(P(X \leq x), P(X = x), |D|, R)$ {Algorithm 1}
$S \leftarrow generatesSubsetWithDefinedRatios(D, |S|_{desired}, R, L_0, L_1)$ {Algorithm 2}
while $|S| < |S|_{desired}$ **do**
  $D_{new} \leftarrow createBaselineSyntheticSet(P(X \leq x), P(X = x), |D|, R)$ {Algorithm 1}
  $D \leftarrow concat_{row}[D\&D_{new}]$
  $S \leftarrow generatesSubsetWithDefinedRatios(D, |S|_{desired}, R, L_0, L_1)$ {Algorithm 2}
end while
return S

Target specification bias, counterfactual prediction, and algorithmic fairness in healthcare

Eran Tal
McGill University
eran.tal@mcgill.ca

ABSTRACT

Bias in applications of machine learning (ML) to healthcare is usually attributed to unrepresentative or incomplete data, or to underlying health disparities. This article identifies a more pervasive source of bias that affects the clinical utility of ML-enabled prediction tools: target specification bias. Target specification bias arises when the operationalization of the target variable does not match its definition by decision makers. The mismatch is often subtle, and stems from the fact that decision makers are typically interested in predicting the outcomes of counterfactual, rather than actual, healthcare scenarios. Target specification bias persists independently of data limitations and health disparities. When left uncorrected, it gives rise to an overestimation of predictive accuracy, to inefficient utilization of medical resources, and to suboptimal decisions that can harm patients. Recent work in metrology – the science of measurement – suggests ways of counteracting target specification bias and avoiding its harmful consequences.

1 INTRODUCTION

Supervised machine learning (ML) is an increasingly common methodology for training models that support medical tasks such as diagnosis, treatment planning, and resource allocation. A growing body of research addresses the biases associated with such models and the impact of their use on the fairness and safety of medical decision making [1, 5, 9, 13, 15, 16, 32, 34, 36, 37, 39]. Currently, there is no consensus on how such biases should be reported to decision makers, e.g., to medical staff who prioritize hospital beds or refer patients for diagnostic tests. Particularly, it is unclear whether and how the presence of biases should affect the estimated *accuracy* of model outputs that is reported to medical staff. The literature on bias and fairness in ML tends to treat bias and accuracy as orthogonal properties of a model, and to allow the possibility that a given model is highly accurate but deeply biased, and vice versa [29, 35]. This is consistent with the technical, probabilistic definitions of bias and accuracy accepted by ML researchers. And yet, from the perspective of a typical healthcare professional, these technical definitions are obscure and counterintuitive. Healthcare professionals take their understanding of bias and accuracy from medical measurement: when a blood test or echocardiography is biased, it suffers from a systematic measurement error, and is therefore inaccurate.

The tension in the meanings of terms like 'accuracy' and 'bias' between measurement and ML is not merely a terminological issue. Instead, it is emblematic of a mutual misunderstanding of how medical professionals think about the targets of prediction versus the way algorithm designers operationalize target variables. If not addressed, this misunderstanding can give rise to misinterpretation of model outputs and to suboptimal decisions that are harmful to patients. In what follows, I propose a way of conceptualizing and communicating the accuracy of ML-based decision support tools that is in line with medical expectations and reduces health risks due to interpretive gaps between algorithm designers and users.

The accuracy of ML-based medical decision support tools depends on two broad factors: the predictive accuracy of the model, and the accuracy of the benchmarks against which model accuracy is evaluated. Sources of inaccuracy that fall under the first factor include under- and over-fitting, unrepresentative or small datasets, and imbalanced datasets, among many others. This article focuses on the second factor, namely, the accuracy of the benchmarks used to evaluate the accuracy of ML models. In supervised ML, these benchmarks are usually taken to be the labels in the validation and test datasets. Accordingly, significant efforts to improve accuracy in medical ML decision support tools have concentrated on improving the quality of labels [2, 40, 44].

While these efforts are important and laudable, this article highlights another source of benchmark inaccuracy in medical decision support tools that cannot be remedied simply by improving the quality of labels, and persists even in the hypothetical case where labels perfectly reflect the medical reality underlying the data. This additional source of benchmark inaccuracy is *target specification*

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08…$15.00

bias. As its name suggests, this kind of bias arises due to differences between the way the target variable is specified from the perspective of medical decision makers, and the way the target variable is operationalized by the labels in the validation and test datasets. As I will show, a common source of target specification bias is that medical decision makers are typically interested in predicting variables that are specified under counterfactual conditions, while labels can only operationalize those same variables under actual conditions. As a result, labels may be biased with respect to the target variable even when the labels are reliably obtained and carefully curated.

I borrow the theoretical framework for the concept of target specification bias from *metrology*, the science of measurement. A central goal of metrology is to supply universal and replicable benchmarks for evaluating measurement accuracy, such as the standard metre, kilogram and second. I will contrast the modern concept of metrological accuracy with the 'label-matching' concept of accuracy currently prevalent in the literature on supervised ML, and find the latter lacking for the purposes of reporting to decision makers. I will then propose a broader concept of benchmark accuracy for medical ML decision support tools that is inspired by metrology. This broader concept of benchmark accuracy takes into account not only label quality, but also target specification bias.

Target specification bias is closely tied to fairness. The counterfactual scenarios under which medical decision makers typically specify their target variables are also the ones they use to define what counts as a fair decision. This is consistent with counterfactual conceptions of fairness in ML [6, 28]. I will conclude by arguing that substantive considerations concerning fairness and the dynamics of healthcare decision making are intrinsic to specifying benchmarks for model accuracy. The accuracy of ML decision support tools in medicine should be reported relative to such benchmarks, rather than merely based on their label-matching rates. Doing so would increase the fairness and safety of such tools.

2 THE LABEL-MATCHING CONCEPTION OF ACCURACY

Several measures of accuracy are used in the machine learning literature. The most straightforward one is the probability of a match between a model's predictions and the values of the target variable, $p(Y = \hat{Y})$. Other, more sophisticated measures of accuracy, such as the area under the ROC curve, are functions of the probabilities of a match or mismatch between predictions and target variable values. Determining the accuracy of a machine learning model thus requires an estimation of the values of the target variable. The common practice in supervised machine learning is to estimate target variable values from labels in the test dataset. These labels are produced by a source that is assumed to be reliable. In medicine, labels for diagnoses are commonly produced by 'gold standards' of evidence. These may include the verdict of a pathologist based on an analysis of a biological sample. For example, labels in a screening tool for skin cancer are produced by pathologists who examine the results of a biopsy of a skin lesion [1, 12]. The predictions of the screening algorithm are deemed accurate to the extent that they replicate biopsy results.

The machine learning research community is well aware that labels may be inaccurate, and that training datasets may misrepresent the target population. Much recent attention has been given to overcoming 'label bias' and data acquisition error (or 'measurement error') and to diversifying commonly used training datasets [2, 40, 44]. These efforts increase benchmark accuracy, and with it the reliability of evaluations of predictive accuracy. However, the question remains as to whether a model that replicates the labels in a reliable and representative dataset should for that reason be deemed accurate. Current practice suggests that much of the machine learning community assumes that the answer is 'yes'. A look at recent reports of machine learning applications in medicine shows that researchers consistently select measures of accuracy that strictly track the replication of labels [10, 14, 20, 25, 27]. By 'strictly track' I mean that the model's accuracy is evaluated as a monotonically increasing function of the probability of a match between predictions and labels in the test dataset, and that the model is considered 100% accurate if and only if its outputs match all the labels in the test dataset.

Should evaluations of algorithmic accuracy strictly track the match between predictions and labels? In what follows, I will call the view that a machine learning model is predictively accurate to the extent that its predictions match the labels in a reliably obtained and representative dataset the 'label-matching conception of accuracy'. The label-matching conception takes labels in a reliable and representative dataset to be unbiased operationalizations of the target variable. For example, if the target variable is the risk of cancer associated with a skin lesion, and the labels are biopsy results, the target variable is operationalized by the probability that a lesion with similar features would result in a positive biopsy result. As long as the dataset is a reliable representation of medical diagnostic practice, the label-matching conception assumes that the probability of a positive diagnosis tracks the risk of skin cancer.

The main advantage of the label-matching conception of accuracy is its simplicity. As long as the dataset is of sufficiently high quality, evaluating accuracy is simply a matter of counting matches (or calculating distances) between predictions and labels, and applying one of several mathematical transformations to the results. No additional information or expertise concerning the target problem domain, e.g., dermatopathology, is required to evaluate accuracy. On the other hand, the disadvantage of this conception is that it runs the risk of operationalizing the target variable in a manner that misaligns with the way users and stakeholders define it. For example, there are reasons to doubt that the occurrence of positive biopsy results is an adequate operationalization of the occurrence of skin cancer. Due to racial disparities in the diagnostic process, Black patients in the US are typically diagnosed at a later disease stage. Hence, samples from early-stage Black patients may be underrepresented in the data [19]. In other words, while biopsy may be highly reliable in detecting skin cancer, and while the dataset may be representative of diagnostic practice, diagnostic practice is not directly reflective of the target variable that decision-makers and stakeholders are interested in predicting. Decision makers are interested in the occurrence of skin cancer, and are thus interested in predicting the diagnosis that a patient with a given set of features *would have received* had diagnostic practice been equally reliable for Black and white patients. The correct way to operationalize the

target variable from the perspective of decision makers is as a predictor of a counterfactual scenario, rather than the actual scenario the model is trained to predict.

There are several reasons why actual medical practice may give rise to data that, despite being reliable, cannot be used to directly track the variable of interest. Not all such reasons involve a disparity that needs to be corrected, such as the late diagnosis of skin cancer in Black patients. In many cases, the mismatch between labels and target variable arises precisely because medical practice proceeds correctly and responsibly. Brian Christian discusses an early example of such mismatch [8]. In 1995, computer scientist Rich Caruana, then a graduate student at Carnegie Mellon University, was part of a team developing machine-learning algorithms to inform hospital admission decisions for pneumonia patients. The goal was to help physicians decide which pneumonia patients to hospitalize and which to follow up as outpatients. Caruana used patients' health outcomes, and specifically patient mortality, as labels. The neural net he trained achieved good accuracy (AUC=0.86) in predicting patient mortality [4]. However, a rule-based learning algorithm that was trained on the same data learned the rule that having asthma *lowers* the risk of mortality of a pneumonia patient. Conversations between the computer scientists and physicians revealed the likely cause: physicians tended to direct more resources to treating pneumonia patients with a known history of asthma. For example, such patients were often admitted directly into the intensive care unit, where they received aggressive care. This reduced the mortality rate of asthmatics with pneumonia relative to the overall pneumonia patient population. Ironically, this meant that these patients were deemed low-risk by Caruana's model, which was trained on the same data and was accurate in predicting mortality.

It is worth examining precisely what went wrong with Caruana's model. The model's target variable – the thing it was designed to predict – was patient mortality. Risk of patient mortality was specified as the deciding factor for priority of hospital admittance as an inpatient. The labels used to train and test the model were records of patient mortality, and there is no reason to think that the labels were plagued by significant data acquisition error, i.e., that deaths were miscounted. Prima facie, then, the labels seemed to be good representations of the target variable. On a closer look, there was a misalignment between what the labels represented and the intended target variable. While the labels were records of actual mortality, the intended target variable was *ceteris paribus* mortality, that is, mortality 'all other things being equal'.

The variable physicians were interested in estimating when making decisions about inpatient admittance was not whether a given patient would in fact die of pneumonia. Whether or not a patient dies of pneumonia depends on other factors besides their health state and health-related risk factors. Specifically, it also depends on the quality and timeliness of the medical treatment they receive. The target variable of interest, rather, was the risk of death from pneumonia under a counterfactual scenario where all patients receive the same quality of care. Only under such counterfactual scenario can physicians control for the impact of care on a patient's health outcomes. The target variable is therefore *idealized*, in the sense that it represents a simplified and unrealistic scenario. The labels used to train and test Caruana's model reflected a real, complex scenario that was an imperfect approximation of the idealized, *ceteris paribus* case. These imperfections, if not detected in time, would have caused harm to asthmatics, who would have been de-prioritized for inpatient care had they contracted pneumonia.

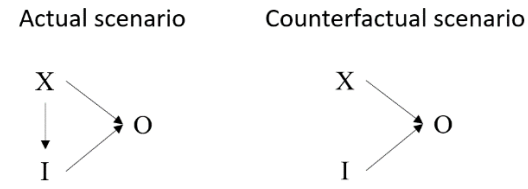

Figure 1: A simplified causal model of data generation for health outcome prediction. X stands for patient features prior to medical interventions, I stands for the characteristics of medical interventions, and O stands for the patient's health outcomes. Actual data are generated by the scenario on the left, whereas decision makers are typically interested in predicting outcomes under the scenario on the right.

3 DECISION MAKERS CARE ABOUT COUNTERFACTUAL PREDICTION

The cases discussed above suggest that the label-matching conception of accuracy is misaligned with the interests of decision makers and other stakeholders. Even when the data are representative of the actual world, and the model is generalizable to other, real-world cases not included in the training data, model predictions may still be inadequate as operationalizations of the target variables decision makers care about. Figure 1 illustrates this mismatch for a simplified use case of ML in healthcare. The use case concerns decisions about treatment based on a prediction of a patient's health outcomes. In a simplified causal model of the underlying data generation process, two variables affect a patient's health outcomes (O): the characteristics (features) of the patient prior to medical intervention (X), and the characteristics of the healthcare interventions that the patient undergoes (I). This causal model is simplified inasmuch as other, e.g., environmental and social factors also contribute to health outcomes. Nonetheless, the simplified causal model is sufficient to demonstrate the mismatch between operationalization and definition that gives rise to target specification bias.

Two scenarios of the simplified causal model may be distinguished. In an actual scenario, the characteristics of the healthcare interventions that a patient undergoes are affected by the features of the patient. For example, different patients that present symptoms of a similar kind are often treated differently based on the severity of their symptoms, their age, and their medical history. Moreover, the same intervention may be more or less effective depending on a patient's age, sex, and background medical conditions. Some patients refuse certain treatments, and this again may be correlated with the patient's age, sex, religion, and health condition. Finally, patients belonging to different socio-economic, racial, or ethnic groups often do not have the same range and quality of medical interventions available to them. As a result, the demographic and medical characteristics of a patient affect the type, duration, and quality of the medical interventions they undergo. Any accurate

prediction of actual health outcomes is, by virtue of being accurate, necessarily sensitive to the interaction between patient features and the characteristics of the intervention.

To physicians who are tasked with making decisions about treatment, this interaction is a confounding factor. Physicians are typically interested in the difference a given intervention would make to the health of a patient, such as reducing their risk of death or increasing their quality of life. For this evaluation to be possible, physicians need information on how different patients are likely to respond to the *same* intervention. In other words, physicians are interested in the counterfactual scenario under which patient features and the characteristics of the intervention do not interact. For example, they are interested in the health outcomes different patients with pneumonia would have had 'all other things being equal', that is, if they had been given the same treatment. As Jessica Paulus and David Kent put it, "observed mortality is an imperfect proxy for mortality under ideal care, the true outcome of interest when constructing models for [medical] futility" [34].

Depending on the number of treatment options under consideration, physicians may be interested in multiple counterfactual predictions. For example, they may be interested in comparing the counterfactual health outcomes of a patient in a given population where all patients receive the same treatment T1 to their health outcomes in a population where all patients receive the same treatment T2, or perhaps no treatment at all. Only relative to such counterfactual scenarios can decision makers isolate the contribution of patient features to health outcomes, and select interventions accordingly.

A similar point holds for diagnostic use cases. Under a simplified causal model, patient characteristics and the characteristics of the diagnostic procedure both affect the diagnosis a patient receives. In an actual scenario, the features of a patient affect the characteristics of the diagnostic procedure they receive. Different patients presenting similar symptoms are often offered different diagnostic procedures depending on their age, sex, and whether or not they are known to belong to certain risk groups. The same diagnostic procedure may have varying sensitivity and specificity for different patients depending on age, sex, genetic profile, background health conditions, and a variety of other factors. The proportion of patients who refuse to undergo a certain diagnostic procedure may vary in correlation with demographic properties. And patients belonging to different socio-economic, racial, or ethnic groups often do not have the same range and quality of diagnostic procedures available to them.

Here again, the demographic and medical characteristics of a patient affect the type, quality, and timeliness of the diagnostic procedure they will undergo. A machine-learning model that accurately predicts actual diagnoses is necessarily sensitive to the interaction between patient features and the characteristics of diagnostic procedures. However, from the point of view of a physician who is required to decide whether or not to refer a patient to a diagnostic test, this interaction is a confounder. Such a physician is interested in evaluating the likelihood that the test would reveal important information, e.g., confirm or rule out the presence of a medical condition. As part of this evaluation, physicians are interested in determining a patient's risk of developing a given medical condition, regardless of whether or when that condition will, as a matter of fact, be diagnosed. In other words, physicians are interested in predicting the diagnosis the patient *would* receive in a counterfactual scenario where all patients with a given set of symptoms undergo a timely and accurate diagnosis procedure.

The comparison of actual and counterfactual scenarios demonstrates the limitations of the label-matching conception of accuracy. The ability of an ML model to reproduce labels in a generalizable way is an important step toward clinical utility, but is not sufficient. Labels in the dataset reflect health outcomes (or diagnoses) obtained in actual healthcare scenarios, whereas decision makers typically require information about counterfactual scenarios where some background causal factors are held fixed. To be clinically useful, an ML model must predict the health outcomes (or diagnoses) associated with patient features under such counterfactual, *ceteris paribus* scenarios. These counterfactual health outcomes (or diagnoses) differ from the labels in the dataset, not due to any measurement error, but because real data includes correlations that confound the relationship between patient features and health outcomes (or diagnoses) that decision makers are interested in learning about. As a result, when the accuracy of an ML model is evaluated based on the model's ability to reproduce labels, it is evaluated against a different variable than the one decision makers typically care about [34, 36].

From the point of view of decision makers, then, the label-matching conception overestimates the accuracy of model predictions. Specifically, it does not account for discrepancies between the values of the target variable as it is operationalized by labels, and values of the target variable as it is defined by decision makers. Such discrepancies constitute target specification bias.

In response to this charge, one could argue that machine learning is not designed to predict counterfactual scenarios. Rather, a machine learning model is deemed accurate when there is a good fit between the associations learned by the model and the associations found in the real world. As long as the labels in the dataset are accurate and reliable representations of the target variable of interest, and the model generalizes well from the training dataset to new examples, the model should be deemed accurate for the patient population from which the data was collected.

This objection, though plausible at first, rests on a confusion between intended labels and target variables. Intended labels are the labels a dataset would have if the data were representative and reliably collected. Examples are cancer diagnoses, records of hospital admission, and records of death. However, even the labels in an ideally collected and curated dataset are not values of the target variable. Rather, they are *operationalizations* of the target variable, that is, empirically accessible stand-ins for the values of the target variable. The target of prediction in most applications of machine learning is a *latent variable*, that is, a variable whose values are not directly accessible through any empirical procedure, but require inference from available data [21]. To access their values, target variables must be operationalized. Whether or not labels are an adequate operationalization of the target variable depends on the definition of the target variable, and on the validity of the inference from labels to target variable values. The need for such inferences and their complexity have long been recognized in sciences that specialize in measurement, such as metrology and psychometrics.

In the next section, I turn to an example from metrology, and examine how the accuracy of measuring instruments is evaluated in the face of gaps between the desired target variable and its operationalizations. I then build on this example in the following section, where I elaborate on the sources of target specification bias and offer ways of mitigating it.

4 A METROLOGICAL CONCEPTION OF ACCURACY

Metrology, the science of measurement, is concerned with the practical and theoretical aspects of measuring. Metrologists are typically physicists and engineers who design and calibrate highly accurate measuring instruments, maintain and improve measurement standards, and regulate national and international systems of measurement, including the International System of Units (SI). While its orientation is mostly applied, metrology has also generated a considerable body of conceptual and methodological work. The *International Vocabulary of Metrology* (VIM), for example, discusses the meanings of general terms such as 'measurement accuracy', 'measurement error' and 'measurement uncertainty' [22]. Similarly, the *Evaluation of Measurement Data – Guide to the Expression of Uncertainty in Measurement* (GUM) provides a wealth of concepts and methods for evaluating measurement uncertainty [26].

Metrology provides valuable conceptual tools for judging the adequacy of an operationalization of a variable. In metrology, the quantity intended to be measured is called a 'measurand' [22]. The task of defining a measurand is distinguished from the task of realizing it. The distinction between realization and definition of measurands is central to modern metrology, and a key to its success in delivering reproducible measurement results. The *definition* of a measurand is a linguistic entity that specifies the conditions under which the quantity is intended to be measured. These conditions are often ideal and not obtainable in practice. For example, the standard unit of time, the SI second, is defined as the duration of exactly 9,192,631,770 periods of the electromagnetic radiation corresponding to the transition between two hyperfine levels of the unperturbed ground state of the cesium-133 atom [3]. The cesium atom in question is assumed to be unaffected by gravitational fields, magnetic fields, or thermal radiation, and to have no interactions with other atoms. These are counterfactual conditions that cannot be practically achieved in a laboratory.

The definition of the SI second assumes a counterfactual scenario, and thus cannot be fully satisfied. Yet it can be approximately satisfied. A metrological *realization* is a system that approximately satisfies the definition of the measurand. Realizations are used to operationalize the definition of the measurand, so as to make its value (or values) empirically accessible. For example, there are currently over a dozen primary frequency standards operational around the world. These are atomic clocks that serve as the most accurate measurement standards for time and frequency metrology. Each of these clocks measures the radiation frequency associated with cesium-133 atoms under conditions that closely approximate the ideal conditions specified by the definition of the second. However, no approximation is perfect, and different realizations deviate from the ideal in different respects and degrees. Consequently, metrologists do not consider any of the primary frequency standards to be completely accurate. Doing so would lead to inconsistencies, as the clocks 'tick' at slightly different rates due to differences in the conditions affecting the cesium atoms in each laboratory. Instead, metrologists develop detailed theoretical and statistical models of each clock, and test these models by experimenting on the clocks and measuring their surrounding environment [18, 23]. These models are then used to estimate the deviation of each clock from the ideally defined frequency [41].

When a less accurate clock is calibrated against a primary frequency standard, the accuracy of the clock is not evaluated simply by its ability to reproduce the frequency of the primary standard. Doing so would make the less accurate clock inherit the frequency biases of the standard. Instead, the biases and uncertainties associated with the primary standard are included in the accuracy evaluation of the less accurate clock [33]. This procedure ensures that accuracy is evaluated relative to the theoretical *definition* of the second, rather than against any of its idiosyncratic, concrete realizations. By following this procedure, clocks that were calibrated against different primary realizations of the second provide consistent estimates of time and frequency, even though the raw frequencies ('tick' rates) of primary realizations disagree with each other.

Metrological accuracy is the closeness between the measured quantity value and the value of the measurand as defined. The defined value of the measurand is considered to be unknowable, and only capable of approximation with some uncertainty. Much of the conceptual and mathematical apparatus of metrology is dedicated to estimating bias, understood as a systematic difference between measured and defined quantity values. As the defined value of the measurand is unknowable, estimations of bias are necessarily inexact and involve some uncertainty. To evaluate this uncertainty, metrologists assess the extent of deviation between the actual operating conditions of their instruments and the ideal operating conditions specified by the definition of the measurand.

Metrologists employ a variety of strategies to acquire this counterfactual information. Some of these strategies involve physically controlling elements of the apparatus and environment so that they more closely approximate the ideal, e.g., controlling the temperature of the environment. But these physical control strategies ultimately reach a practical limit. To go beyond this limit, metrologists use a combination of theoretical predictions and secondary experiments to assess how the apparatus *would have* behaved if its operating conditions were closer to the ideal. For example, they vary the density of cesium atoms in the atomic clock, and use theory and statistics to predict what the frequency of the clock would have been at zero density [17]. The uncertainty associated with this prediction becomes a component of the measurement uncertainty of the clock.

The upshot is that a clock's accuracy is a property of a *predictive inference* [42]. Accuracy ultimately depends on the ability of scientists to use the clock's indications ('ticks') to predict the value of a latent, counterfactually defined frequency. The accuracy of this prediction, and therefore of the clock itself, depends on extensive and domain-specific background knowledge, and cannot be reduced to an association or matching between observations.

5 TARGET SPECIFICATION BIAS AND ITS IMPLICATIONS FOR FAIRNESS

The discussion of time and frequency metrology provided above leaves out much detail, but even this cursory survey suggests similarities between the inferential structures of measurement and supervised ML-based prediction. Both are types of method for evaluating variables based on concrete input (whether a new example, or an object to be measured). Both involve a modeling (training or calibration) phase, in which reliable data (training dataset, or values associated with standards) are used to generate stable associations between the inputs and outputs of the instrument [31]. In both cases, the associations revealed during the modeling phase are generalized to new objects or events in the application (deployment or measurement) phase. In both cases, the model is optimized to increase the accuracy of predictions of values of the target variable (measurand). Finally, both types of method presume to provide evidence for decision making, and are often presented to decision makers as trustworthy within reasonable limits.

These similarities are perhaps not surprising, given that both measurement and predictive ML rely on inductive reasoning. I do not wish to overemphasize the similarities: there are many dissimilarities between measurement and predictive ML as well. These include different modes of implementation (computational versus material), the fact that the input of ML is a representation rather than a concrete object or event, and the fact that an ML model is a model of the *data* rather than a model of the measurement process. There are also many methodological and institutional dissimilarities. Yet the similarities in inferential structure are sufficient to support a reasonable hope that some helpful lessons may be drawn from metrology, which is a significantly older and more methodologically mature field than ML research, for tackling current challenges facing ML research. In what follows I will focus on four such lessons.

5.1 Lesson One: labels are not intended to reflect target variables, but to operationalize them

From an abstract, mathematical perspective, ML may be viewed as no more than a 'regression machine' that fits a function to data under specified constraints. However, the practical problems that ML tools are commonly deployed to solve, such as optimizing resource allocation or predicting the occurrence of a disease, are not identical to the regression problems that ML tools are designed to solve. Rather, the regression problem meant to be solved by a given ML tool is an *operationalization* of the real-world problem. Even if the model is a good solution to the regression problem specified by algorithm designers, it does not yet follow that the model is a good solution to the real-world problem that the model will be deployed to solve. This is a familiar situation in measurement: a measuring instrument almost never measures precisely the same variable that users are interested in measuring. The difference between the target variable and the variable being measured is often subtle. Unless the target variable is carefully defined, the discrepancy may go unnoticed. In some cases, the discrepancy may be practically negligible, while in others, an unnoticed discrepancy can entail significant harm. To avoid such harms, the real-world problem and its operationalization need to be clearly distinguished from each other, and their relationship carefully studied.

Metrologists are used to asking themselves whether the target variable as defined is identical to what the instrument is designed to measure, and whether the instrument *in fact* measures what it is designed to measure. Most commonly, the answer to both questions is 'no'. Similarly, designers of predictive ML tools typically benefit from asking: (i) What variable do labels in the actual data reflect? (ii) What variable are labels *intended* to reflect? and (iii) How does the variable that labels are intended to reflect differ from the target variable as defined by stakeholders?

Questions (i) and (ii) are increasingly at the center of attention in ML research, as evidenced by recent work on measurement error, label bias, and biased proxy variables [24, 30]. The third question is more seldomly raised, perhaps due to the belief that the variable the labels are intended to reflect is identical to the variable of interest to stakeholders. But in well-designed predictive tools, these two variables should usually be distinct. As already mentioned, the variable of interest to stakeholders is typically not practically realizable even in principle. Much like the frequency of an ideal, unperturbed cesium atom, decision makers are typically interested in counterfactually defined variables, such as the *ceteris paribus* prognosis of patients under equal treatment, or the *ceteris paribus* health risks to a patient if diagnostic testing were not selective. Even in the best practically possible data acquisition scenario, labels that reflect the variables of interest to stakeholders are not attainable, because the conditions the define such variables are never fulfilled. Intending labels to directly reflect target variables ignores the inferential gap between the two, with potentially harmful and unjust consequences to patients.

Instead, fairness and safety are better served by viewing intended labels as operationalizations that necessary satisfy the definition of the target variable only approximately, and to account for this approximation when reporting accuracy to stakeholders. Metrologists are already taking this responsible approach to accuracy evaluation and reporting: they reconcile multiple, idiosyncratic measuring instruments by accounting for their deviations from a common, counterfactual ideal. The mutual reconciliation of measurements results relative to a counterfactual ideal is essential to their reproducibility, and a precondition for many practical applications, including precision timekeeping, modern manufacturing, and reliable communications.

5.2 Lesson Two: target specification bias is distinct from data acquisition error and label bias

Operationalizing a target variable is a complex activity. It involves an iterative investigation of the degree of alignment between the goals of variable estimation and the design of concrete estimation procedures. The result is often a chain, or a hierarchy, of variables starting with a highly idealized variable definition, proceeding through successive approximations, and terminating with the results of one or more concrete methods. For example, when measuring mass in kilograms, the idealized variable is a ratio between the mass of an object and a defined physical constant. The physical constant that currently defines the kilogram is a function of the

Planck constant, the speed of light in vacuum, and the ideal cesium transition frequency [3]. If everyday kitchen scales were required to directly estimate this ratio, they would have been tremendously complex and expensive. Instead, kitchen scales are calibrated to a variable that is located at the bottom of a long chain of operationalizations, namely to the mass of a standard metal weight that approximates the defined constant. Operationalization is successful, not when these variables are identical, but when the relationships among them are stable and sufficiently well-known.

Different links in the chain of operationalizations introduce different kinds of error. This holds true for measurement as it does for the operationalization of variables in ML-based decision support tools. A typical case of supervised ML is illustrated in Figure 2. Errors that originate at the lowest levels of the chain – the level of data acquisition – are commonly known as 'measurement errors' or 'measurement biases' [30]. These include, for example, incorrect or missing data, noise in the data, and duplicate records. Such errors introduce bias into the relationship between labels in the training data and the events or objects in the world that the labels are meant to represent. For example, an error in the recording of a diagnostic test could cause a positive test result to be recorded as negative, or vice versa. Next comes 'label bias', namely errors that arise due to differences between the intended and actual labels. Labels are usually intended to reflect some actual state of affairs in the world, such as the existence of a pathology. Actual labels are indirect approximations of intended ones. A common source of label bias is error in the underlying evidence-collection process. For example, the diagnostic test itself may be inaccurate, e.g., a pathology exists but is not detected. Even if the diagnostic test is completely accurate, label bias could still arise if, for example, the sample on which data is collected is not representative of the intended population, e.g., the sample contains significantly more men than women or an unbalanced age distribution relative to the population of interest.

Target specification bias is distinct from data acquisition error and label bias. This kind of bias arises due to differences between the intended labels and the target variable. As mentioned, in decision-making scenarios target variables are typically counterfactually defined, and concern a state of affairs where confounders are absent. It is often practically impossible to remove confounding factors by directly intervening in the world. For example, it is impossible to remove systematic health inequalities from society before collecting the data. Even when direct elimination of confounders is practically possible, it may not be ethically or legally permissible. For example, doing so in the pneumonia case would require withholding special treatment from asthmatics who present pneumonia symptoms. Consequently, target variables must usually be defined in a counterfactual world.

The counterfactual nature of target variables distinguishes them from intended labels. Labels are data about the actual, rather than a counterfactual, world. For example, they are intended to reflect the actual health outcomes of pneumonia patients in a manner that is free from inaccuracies, i.e., free from data acquisition error and label bias. At the same time, labels are *not* intended to reflect a counterfactual world free of upstream decision making (such as differential treatment of at-risk patients), diagnostic suspicion bias (such as unjustified differences in diagnostic procedure based on patients' race, gender, or age) or systematic injustices (such as unequal access to healthcare). No method can directly collect data about such counterfactual worlds, because they are not empirically accessible. Properties of such counterfactual worlds – including the target variable – must be inferred from data about the actual world based on some assumptions. The nature of these assumptions will be discussed under Lesson Four.

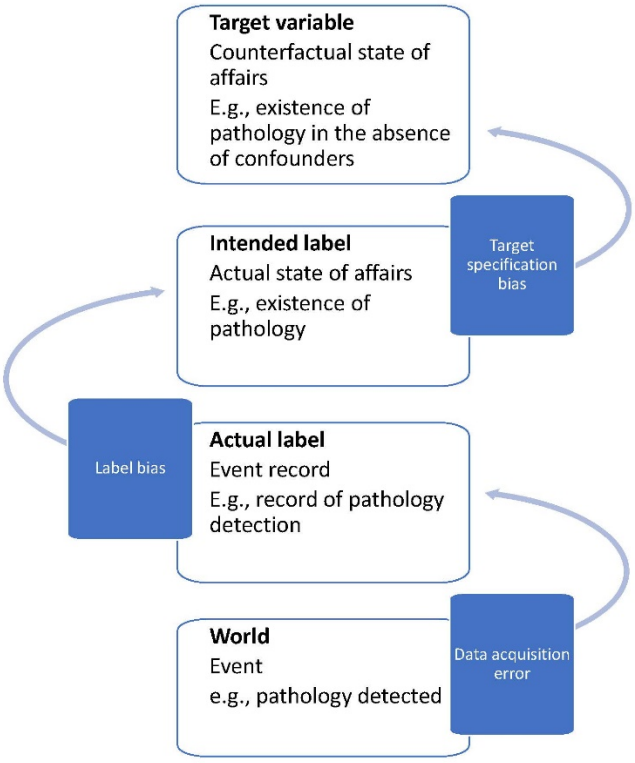

Figure 2: A typical chain of operationalizations of a target variable in supervised ML for healthcare decision making. Target specification bias arises due to differences between intended labels and the target variable, and is distinct from label bias and data acquisition error.

It should be noted that target specification bias is a broader category than proxy bias, at least under a common interpretation of the term 'proxy'. Proxy bias arises when the labels and the target variable are defined as different *kinds* of properties, such as when the cost of healthcare serves as a stand-in for the severity of illness. The difference between the target variable and its operationalization is especially stark in such cases. Nonetheless, target specification bias persists even when the two variables are of the same kind, such as when actual severity of illness is used to estimate counterfactual severity of illness in the absence of confounders. Consequently, unlike proxy bias, target specification bias cannot be completely solved simply by picking better labels [34]. Of course, one could decide to use the term 'proxy' very broadly and apply it to any operationalization. Broadly speaking, all measurement and supervised ML involve proxy variables, because the variable of interest is

never completely identical to its operationalization. However, such linguistic usage would obscure the specific challenges presented by what ML researchers typically call 'proxy variables' and the special solutions available to address these challenges.

5.3 Lesson Three: target specification bias affects both accuracy and fairness

If not corrected, target specification bias diminishes model accuracy. To see how, one must first consider the concept of accuracy itself. On a narrow, label-matching concept of accuracy, the optimal targets of prediction in supervised ML are actual states of affairs, such as the actual rates of patient recovery and mortality. Accordingly, when a model is optimized in a manner that sacrifices its degree of fit with labels – for example, to accommodate fairness constraints – its predictions are viewed as less accurate than they would be in the absence of such constraints. This conclusion is consistent with the claim, commonly made by ML researchers, that accuracy and fairness trade-off against each other [11, 35].

On a closer look, there are at least two distinct concepts of benchmark accuracy to consider when evaluating the performance of ML-enabled decision support tools. The first is the accuracy of labels relative to the actual states of affairs that labels are intended to describe, e.g., whether a patient that is recorded as having survived pneumonia in fact survived. Here the benchmark is the intended label. This is the benchmark commonly used under the label-matching concept of accuracy. The second concept of benchmark accuracy is the accuracy of labels relative to the variable decision makers are interested in predicting, e.g., whether a patient that is recorded as having survived pneumonia would have survived if all patients had received the same treatment. Here the benchmark is the target variable. Under this second, broader concept of benchmark accuracy, even the most reliably acquired labels are still imperfect operationalizations of the target variable. By analogy, even a physical clock that works precisely as intended would still be affected by confounders that make it an imperfect operationalization of the theoretical definition of the standard SI second.

It is this broader conception of accuracy that usually interests decision makers. Under this conception, accuracy is evaluated relative to a benchmark that is meaningful to decision makers, i.e., that represents the kind of evidence decision makers are seeking, rather than a technical aspect of the algorithm's validation and testing. The upshot is that a good fit to the labels – even once the labels are corrected for data acquisition errors and label bias – may not be sufficient to guarantee accuracy from the perspective of decision makers. Indeed, in some cases a good fit between model predictions and corrected labels may be a sign of *inaccuracy*. This is especially the case if there are reasons to think that the actual world in which the labels were collected differs substantially from the counterfactual world about which decision makers seek evidence. Evaluating model accuracy relative to a counterfactually specified target variable takes target specification bias into account, resulting in more complete and user-relevant accuracy estimates than those based strictly on label-matching.

Target specification bias also diminishes the fairness of decisions that are based on model predictions. From the perspective of a decision maker who is interested in making fair decisions, upstream medical decisions that affect the distribution of health outcomes across groups are confounders. This is the case regardless of whether those decisions are unjust (e.g., due to health disparities) or due to justified differential treatment (e.g., preferential treatment to asthmatics). The target variable is specified in the absence of such confounders, on a counterfactual world that is free from differential intervention. This counterfactual approach to defining target variables does not free decision makers from addressing difficult theoretical questions about what exactly they mean by 'fairness'. On the contrary, the emphasis on target specification as a distinct, theoretical task that involves societal and ethical considerations highlights the potential conflicts among different conceptions of fairness.

Fairness criteria that are incorporated into the definition of the target variable become part of the accuracy benchmark for the relevant decision support tool. Under a broad, user-oriented conception of accuracy, implementing such fairness criteria does not trade off against accuracy, but rather aligns with the aim of improving model accuracy. For example, correcting the predictions of the pneumonia hospitalization decision support tool so that asthmatics are prioritized (rather than de-prioritized) increases both accuracy and fairness. Accuracy is increased by providing decision makers with evaluations of the target variable they are interested in – in this case, how asthmatics would fare in the absence of differential treatment – and fairness is increased by better aligning resource allocation with medical need. Target specification bias therefore defies the typical trade-off between fairness and accuracy.

5.4 Lesson Four: mitigating target specification bias requires domain-specific knowledge

In the analogy with measurement, target specification bias is a type of systematic measurement error. Unlike random error, systematic error is a "component of measurement error that in replicate measurements remains constant or varies in a predictable manner" [22]. Systematic errors often stem from background processes and assumptions that remain stable when the measurement is repeated, such as a background gravitational field or a biased estimation of a physical constant. Such errors cannot be detected by applying statistical tests to repeated measurements, but must be inferred from theoretical models of the measurement process, by performing additional measurements, or by using established measurement standards.

Similarly, target specification bias stems from processes and assumptions that remain stable when the same part of the world is resampled. Gathering additional data from the same hospital would not reveal that the model underestimates the risk of pneumonia to asthmatics, because the process of differential treatment that gives rise to the bias remains constant. Nor would the bias be revealed by using different labels, employing different measures of fit between predictions and labels, or employing a generic fairness criterion that equalizes some performance parameter across patient groups. Recall that the performance parameter that decision makers are interested in equalizing is defined counterfactually: it is the allocation of resources by health risk when all other things are equal. The relevant sense of 'all other things' is domain-specific,

and depends on the context of the decision at hand. Mitigating target specification bias requires decision makers and algorithm designers to explicitly specify their assumptions concerning what needs to 'remain equal' in the counterfactual scenario. Then, they must formulate and empirically test hypotheses concerning the differences between this counterfactual scenario and the actual one. In doing so, they would be following the example of metrologists, who theorize about the deviations of their clocks from the idealized definition of the SI second.

This is not to imply that collecting and analyzing data cannot help to mitigate target specification bias. One way of formulating hypotheses about the actual processes that give rise to data is to increase the transparency of the model, so that the correlations it discovers become more easily surveyable. In the case of Caruana's model, this was achieved by training a rule-based learning algorithm on the same data. Another helpful family of techniques employ methods of causal inference that reveal counterfactual probabilities in the data. For example, the use of Bayesian networks or structural equation models can reveal causal dependencies that are relevant to healthcare decision making [36]. Recent work in explainable AI (XAI) has featured breakthroughs in extracting counterfactual information from ML models and presenting it to users, with potential applications for clinical decision support tools [7, 38].

Such methods should be used in combination with clinical judgment to interpret the resulting counterfactuals and determine which of them is relevant for the decision at hand. Importantly, decision makers need to exercise judgment when deciding which counterfactual conditions need to be equalized across which patient groups. For example, it makes little sense to allocate medical resources to children suffering from asthma based on the diagnosis they would have received if they were adults. The medical resources, diagnostic criteria, and treatment options are far too different between these two groups to make such counterfactual information relevant for decision making. Domain-specific and contextual knowledge remains crucial for specifying which counterfactual information is relevant for a given type of medical decision. This point is further strengthened by the fact that various stakeholders, including patients, physicians, healthcare administrators, insurers, and health policymakers may have conflicting specifications for the same target variable. In such cases, addressing target specification bias requires an inclusive consultation regarding the precise aims of prediction.

6 CONCLUSION: TOWARDS A METROLOGICAL EVALUATION OF ACCURACY FOR MACHINE LEARNING

With the proliferation of ML-based tools into areas of high-stakes decision making, such as healthcare, criminal justice, finance, and defense, the methods used to evaluate and report the accuracy of ML models need to conform to stringent standards. The discussion above suggests that the label-matching conception of predictive accuracy is inadequate and potentially harmful for supporting high-stakes decisions. It is misleading to report the rate of label-matching to stakeholders (whether in terms of sensitivity, specificity, AUC, or some other metric) and present it as the ultimate evaluation of the model's accuracy, even if the labels themselves are highly reliable. Instead, the accuracy of decision support tools should be reported relative to a counterfactually defined target variable, with an uncertainty margin that reflects the unknown degree of error around reported values. Methods for reporting this sort of counterfactual information are still in their infancy in ML [43], but are highly developed in metrology, which could serve as a role model for future developments.

Label-matching metrics of accuracy may still be useful for internal model validation, including testing for under- and over-fitting of the model. Such metrics can reflect the internal validity of the model, that is, an evaluation of the fit between the associations learned by the model and the associations found in the part of the world from which data was collected. Such metrics express how well model predictions generalize from the training dataset to the test dataset, and are therefore tied to the idiosyncratic conditions under which these datasets were obtained. This sort of generalizability may be sufficient for some low-stakes decisions, such as retail consumer purchasing recommendations, but not for medical decision making, which is subject to a higher standard of harm prevention and requires a systematic exclusion of confounders. Rigorous, metrological accuracy evaluation of ML decision support tools will have the benefits of reducing target specification bias, providing clearer and more actionable information to users, increasing fairness, and improving reproducibility and public trust.

ACKNOWLEDGMENTS

I am grateful to Yasmin Haddad, Ljubomir Raicevic, Branden Fitelson, and Momin Malik for our discussions, to three anonymous reviewers for their comments, and to audiences at Northeastern University, University of Oregon, University of Guelph, Leibniz University Hannover, University of Memphis, and Université du Québec à Montréal for their feedback. ABSTRACT

Applications of Artificial Intelligence (AI) in the domain of Personal Health Informatics (PHI) offer potential avenues for personalised treatment and support for people living with long-term conditions, however, they also present a number of ethical challenges. Whilst participatory approaches can help mitigate concerns by actively involving healthcare professionals, patients, and other stakeholders in design and development, these are constrained by the limits of epistemic standpoints and the risks posed by extrapolation from individuals to groups. In this paper we draw upon interviews with stakeholders involved in Human Immunodeficiency Virus (HIV) care, including clinicians, insurance providers and pharmaceutical industry representatives, to map intentions and ethical considerations for developing PHI tools for people living with HIV. Whilst treatment efficacy for HIV has improved patient quality of life and life expectancy, management and care is complicated by knowledge gaps about what living and ageing with HIV entails. We investigate how the critical concept of epistemic injustice can inform the design of data-driven technologies intended to address these gaps, helping orient expert perspectives within the broader structures and socio-historical influences that shape them. This is of particular importance when designing for marginalized populations such as people with HIV (i.e. who may experience social stigma and be under-resourced, managing multiple conditions), helping to identify and better account for fundamental ethical considerations such as equity.

1 INTRODUCTION

A plethora of recent work at the intersections of Artificial Intelligence (AI) and digital health illustrates the potential of data-driven technology to support people living with long-term health conditions such as Human-Immunodeficiency Virus (HIV). This has spurred dialogue around the implications of datafied healthcare, emphasizing how social contexts shape digital design for Personal Health Informatics (PHI), especially given how socio-political contexts impact engagement with care [10] [58] [83]. Recent work in the international AI ethics research community has highlighted the role of epistemological assumptions and knowledge asymmetries in shaping both system design and approaches to practical ethics [18] [48] [53] [78]. This poses a particularly salient ethical concern given recursive looping between AI systems and the social contexts which they are employed within, whereby algorithms shape societal contexts which then form a baseline upon which to construct another algorithm, and so on [8]. [5]. Given this, it is crucial to account for broader structural contexts shaping participant perspectives [77] when conducting user interviews with domain experts to inform AI system design, cognizant of the risks posed by conflating individual views with normative ethical aims [33]. Given aims to design models which explicitly draw upon the data collected by users of health apps, touted as resources for high-stakes domains such as personalized medicine and public health planning, gaps in data mean poorer quality care for individuals in the missing groups. This is of particular concern given that resource scarcity in domains such as public health, with datasets re-appropriated to fulfil needs such as policy development [5].

This paper examines how historical and socio-political factors combine to invisibly impact design of medical AI. We employ the conceptual lens of epistemic injustice [39], which references the exclusion of or devaluation of the knowledge contributions of marginalized epistemic subjects, to unpick some of the assumptions which can underlie how healthcare providers frame suggestions for these technologies, and look at how structural and relational factors can influence this by impacting patient engagement with care. We report insights from a recent interview study conducted in the United Kingdom (UK) with stakeholders involved in the management of HIV, including healthcare professionals, insurance providers, and researchers in the pharmaceutical industry, to map stakeholder aims and ethical concerns around using PHI tools for HIV management. Drawing upon these findings, we examine how well-being and care relationships are understood by care providers, seeking to inform the ethical design of technologies that aim to support people living with HIV. We illustrate this with a case study designed to scaffold understanding of how to support the self-management of HIV in daily life, looking at what shapes the concept of whole-person care within the HIV sector.

1.1 Background Motivation

Improvements in HIV treatment have considerably increased prognoses for people living with HIV [2]. However, longitudinal studies have shown that, on the one hand, HIV is associated with comorbid conditions such as heart disease, anaemia and hypertension, [49] [74], whilst, on the other hand, antiretroviral treatment has been linked with the development of comorbidities such as diabetes mellitus [60]. This means that people living with HIV now live longer with multiple complex conditions, therefore the aim of HIV care provision is transitioning beyond a focus on medical treatment and adherence, to improving quality of life [59]. In the UK, where this study was based, recent advances in HIV treatment have meant the UK has surpassed UNAIDS 2020 targets, which aim for 90% of people living with HIV to be diagnosed, 90% be on treatment, and 90% show suppression of viral load - in the UK this target was hit in 2017 [62]. Building upon this success, a fourth metric has been proposed; that 90% of people with viral suppression have a good health-related quality of life [52]. This measure includes understanding both the incidence and impact of co-morbid conditions, and self-reported functional impairments such as fatigue and insomnia ([52]).

These metrics conceal inequities in HIV care and health outcomes. Complicating the picture is the pervasive social stigma associated with HIV - stigma being a "a social process, experienced or anticipated, characterized by exclusion, rejection, blame or devaluation that results from experience, perception or reasonable anticipation of an adverse social judgment about a person or group" [80]. HIV Stigma disproportionately impacts people from marginalised groups [34], and has a direct impact on engagement with care [41], resulting in inequalities in how groups are represented within the UNAIDS targets, even within a country which has reached the targets at an overall population level.

Identifying potential gaps in knowledge about the interpersonal relationships and socio-historical factors shaping care contexts is crucial to designing equitable technologies for HIV care. Best practice involves ongoing, equal participation of the intended care recipients in the steering of projects, and a commitment to improving engagement [15]. This must be facilitated by consideration of how structural inequities impact problem definition [51] – meaning that certain voices may not have been sufficiently heard in the initial framing of the issue - especially given the impact of HIV stigma in devaluing the perspectives of people living with the condition [29]. There have been calls for further research demonstrating how contemporary theories of knowledge and practice may be employed within design to construct epistemological/ontological angles to proceed from, to go from passive reaction to active world-building [72]. This requires expanding from focusing on individual interaction with technology, to situating these interactions within a broader understanding of the relationships and contexts that they are employed within, and the power dynamics that shape them. This study (reported herein) contributes tools for doing this, advancing a discussion about how ethical concerns in data-driven design are situated within broader structural causes (e.g., research motivated by the need to consider not just the impact of stigma, but the causes of it [56]. We contribute to a growing body of literature in the AI Ethics and Society (AIES) and Fairness, Accountability and Transparency (FAccT) communities that investigate socio-political dimensions of AI and suggests conceptual tools to inform equitable design practice [4] [6] [12][48] [67]. Connecting with Critical Digital Health Studies [55], we offer the following contributions; presenting empirical findings about the technological interventions that HIV Healthcare Providers (HCPs) favor, probing the ways in which epistemic injustices can invisibly influence these perspectives, and considering the implications of our findings for designing data-driven technology for HIV (self-)management.

2 RELATED WORK

This paper is situated in dialogue with AI ethics and Critical Digital Health Studies [ibid.], exploring the interplay between collaborative care practices, structural inequities and digital health design and how this can perpetuate social and epistemic injustice [18] [53].

2.1 Ethical Dimensions of Health Informatics

The use of technology for managing long-term conditions includes sharing of patient information such as electronic health records to facilitate patient agency in self-management, improve care provider management of other clinic-related information such as appointments, and facilitate peer support networks [57] [69] [81] [82]. Other studies have investigated using health apps to track adherence, via devices such as pill bottles which track time and date when bottle is opened and closed, a seeming lapse in adherence to medication triggering interventions such as text messages or phone notifications, to patients or to support workers [42], or developed apps to enable patients to track stress levels and mood in addition to medication adherence, and facilitate interaction with clinical staff and peers [32]. Within applications of PHI for HIV self-management run the themes of trust, impact of stigma, confidentiality. The impact of HIV stigma has led to a thorough focus upon confidentiality and related issues of security and trust around patient data [22] [57] , investigating participant perspectives on sharing certain types of data [21].

The introduction of smartphones has enabled development of several apps aiding in HIV self-management, resulting in increased amounts of patient-generated health data being recorded. This information may have useful applications not just in patient-involved but also in *data-driven* approaches to HIV Care, for example in monitoring risks associated with HIV [50], which would be of interest to a range of stakeholders involved in the current care system. Furthermore, the impact of the COVID-19 pandemic has resulted in many services being conducted remotely [23], with the UK seeing rapid expansion in the use of telehealth services during the pandemic [38], raising concerns about the quality of care provision. Although there are potential benefits of these modalities in administering healthcare, there are drawbacks too, with a lack of consensus on how they impact equity of access to care. Such technologies require rigorous ethical oversight if they are to meet the ethical and health needs of patients [14]. In order to design/ re-design technologically-mediated care to best fit the needs of patients, healthcare providers and other stakeholders need to understand how proposed tools intersect with the broader care environment, especially in light of systemic inequities.

2.2 Epistemic Injustice and Critical Health

Epistemic injustice takes place when knowledge contributions of an individual or community are afforded less visibility due to direct or indirect discrimination [39], including being denied "concepts to make sense of experience, procedures to approach the world, and standards to judge particular accounts of experiences" [64]. These denials can take different forms, whether resulting from inequities in assignment of credibility (testimonial injustice), inequities in available communicative tools (hermeneutic injustice) or indeed that the existence of these inequities prevents even the initial contribution of knowledge (anticipatory injustice) [25] [47] [54]. Evidence from the domain of public health has demonstrated that health inequities – the unfair distributions of health outcomes due to preventable causes – present in the provision of healthcare (including HIV care), are due at least in part to the presence of epistemic injustices [47] [63]. Furthermore, the knowledge practices of health research may contribute to and even exacerbate existing epistemic injustices [9]. Studies investigating perspectives of specific groups in order to interrogate existing dominant narratives can still reproduce reductive understandings and perpetuate injustices, as they are used to establish new "standpoints" which are considered representative of people who share demographic characteristics with the participants. In a similar vein of injustice perpetuating injustice, Lupton (2016) [55] positions health technologies as sociocultural artefacts which assume certain capabilities on the part of the user base, with technologies constructed based on these assumptions, and that tech outputs then have a material impact on users. Applying this within the specific domain of women's health or 'FemTech', Hendl and Jansky (2022) [43] examine the discriminatory assumptions underlying narratives of empowerment which are used to support development of period-tracking apps through several feminist conceptual lenses. In an analysis of promotional material about FemTech apps, they describe tensions which privilege certain groups over others underlying the general message of empowerment, concluding that further research is needed into user experiences of epistemic injustice.

In relation to Health and Care more broadly, epistemic injustice can impact on care due to "epistemic wrongs... that occur in the processes involved in knowledge production, use, or circulation" (p. 1465) [9]. The practical causes of such injustices include immediate constraints of clinical practice such as time pressures. Importantly, they exist at the structural as well as individual or interpersonal levels [3], which includes the design, development and delivery of data-driven technologies [70]. Drawing on such limited knowledge, care providers often generalize patient groups, leading to inappropriate responses to care needs, for example long-term illness care provision in West Africa negatively impacted if it does not conform to the practices developed globally [51]. Indeed, PHI tools can potentially reinforce medicalization of long-term conditions, reframing human issues to problems existing in isolation which come under the control of a medical professional [26]. Responses to these risks of medicalization includes suggestions to move away from designing PHI for structured clinical processes or conceptualizations [44], including to support people with HIV [27]. This outlook is complicated, however, by the potential for dual use of such technologies, for example, if data gathered when practicing self-care is potentially used for other types of care, especially if seamlessly feeding back to healthcare providers [61].

There is a tendency towards individualised approaches to HIV care; for example, a focus on the role of behaviour in HIV risk, which largely excludes the impacts of the communities and contexts within which individuals operate [63]. Furthermore, there are information asymmetries between sites of care, for example, a patient with HIV may not wish their primary care physician (e.g. General Practitioner to know about their status, due to factors such as impact of social stigma [65]. However, the trend towards increasing integration of healthcare systems and linking of datasets risks overriding this. Epistemic injustice provides a useful conceptual lens for looking at the design of tools used for capturing and interacting with patient-generated data, precisely because it foregrounds these tensions between the needs of the patients and the objectives of stakeholders involved in service design - the same tensions that underlies these concerns surrounding stigma and confidentiality in HIV care [11]. Given this potential to facilitate data capture for medical, insurance and pharmaceutical applications of AI, it is important to examine factors motivating development of PHI tools, and indeed the factors which are making these specific needs visible. Numerous studies have investigated barriers to sharing patient-generated data between providers and services, addressing worthy concerns including access to data, clinician trust in data validity and ability to interpret it [40] [57], however, some of these barriers are rooted in dismissal of patient data as unreliable, reflecting clinician distrust of patient-generated data [81]. These dismissals illustrate how the oft-foregrounded (and well-intentioned) perspectives of healthcare providers shape modalities of care. In the face of increasing datafication, critical engagement with the situated nature of expert perspectives is crucial to equitable design of technologically-mediated care. In doing so, we are better situated to examine the impacts of PHI tools beyond their individual use-cases, to consider them as relational elements of emerging ecosystems shaping future AI applications.

2.3 Summary

Given the risk of algorithmic harms compounding existing healthcare inequities, designing PHI tools for HIV self-management necessitates careful consideration of sites of epistemic injustice, including analysis of the interpersonal practices forming the intended context of technology use. Awareness of the presence and impact of epistemic injustices can also help facilitate critical reflection on the downstream implications of PHI tools, such as utilizing health data for medical AI or personalized insurance, and aid in deliberating the ethical and social impacts of these.

3 STUDY DESIGN

We now report on the study method and procedure, which investigated the ethical implications of designing data-driven technologies to support people living with HIV in self-managing their condition.

3.1 Aims, Objective and Approach

This study took place as part of a broader program of research investigating co-design of supportive technologies for HIV self-management (INTUIT: Interaction Design for Trusted Sharing of Personal Health Data to Live Well with HIV). We drew upon semi-structured expert interviews to explore the nuanced experiences of stakeholders supporting HIV care across the UK. We interviewed care providers in a spectrum of roles including those involved in central care such as clinicians, and those in peripheral roles such as developing new treatment regimens or negotiating inclusive insurance packages. This approach allowed for exploration of the everyday professional practices of stakeholders, contextualizing potential uses and implications of PHI tools. We set out two main aims; firstly, to understand the types of patient data that stakeholders involved in HIV care would wish to access, including their motivations for this; and secondly, to investigate their perspectives on the ethical and social implications of potential uses of patient data.

Our choice of method reflected our aim to understand the experiences and perspectives of participants "responsible for the development, implementation or control of solutions/strategies/ policies" [76]. These participants occupy a position of power in relation to their service users in the HIV population not only because they have access to privileged knowledge, but also because they can influence both the generation of this knowledge and the uses to which this knowledge is put [17]. Given this approach, the interview schedules were designed to guide the discussion but maintain flexibility to explore emerging concepts. The research approach taken by this study was approved by the departmental research ethics board at the lead author's University.

The interview structure consisted of three parts: Part 1 sought to understand the role of the participant and their team, their existing use of health data, and their motivations for this work. In Part 2 we investigated stakeholder perspectives on PHI use in the HIV community and the types of information/data they felt might be useful in their professional work, probing stakeholder perspectives on the nature and impact of intersections of identity within these areas. In Part 3 we set out to investigate stakeholder perspectives on the relationship between data-sharing and use, and the ethical considerations which they felt were central to this.

Table 1: Table of Participants

Role	Pseudonym
HIV Clinician (HCP)	Tom, Anna, Rocio
Youth Officer	Katy, Clara
Researcher	Zara, Riza
Insurance Broker	Nia
Pharmaceutical Representative	Ben

3.2 Procedure

We recruited nine stakeholder representatives across a range of roles, using purposive sampling to recruit participants through the advisory group of the research program described above. All participants were UK-based and held roles working with the HIV sector; healthcare, the pharmaceutical industry, insurance, Higher Education and Non-Governmental Organisations (NGOs). Pseudonyms were attributed in transcripts to protect participants' identities and to maintain confidentiality.

The interviews were conducted online on Zoom and audio recorded, transcribed by a third-party company which complies with the rigorous ethical standards of the University, and then analyzed using Reflexive Thematic Analysis (RTA) [20]. RTA is an inductive approach to thematic analysis that accounts for patterns in the data whilst allowing researchers to account for emergent themes, to investigate phenomena beyond participant experiences and relate subsequent findings to "wider socio-cultural contexts" [20]. We began by coding the experiences and motivations expressed by participants, iteratively grouping codes describing similar experiences and descriptions together into broader themes. The research team included an HIV peer researcher, who had research experience and lived experience [45], and regularly met to discuss codes and themes and update or create themes as deemed necessary. After several roundtable meetings to collectively develop the themes, we refined to the framework discussed in the paper.

4 CONTEXTUALIZING DIGITAL HEALTH

Our findings shed light on the main motivations and intentions expressed by stakeholders about accessing patient-generated data, and help illuminate the contexts that shape its generation, access and use. We begin by exploring which aims would motivate data access and development of AI models. We then explore categorizations of patient groups based on the types of patients which stakeholders hypothesized might be best suited to, or benefit most from, these aims. Next we move to the more individual level of tracking medication adherence, where we have more linear mappings of patient to care provider. Finally, we examine some of the assumptions underlying the core motivation of improving patient wellbeing.

4.1 Stakeholder Motivations and Intentions

In the first part of the interview, we asked about stakeholders' roles and discussed whether they would hypothetically find access to patient-generated data useful in their line of work. If so, we then explored how they would use it and why this would be beneficial. All

stakeholders wished to be able to access HIV care-related information: for example, which additional medications that patients were on, nutritional supplements they were taking, side-effects they were experiencing. Linked to this, they were also interested in lifestyle information; movement/exercise levels, sleep quality, weight, mood, and health issues such as headaches that could be side effects of HIV medications. Healthcare providers, researchers and the pharmaceutical researcher wished to be able to access information pertaining to mental health and functioning information: including anxiety levels, energy levels, productivity. For example, Nia's role was aiding people with long-term conditions (who are often excluded from insurance policies) in accessing insurance. She explained how accessing information about comorbidities and lifestyle could support applications to products such as life insurance by enabling more detailed modelling of risk. Meanwhile, clinicians felt that there could be benefits to accessing data that provides insight into the lifestyle factors and comorbidities of patients, in moving beyond the medicalization of measures such as Clusters of Differentiation 4 cell count or CD4 counts (which indicate the effectiveness of treatment):

> "All of those other things we were talking about before like lifestyle things like smoking, weight, fracture risk, and all of that stuff is about trying to...cardiovascular risk is monitoring for comorbidities, and then sexual health and wellbeing, mental health, and, I think, those are the main...those are the main areas" [Anna]

In accessing such information, the clinicians wished to gain a broader purview than blood test results, moving away from medicalization by gaining a holistic view of the patient through patient-generated data:

> "I think for my own personal work it would be, like, how people are feeling, and how they're getting on, day to day. Not just in a kind of mood sense, but also in, you know, are they getting the things out of their day that they find valuable, so kind of like functioning measures." [Rocio]

They also considered how reductions in resources could motivate development of such technologies, reflecting on how improvements in HIV treatment were contributing to a decrease in clinicians specializing in HIV. One outcome of this was felt to be that approaches to care would have to change, perhaps motivating a move towards use of data-driven technologies. Ben described how as stable patients increase, HIV management becomes simpler and presents less of a challenge, and is better suited to nurses, pharmacists...or, as suggested below, by technologies.

> "I understand the number of trainees going into HIV is substantially down. A lot of the cohort that got interested in HIV was precisely because it wasn't treatable, but now ...I think this means you're going to see task shifting to nurses and pharmacists which actually is probably appropriate in the sense of the clinical complexity of some of the patients now who are stable and well, which suggests the more patient data you can collect and the more guidance and the more air traffic controlling you can do is probably a good thing." [Ben]

However, the nurses may also be better suited because they are less likely to medicalize the patient and can provide a more relational role, perhaps contradicting the distanced "air control" view, which could encourage reliance on the data which Ben envisioned might prove useful for such a task. This suggestion to rely on data for treatment-related decisions can be seen as an example of how epistemic justices could result from (and be perpetuated by) limited perspectives of care providers, and be perpetuated in suggestions for design of self-management technologies.

4.2 Categories and Categorizations

When discussing experiences and first-hand knowledge of providing support, the stakeholders tended to focus on relational aspects, contextualizing practices by giving examples of the nuances of patient experiences and backgrounds and how these changed the nature of the care they supported. When discussing potential uses of data and PHI tools within stakeholders roles, and indeed their roles at a more abstract level, they talked in terms of categories. In order to manage their roles, stakeholders were engaged in quite complex categorizations of patients. At the most abstracted, these categorizations existed as a binary of "stable" and other, where other was most frequently referred to as "chaotic". This split was central to clinician and insurance stakeholder concepts of how to design for care, with participants describing the most relevant groups for such technologies as consisting of people engaged with care, categorized as 'stable', meaning that viral load is sustained at a very low level. Maintaining these categorizations of groups may be motivated by external factors, for example clinicians need to collect information on stable and other groups in order to fulfil administrative requirements.

> "I think if you were to look at HIV from, like, a policy point of view and the way that we, kind of, collect our stats and all of that, then we are meant to be categorising our patients into different groups and I think that's going to affect the way that we're paid. So, kind of, new patients, what they call stable patients, which would be the majority, and then complex patients." [Tom]

Another HIV consultant suggested that it might be best to design PHI tools for the more stable group, suggesting that already well-managed, health-literate patients might be the most suitable demographic;

> "You've got people that are very health literate. That are very good at accessing systems and, you know, a lot of gay men, for instance, are very educated, tech-savvy, very good at media[...] A lot of the stable patients would like it I think - especially our patients who are getting older, focus on their health quite a lot. To be able to provide that extra data or monitor themselves would feel empowering for them, as well. Because it may be that something comes up that we don't need to deal with, that they need to go to their GP about, for example...But there probably are a few patients who are slightly more chaotic and may also like the opportunity to be able to do this." [Anna]

Anna described a "spectrum" of patients with different capabilities and experiences, and reiterated the importance of third sector, community-based organisations in managing care for many marginalised patients. She contrasted the stable group described above with a marginalized group she described working with quite often; asylum seekers who "don't really know why they're in the clinic because they don't understand the system", and stressed the importance of collaboration with patients when developing new modes of care:

> "if you're talking about trying to empower people to help themselves, I think, you've got to look at it as a collaborative thing, and it's not some...I don't think it's necessarily clinic-delivered, but it's partnership-delivered."

The view from the pharmaceutical researcher revealed a similar binary classification, with Ben describing how two groups, stable and chaotic, had different requirements, with QoL being a priority for the former but perhaps less so for the latter:

> "There's definitely two camps in HIV management now of well... stable, informed, on top of it, maybe work to do in the fourth dimension, the patient-reported outcomes dimension of care... and then the other group which are still struggling to even face taking their medicines and are hard to reach and chaotic and HIV is not the biggest issue in their life basically."

These pre-existing categorisations potentially shaped how apps were likely to be conceptualised, considering that the needs and capacities for self-management by people deemed to be in these groups would influence the features and uses of data. Apps could be tailored towards those considered "stable" due to the expectation of greater engagement with them. The healthcare providers reflected on how the privilege of stability and lack of constraints to engage with care can even lead to better care, and greater access to and engagement with tech.

> "So, I think there's something...there are some patients, and again, I think maybe some of our older patients who've been diagnosed for a few decades and they tend to be some of our older, gay men, they seem to have a good idea of what they're taking. And, kind of, maybe just because they've been coming to clinics for longer and knowing what information we want. So, maybe they do." (Rocio)

As we illustrate with these quoted examples, a number of stakeholders (5 in total) suggested to design for the stable group. This was informed by several factors – perceptions of patients in this group as more likely to engage, as more knowledgeable and therefore suitable. Marginalized populations were thought to be less likely to engage with, have access to or understand the technologies proposed. Stakeholders also expressed concern over situations where engaging with PHI tools might potentially put patients at risk of physical as well as emotional harm.

Identifying groups who would benefit best from proposed tools is a standard approach to design. However, employing technology that reproduces the status quo also reinforces existing inequalities. In the case of developing further treatment modalities (such as better drugs) based on patient-generated data, this would mean less suitability to marginalized groups.

4.3 Situated Contexts of Care

This section considers stakeholder interactions within care provision and the contexts shaping them, and how the introduction of data-driven technologies into care might affect patient engagement, which has a knock-on effect upon visibility within the healthcare system and other support services. The vulnerability of patients came to the fore across different accounts, with participants carefully considering the social implications of these for providing care.

Participants discussed use of PHI for monitoring adherence, building upon existing categorisations of patient groups within the health system. Across stakeholders, a major reason for development of PHI tools to support self-management of people living with HIV, and access to data generated by these, involved adherence to medication. Their focus was on patient behaviour at a level of more individual care, although data regarding adherence was also considered vital knowledge for pharmaceutical companies developing medications. Clinicians were keen to have adherence information in order to be able to contextualise medical findings;

> "You want to look back at their bloods and you want to know that they've been undetectable and you...you know, because immediately if you're seeing somebody that's not got a good CD 4 count or an undetectable viral load, you're asking yourself why, like is it...is it an adherence thing?" [Anna]

However, sharing adherence data has social implications stemming from patient relationships with healthcare providers. Katy, who worked in youth support, discussed the relational nature of how young people report adherence to their medication. She described how they would build up relationships with the clinicians supporting their care, over years, resulting in a very close relationship. As a result of this relationship, perhaps perceived at a familial type of level, young people may be hesitant to report that they had not been regularly taking their medication.

> "Quite a big issue that we find is that a lot of young people find it really hard to be honest about their medicine adherence sometimes with their clinic teams... And I think that's really the sorts of interesting element; a lot of it is because they have grown up, a lot of them, going to this same sort of clinic team, same consultant, same nurse, from when they were quite young. And so there's a real interesting relationship and dynamic where they almost see this person as like an auntie or an uncle and they find it really hard, they feel like they're letting them down when they struggle."

Katy would find herself in a role of mediator for the anxious teen, "they've touchingly said, oh, I've got an appointment tomorrow and I know I've really messed up, and I'm really scared about telling them, can you help? And in those kinds of scenarios I will offer to talk ahead with the doctor".

Nearly all the stakeholders interviewed described the complex relationships between personal privacy, stigma and intersections

of identity. Tom, an HIV physician, reflected on the risks of even just accessing data about HIV care via a computer.

> "They may live with a lot of people who don't know their status, so trying to...being at home and being able to look something up on a computer when you've got kids around you who don't know about your HIV."

Katy, who worked with young people with HIV, was concerned that experience of stigma may reduce the ability of users to productively engage with PHI. For example, she suggested inherent risk in using technology which could be linked to HIV care, which recognised by another party might out the user.

> "But still, young people were nervous about having an app on their phone that would be about their HIV and about, you know, potentially, other people seeing that and then, you know, there are still a number of young people that would say, oh, I wouldn't actually use it, or I wouldn't download it, you know. Because I don't want...if one of my mates has got my phone, you know I don't want them to see it and Google it, or...you know."

In some situations, it might even be safer to only have direct human interactions, for example in cases where domestic situation meant disclosure of status could result in physical violence. Katy spoke about risks of abuse resulting from disclosure of status;

> "We know that there are people who live in homes where it's not safe for them to share their status. They might have an abusive partner, or something. So again, I would worry for those people. If their status was accidentally disclosed because they were using technology at home. You know, for some people it's almost safer for them to go somewhere to talk about their HIV than to do stuff at home. So, there are a few people like that in terms of safety as well as confidentiality, I think."

These concerns linked to participants' perspectives on common understandings within, or cultural differences between social groups, (perhaps including ties to morality and/or attitudes towards sexuality). Ben gave his perspective on the composition of patients living with HIV in the UK, reflecting on how different cultural norms affect how association of HIV with shame and vulnerability.

> "I think it partially reflects in the UK predominantly, HIV is a gay, white, male disease and that's often a pretty evocative group. I would say it's quite different amongst some of the black immigrant populations for whom HIV stigma is much, much, much worse."

Reflecting on the impact of social stigma upon disclosure of HIV status [65], Ben considered patient and stakeholder motivations (including direct care providers and others involved in the process), and how misalignments between these motives may present barriers to providing care.

> "And I think that the challenges sometimes with these monitoring things is it takes two to tango, meaning the patient, the person living with HIV has to want to allow it and the person at the other end, the doctor or the payer or whoever it is, the pharma company has to need it, and often those things don't align..."

The impact of stigma intersected with other factors. Participants raised concerns about the impact of inequities such as language barriers in access to healthcare technology, impact of geographic disparities or immigration status in access to healthcare, and so on. Marginalizations are interwoven with other inequities such as access to health technologies, or indeed who gains access to the data generated by them, given concerns about stigma and discrimination. Pat was concerned about her experiences of a lack of access to computing technologies:

> "Some people don't have phones, some people don't have access to the internet. Lots of people do, but it's definitely not even in terms of distribution. So, if we are, kind of, expecting people to have that...everyone to have that access, I think that would be unlikely to happen"

Given the prior discussion on patient categories, stigma often served to define concerns within the more "chaotic" group of those requiring care, for whom technologically mediated services were seen as less appropriate.

The accounts we discussed above, which show the importance of adherence to treatment and impact of stigma, illustrate the deeply interpersonal aspects of care provision. They also have implications about the impacts that data-driven technologies may have upon existing care practices. For instance, as earlier described, Katy highlighted how she has on occasion provided care as an intermediary between a young person and their doctor, in situations where their close relationship resulted in patient discomfort around revealing gaps in adherence to medication. In the situation she described, introducing technologies which would directly share adherence information with clinicians might result in inaccuracies in reported data, and remove the opportunity for a mediator to enable sharing of accurate data. This case illustrates why it is important to understand the situated nature of care as well as the behaviors that might be associated with direct interaction with technologies. In this case, the patient's fudging of adherence is due to the closeness of the relationship, rather than lack of trust; therefore, making the application more trustworthy would not address the issue. When discussing impact of stigma, Ben pointed out the importance that patients recognize that care provision matches their needs. The risk of stigma is not just that someone might not use an app, but that using an app associated with the stigmatised health condition might put them at risk. These issues complicated the relationship between the expressed intentions of care providers and the needs of care recipients, which we discuss in the next section.

5 DISCUSSION

Our findings illustrate stakeholder interest in (or active use of) PHI tools to support patient self-management (and resultant patient-generated data) in HIV care. Stakeholders were cognizant of the impact of intersecting marginalizations on patient interaction with PHI tools, discussing impacts of racism, stigma, the digital divide and poverty. They expressed some apprehensions regarding the impact of inequities in shaping this data, however the primary concern was found to be improving wellbeing. In this section we

suggest that historical, socio-political and technologically mediated Epistemic Injustices invisibly inform definitions of wellbeing and visions of how wellbeing can be designed for. We examine how epistemic injustice is surfaced in PHI and patient-generated data; an issue of particular concern given how patient-generated data has the potential to inform design of future care provision such as medication or patient pathways. We investigate how widely-accepted conceptualizations of wellbeing are shaped by intersecting marginalizations and consider how designing for wellbeing might unintentionally encode epistemic injustice into datasets and downstream development of medical AI models.

5.1 Motivations and Barriers

A key motivation for this study was to gain understanding of how healthcare providers might integrate patient-generated data and related data-driven models into care provision, and the motivations for doing so. We found that discussions of specific applications of PHI and data-driven technologies for care were framed in terms of a broader concern for wellbeing of people living with HIV. Although the discussions differed across stakeholders in many respects, all stakeholders were eager to improve the wellbeing of people living with HIV through data-driven technology design and use. For example, clinicians wished to gain a broader purview than blood test results, moving away from the epistemic injustices of medicalization [79] by gaining a holistic view of the patient. However, whilst wellbeing appears a broad and beneficent concept in the abstract, it is shaped by assumptions which surface in the context of application. One example of this is in deciding which groups stand to benefit most from designing for wellbeing based on information which reflects ongoing inequities in care provision [71]. In this section we explore the contexts within which wellbeing as a concept has developed, and the often-invisible role of the interplay of Stigma, adherence, and categorization of patient groups.

5.2 Paradigms of Knowledge

This concern with wellbeing was predicated upon the current goals of HIV Health organisations. In describing the aim of improving wellbeing, participants from Consultant, Insurance, Pharmaceutical and Youth Officer roles all referenced the proposed fourth 90 that has evolved from the 90-90-90 UNAIDS continuum (as described in Section 1.1 on HIV Care). The fourth 90 concept mirrors the stable and complex categorizations discussed in the previous section.

Despite the UK achieving the 90-90-90 aims, health related Quality of Life (QoL) amongst people with HIV, even when well-controlled by effective treatment, remains considerably reduced compared to those living without HIV [24]. Furthermore, even the rate of attainment of the first three measures varies between demographics within the UK. Trans (including non-binary) adults in the UK are twice as likely to be diagnosed late compared with cisgender adults [46]. [31] recently reported that among heterosexual patients, those from Black and minority ethnic (BAME) groups were diagnosed later than white group members, and although they received similar access to retroviral therapy, the BAME group was more likely to show a viral rebound. Indeed, Black and other/mixed patients were more likely to disengage from care and have gaps in attendance in clinic [31]. This can be attributed to various factors such as structural racism [37] which is well-documented to contribute to medical mistreatment [30] causing mistrust [66], reluctance to discuss diagnosis with others [13], and barriers associated with migration status [73].

Varying degrees of stigma result in disparities of HIV care and outcomes, compounded by interactions of multiple stigmas, for example stigma due to both HIV and sexual orientation in certain faith-based communities [16]. Another factor influencing wellbeing is anticipated stigma (stigma which the individual believes they will face from others if they disclose their condition), which is linked with a lower quality of life in studies of people living with long-term health conditions [35]. Effects of anticipated and enacted Stigma have negative implications for health and wellbeing of patients, associated with physical outcomes such as lower CD4 counts [36]. This may be due to poor access to care; one study found that participants who experienced high levels of Stigma also were far more likely to report barriers in access to care, and to have lower mental health status as well as lower levels of adherence [68]. Other studies have also charted a link between stigma and low adherence, due at least in part to reduced coping mechanisms and outside support [34]. In the same vein in which Stigma impacts patient engagement with care, in this paper we discussed how Stigma may impact engagement with technology used as a tool in care (for instance, how an app focused on HIV treatment effectively becomes a signifier of HIV). These concerns bring to mind recent discussions of the ramifications of using apps for self-management of reproductive health. Changes in local law can mean that even apps abiding by ethical norms can suddenly put users at risk.

Indeed, certain patients prefer avoiding technological interventions and would rather track their experiences using analogue approaches, for example with pen and paper [21]. As such, where technology is used to establish metrics or indicate willingness to engage in self-management, it produces a distorted picture of patient groups which has further implications in shaping care-providers' understandings of, and attitudes towards those deigned to be in these groups. Given the existing epistemic and socio-historical injustices around HIV management, and the recognised differences in power and access to resources among people living with HIV, it raises issues regarding the role of technology in complicating ideals of care and wellbeing, and mandates interrogations of why and how technologically mediated care could or should be designed.

5.3 Implications for AI Ethics

In this paper, we have illustrated how epistemic injustices can be unintentionally reproduced in PHI tools and resultant data, cogent with recent studies evidencing inequities in HIV care and stigma as intersectional in nature [75]. In framing, designing and deliberating the ethico-onto-epistemological implications of PHI tools, especially those which generate patient data, we should carefully consider the context which the proposed technology is intended to augment, paying particular concern to the epistemic injustices which we risk both creating and perpetuating. This involves explicit consideration of which types of knowledge are being drawn from, conscious of the danger of "bringing population level reasoning to grassroots practice" [1]. When oversimplified observations drawn

from high-level populations are transformed into concrete recommendations, and generalised to other facets of identity, boundaries are drawn between categories and lived experiences. Rather than facilitating further investigation, lived experience of different intersections is then increasingly excluded. Testimonial, hermeneutic and anticipatory injustice implicitly form the landscape shaping PHI tools, medical AI and indeed all applications of AI.

Identifying the specific categorization of the intended end user was important to many of the stakeholders we spoke with as part of this study. However, rather than seeing universal inclusivity as an aim, many proposed that we consider whether or not inclusion is indeed useful or ethical. Certain stakeholders argued this based on practical efficiency, whilst others voiced concern about a risk of tokenization. While designing for visible groups risks excluding those on the margins and reproducing epistemic injustices, tokenization and even the risks of visibility are legitimate concerns, given existing socio-political inequities. This combination of concerns prompts a re-examination of the contextual practices which produce conflicting attitudes towards inclusivity in design. We propose epistemic justice as a tool for thinking through how, and whether, PHI tools and AI models are appropriate given the complexities making up the sites of their proposed application [7], and for scaffolding ethical deliberation regarding their downstream impacts.

5.4 From Epistemic Injustice to Epistemic Justice

We have examined how epistemic injustices can invisibly persist even in care- and domain-centered contexts. Patient categories such as "stable" and "chaotic" are underpinned by cascading epistemic inequities, complicated by compounding marginalizations. The "stable" category primarily consists of groups familiar with care provision services, frequently targeted by public health campaigns and research, and therefore better situated to consistently engage with care. These inequities in care access and management are acknowledged and indeed actively tackled by HIV care providers. However these considerations can be unintentionally sidelined in favour of designing "fair" or "responsible" technologies which are tacitly already assumed broadly suitable. Taking an epistemic justice-informed approach requires mapping the socio-political and historical inequities shaping these assumptions, identifying how these might be reproduced, and addressing these to enable more equitable knowledge construction in PHI and related applications of AI.

Challenging epistemic injustice requires active and situated consideration on the part of the party designing and judging the knowledge contribution - consideration of how social power and intersections of identity affect whether and how knowledge is received [3][19] [78]. There is a shared burden of responsibility between multiple actors in processes of designing and developing AI, particularly in high-stakes domains such as healthcare. Data and AI ethics work plays a crucial role in directing where and to what our ethical attention should be paid. When interviewing domain experts, we should investigate the implications which changing embodied care practices can have for the resultant data. Co-creation can help direct this, helping map sites of unequal knowledge valuation and inclusion, but should form part of a broader mapping of how power inequities shape how knowledge is valued and prioritized, and how datasets can invisibly reproduce systemic inequalities. Rather than looking at AI and data ethics in terms of recourse to challenge specific components of systems such as anonymization of data, the approach is to actively understand and be able to communicate the contexts of application, and in doing so challenge injustice.

Notions of epistemic (in)justice provide useful conceptual tools for understanding the specific nature and contexts of care provision, to aid in designing from the margins [28]. That is, rather than designing for stable or 'all' groups, we should rather start with the marginalised groups, actively charting the existence of epistemic injustice 'fault-lines' [1]. Any approach that aims to design for a clearly visible group such as stable patients requires careful consideration of the conditions that enable patients to exist in this group, or risks perpetuating existing injustices. Rather than isolated tools for management of wellbeing, PHI tools exist within a wider network consisting of patients, clinicians, researchers, and the broader healthcare system. This is of importance given stakeholder interest in designing AI models which explicitly draw upon data generated by users, where gaps in data mean poorer quality care for individuals in the missing groups. These considerations are even more crucial given that resource scarcity in the domain of public health can see datasets re-appropriated to fulfil needs such as policy development [5].

6 CONCLUSIONS

Designing digital tools to support management of long-term conditions is a laudable aim requiring ethical deliberation on the implications of epistemic injustice, such as amplification of inequities when patient data is reused to inform other sites of care provision. This study examined the complexities characterizing the framing of potential PHI tools, especially those aiming to employ AI to inform development of personalized medicines and care pathways. Herein we presented findings about stakeholder perspectives on the design of PHI tools, patient data and their use in HIV care. Care providers were motivated by the potential for PHI tools and patient data use to increase engagement with care, and support wellbeing, particularly in the case of patients aging with HIV and other long-term conditions. Contributing to ongoing discussions in the AI ethics community, we have illustrated how epistemic injustice can serve as a conceptual tool for mapping gaps in knowledge (re)production in the design of data-driven health technologies.

The concrete 'whats and whys' of patient data access and modelling appear abstracted from the day-to-day interactions of the end-user, but when oriented in broader interpersonal and structural contexts the boundaries become fuzzier. Furthermore, when patient data loops back to feed into design of care, patients are placed in a central but passive role in the development of new treatments and products, even if this is made invisible. As such, a critical understanding and engagement with the processes of knowledge production which guide health-care practices – both within the current socio-cultural environment and from potential mediation by data-driven technologies – is valuable to ethical and just development of technologies for people living with potentially stigmatizing long-term conditions.

ACKNOWLEDGMENTS

This study is part of the INTUIT research project funded by EPSRC EP/R033900/2: 'Interaction Design for Trusted Sharing of Personal Health Data to Live Well with HIV'. We sincerely thank our research participants for their time and contribution.

ABSTRACT

Social determinants of health (SDOH) – the conditions in which people live, grow, and age – play a crucial role in a person's health and well-being. There is a large, compelling body of evidence in population health studies showing that a wide range of SDOH is strongly correlated with health outcomes. Yet, a majority of the risk prediction models based on electronic health records (EHR) do not incorporate a comprehensive set of SDOH features as they are often noisy or simply unavailable. Our work links a publicly available EHR database, MIMIC-IV, to well-documented SDOH features. We investigate the impact of such features on common EHR prediction tasks across different patient populations. We find that community-level SDOH features do not improve model performance for a general patient population, but can improve data-limited model fairness for specific subpopulations. We also demonstrate that SDOH features are vital for conducting thorough audits of algorithmic biases beyond protective attributes. We hope the new integrated EHR-SDOH database will enable studies on the relationship between community health and individual outcomes and provide new benchmarks to study algorithmic biases beyond race, gender, and age.

1 INTRODUCTION

The increasing adoption of electronic health records (EHRs) in modern healthcare systems has facilitated the development of machine learning (ML) models to predict the progression of diseases and patient outcomes. Many such models [47, 55, 77] incorporate clinical factors (e.g., labs, vitals, medication, procedures) and basic demographic features (e.g., age, gender, and race) to identify high-risk patients. However, a patient's clinical profile only offers a partial view of all the risk factors that affect their health. Understanding the conditions of their living environment may help to fill in the missing pieces and benefit patients' health and medical care. Human health is affected by many non-clinical factors, commonly known as social determinants of health (SDOH).

The Healthy People 2030 initiative [58], developed by the US Department of Health and Human Services, describes SDOH as "the conditions in the environments where people are born, live, learn, work, play, worship, and age that affect a wide range of health, functioning, and quality-of-life outcomes and risks." They grouped SDOH into five key domains: (1) economic stability [19, 116], (2) education access and quality [52, 73], (3) health care and quality [63], (4) neighborhood and built environment [74, 90], and (5) social and community context [25, 89].

Across all five domains, SDOH can have either a direct or indirect impact on one's health. At a high level, they can be viewed as individual-level determinants or community-level determinants [21]. The former determinants are specific to a person, and examples include education level, annual income, and family dynamics. Access to individual-level SDOH is limited due to the lack of standardized and validated SDOH screening questions [21] and privacy concerns [87]. In contrast, community-level SDOH measure broader socioeconomic, neighborhood, and environmental characteristics such as unemployment rate, access to public transportation, and air pollution levels. They serve as "community vital signs" [12] that

reflect complex societal factors and health disparities that influence one's health [2, 17].

Population health studies have identified many SDOH to be strongly correlated with acute and chronic conditions [6, 38, 41, 45, 102]. SDOH are also underlying, contributing factors of health disparities (e.g., poverty [32, 46, 128], unequal access to health care [25, 35], low educational attainment [8, 36, 52], and segregation [22, 107]). However, to date, there has been less focus in the ML community to include SDOH in common EHR prediction tasks because many SDOH measures are poorly collected, lack granularity, or are simply unavailable. An American Health Information Management Association (AHIMA) survey [96] finds that most healthcare organizations are collecting SDOH data, but they face challenges with a lack of standardization and integration of the SDOH data into EHR and patient distrust in sharing the data. Thus, while SDOH are being increasingly studied in population health [63, 108, 135] and primary care settings [71, 96], data limitations have left the association between SDOH and critical care outcomes largely unexplored.

In this work, we investigate the impact of incorporating SDOH features on common EHR prediction tasks in the intensive care unit (ICU). We first link MIMIC-IV [68], a publicly available EHR database, to external SDOH databases based on patient zip code. We then train models on the common tasks of mortality and readmission risk, evaluating the contribution of SDOH as compared to the EHR data alone. We find that adding SDOH does not improve model performance in the general patient population. We do note that, as compared to the EHR data alone, incorporating SDOH can lead to better-calibrated and fairer models in specific subgroups, with varying levels of contribution depending on the population and predictive task. Finally, we illustrate that fairness audits based on both protective attributes and SDOH features help to connect the commonly observed disparities to the underlying mechanisms that drive adverse health outcomes downstream.

Our work makes three main contributions.

- We release a publicly accessible database that combines EHR data with SDOH measures. To the best of our knowledge, this is the first public EHR database that contains structural features that span all five defined SDOH domains. The database will enable new studies on the relationship between community health and individual clinical outcomes.
- We investigate the impact of incorporating SDOH in predictive models across three tasks, three model classes, and six patient populations. We find that the inclusion of SDOH can improve performance for certain vulnerable subgroups.
- We demonstrate that SDOH features enable more fine-grain audits of algorithmic fairness, reporting the FPR parity – the difference in false positive rates (FPR) – across intersectional patient subgroups.

2 RELATED WORK

2.1 SDOH in Health Prediction

A number of studies in population health have attempted to assess the impact of social factors on health [2, 18, 84, 106]. There is a large, compelling body of evidence showing that a wide range of SDOH is strongly correlated with health outcomes, such as sepsis [6], heart failure [30], pneumonia [89], cardiovascular disease [45], and diabetes [129, 134]. A particular study found that 40% of deaths in the United States are caused by behavior patterns that could be modified by preventive interventions and suggested that only 10-15% of preventable mortality could be avoided by higher-quality medical care [85]. Other studies have also indicated that the effect of medical care may be more limited than commonly believed [63, 81, 82]. However, there are active controversies regarding the strength of the evidence that suggests a causal relationship between SDOH and well-being. These researchers are increasingly utilizing SDOH to predict individual health outcomes [115, 141].

While several studies have shown that machine learning models can predict individual patient outcomes, such as in-hospital mortality [47, 51, 77, 92, 134] and readmission [49, 77, 110], very few have incorporated SDOH into the models due to the lack of granular and high-quality SDOH data at the individual level.

Due to the limited availability of individual-level SDOH data, many studies are limited to community-level SDOH data [28]. Most found that community-level SDOH do not lead to improvement in model performance [15, 66, 126], partly due to the low data resolution. In contrast, researchers who are able to access individual-level SDOH generally report improvements in the model's predictive performance [28, 43, 91]. These studies often focus on a specific outcome for a specific patient group, such as HIV risk assessment [43, 95] and suicide attempts [130, 140]. There have also been studies of model improvements for readmission and mortality prediction in specific subgroups, such as the elderly and obese [138]. One has shown that integrating SDOH into predictive models can improve the fairness of the prediction in underserved heart failure subpopulations [80].

Despite a growing body of SDOH-focused research, the relationship between SDOH and critical care outcomes is unclear. While some have argued that the ICU is not an appropriate setting to collect and identify SDOH, there are several reasons why it could be essential. For example, critical conditions place high demands on the patient and their social network [88, 123]. Social isolation may increase the risk of adverse outcomes, such as mortality [123]. By incorporating SDOH into MIMIC-IV, our work investigates the contribution of community-level SDOH on common EHR prediction tasks in a multi-year cohort in the critical care setting.

2.2 SDOH in EHR

In order for SDOH features to be readily incorporated into risk prediction models, they need to be collected and documented with individual health outcomes. EHRs contain clinical information about patients, such as medical history, vital signs, laboratory data, immunizations, and medications [24]. In the United States, few SDOH features are currently documented in structured EHR data fields due to the lack of adoption of standardized and validated SDOH screening questions [21]. The set of SDOH features available for research use is typically limited to insurance type, preferred language, and smoking and alcohol use, but SDOH information can also be extracted from unstructured EHR data (i.e. clinical notes) [20, 43, 93]. SDOH may also be captured in billing codes [5], but they have not been widely utilized by providers [67].

The integration of SDOH in EHRs is further delayed due to concerns regarding privacy and misuse [87]. The United States Public Health Services Syphilis Study at Tuskegee (Tuskegee Study) among African Americans [131] and efforts to sterilize American Indians [37, 76] are examples of a dark history of structural inequities in healthcare and unethical medical experimentation against racial and ethnic minorities. As a result, mistrust of the healthcare system and medical research has been well documented among minority groups [16, 33, 42]. The collection and utilization of SDOH require the consent and trust of the patients. Patients who identify with populations that medical establishments and medical researchers historically mistreat might not want to share any personal or sensitive information.

Overall, current EHR-derived SDOH data do not constitute a comprehensive set of SDOH domains. In this study, we link a large, multi-year EHR dataset to public SDOH datasets covering *all five SDOH domains* to comprehensively study the relationship between the community-level SDOH and patient outcomes.

2.3 Fairness and Bias in Healthcare

While much work has been done in algorithmic fairness and bias in health, most of the studies that focused on group-based fairness have only examined bias from the lens of protected attributes, namely age, gender, and race [1, 11, 26, 27, 56, 59, 83, 97, 113, 114, 117, 136, 137]. Recent fairness literature has underscored the importance of measuring biases from multidimensional perspectives, focusing on social processes that produce the biases [53, 62, 112].

There is strong evidence that intersectional social identities are related to a patient's health outcomes [71, 114]. Capturing social context beyond protected attributes in the form of SDOH is thus vital for this cause. For example, in the primary care setting, researchers have observed a negative correlation between the odds of receiving appropriate prevention and screening and the number of social risk factors experienced by the patient [71]. The more factors a patient was living with, the less likely they were to receive care such as a mammogram screening or vaccinations. This is not something that can be detected through race or gender alone.

Moreover, a recent meta-analysis [127] ranked 47 studies using a self-developed SDOH scoring system based on the type and number of SDOH features used. The researchers found that Black patients had significantly higher prostate cancer–specific mortality (PCSM) than White patients when there was minimal accounting for SDOH. In contrast, studies with greater consideration for SDOH showed the opposite: Black patients had significantly lower PCSM compared to White patients. The findings of this meta-analysis should not be interpreted as suggesting that racial disparities do not exist. Rather, it suggests that there is a significant interaction between race and SDOH, and health equity researchers should incorporate SDOH features into data collection and analyses to better address the long-standing disparities in healthcare [131].

We hope the new integrated MIMIC-IV-SDOH dataset will enable more studies that follow the complex hierarchical system that defined advantaged or disadvantaged subjects in the first place. Our work serves as a first effort, and we demonstrate how SDOH features allow for more granular, actionable algorithmic audits.

3 EHR-SDOH DATABASE: MIMIC-IV-SDOH

The MIT Laboratory for Computational Physiology (LCP) developed and maintains the publicly available Medical Information Mart for Intensive Care (MIMIC), a database on patients admitted to the emergency department (ED) and intensive care units (ICU) at the Beth Israel Deaconess Medical Center (BIDMC) in Boston [69]. The database is used by researchers in over 30 countries for clinical research studies, exploratory analyses, and the development of decision-support tools [103]. The current version, MIMIC-IV, contains detailed, de-identified data associated with over 70,000 ICU stays from 2008 to 2019 and over 400,000 ED stays from 2011 and 2019. Yet, due to the lack of high-quality SDOH data, none of the studies or tools built based on MIMIC account for SDOH measures beyond basic demographics such as insurance, and language. To enable the study of the relationship between community characteristics and individual health outcomes, we create the MIMIC-IV-SDOH database by linking MIMIC-IV to three public SDOH databases (Table 1):

(1) County Health Rankings (CHR) [34]
(2) Social Vulnerability Index (SVI) [23]
(3) Social Determinants of Health Database (SDOHD) [4]

This database will be made available on PhysioNet [48].

3.1 Public SDOH Databases

While there exist other SDOH databases, such as Area Deprivation Index [72] and Atlas of Rural and Small-Town America [125], they are either domain-specific or not frequently updated. Because MIMIC-IV contains ICU stays from 2008 to 2019, we focus on databases with SDOH variables that span multiple years and all five SDOH domains, as defined by Healthy People 2030 [58].

3.1.1 County Health Rankings (CHR). CHR evaluates counties within each state in the United States based on modifiable health determinants and is updated annually. CHR estimates that clinical care only accounts for 20% of all contributors to long-term health outcomes, specifically the length and quality of life. The remaining 80% stems from health behaviors (30%), physical environment (10%), and social and economic factors (40%) [63].

3.1.2 Social Vulnerability Index (SVI). Based on data from the American Community Survey (ACS), SVI evaluates social factors across four themes: socioeconomic status, household composition and disability, minority status and language, and housing type and transportation. Although the index was designed to assess community preparedness and resilience in face of natural hazards, SVI has been used in many population health and health equity studies

Table 1: Characteristics of the final MIMIC-IV-SDOH tables where d is the number of SDOH features.

SDOH Database	Data Version/Year	Geographic Level	d
CHR	2010-2020	County	163
SVI	2008, 2014, 2016, 2018	County	160
SDOHD	2009-2020	County	1327

[10, 70, 78, 121, 135]. For example, communities with higher levels of social vulnerability experienced greater COVID-19 incidence and mortality [64, 70, 121]. Unlike CHR, SVI is available at both the county level and census tract level.

3.1.3 Social Determinants of Health Database (SDOHD). To incorporate more granular SDOH data into MIMIC-IV, the last database used in the integration is the Social Determinants of Health Database (SDOHD), which is available at the county, census tract, and zip code levels. The database was recently developed to provide a range of well-documented, readily linkable SDOH variables across domains without having to access multiple source files. SDOHD is curated based on the five key SDOH domains defined by Healthy People 2030: economic stability, education access and quality, health care and quality, neighborhood and built environment, and social and community context.

3.2 EHR-SDOH Integration

The creation of the integrated MIMIC-IV-SDOH database is carried out in three steps.

Step 1: SDOH Data Acquisition. For each SDOH database, we concatenate all datasets released between 2008 and 2020. We map each feature to one of the five SDOH domains and provide detailed documentation.

Step 2: Geographic Crosswalk. Although SVI and SDOHD are available at the census tract level, we only use county-level data to minimize the risk of patients being identified. Each patient's zip code is mapped to a county using the crosswalk files provided by the United States Department of Housing and Urban Development (HUD) [133]. The files contain a residential ratio column, the ratio of residential addresses in the zip-county area to the total number of residential addresses in the entire zip. Because the mapping is many-to-many, the residential ratio is treated as the probability that the patient with zip code z lives in the census tract t or county c, as suggested by the HUD [40]. Note that only patients with Massachusetts zip codes that are in the HUD crosswalk files are included in the final MIMIC-IV-SDOH dataset.

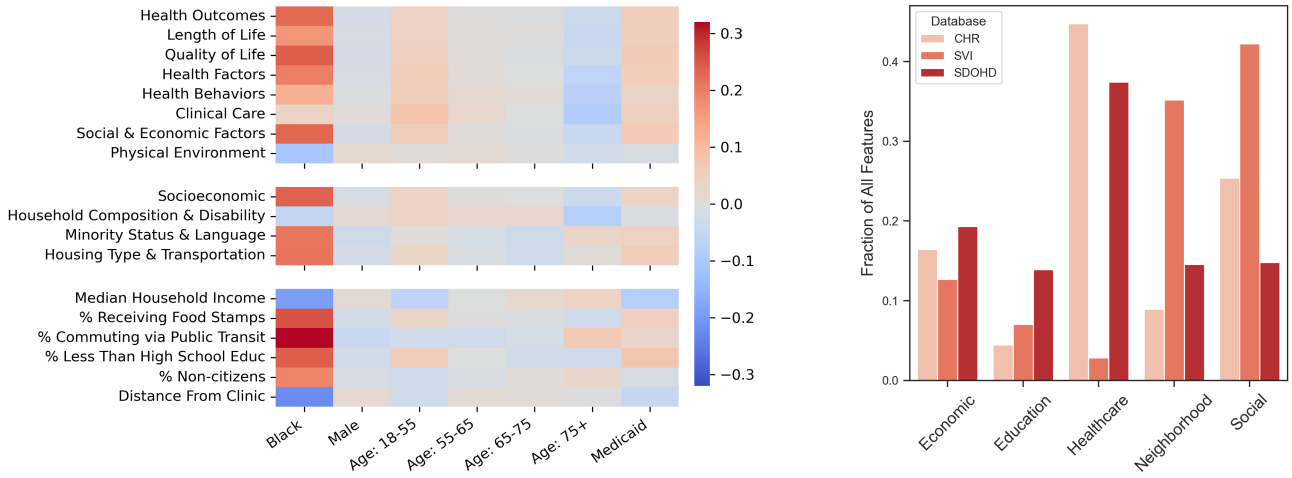
Step 3: Data Merging. MIMIC-IV is merged with each of the three SDOH databases using the geographic location and the SDOH data year closest to the year of admission.

3.3 Comparison of SDOH Features

The demographic features in MIMIC-IV, such as race and gender, are sometimes used as proxies for SDOH features, such as socioeconomic status and health behaviors [27, 111]. We find that many community-level SDOH features are weakly correlated with race in MIMIC-IV. For example, three SDOHD features, the percentage of households that receive food stamps, the percentage of workers taking public transportation, and the percentage of the population with educational attainment less than high school are all weakly and positively correlated with the Black race (Figure 1A).

Though to a lesser extent, subindices from SVI (e.g., socioeconomic) and CHR (e.g. health outcomes, quality of life, and social and economic factors) are also weakly associated with race. There are no strong correlations between SDOH features and other tabular features such as labs, risk scores, and Charlson comorbidities.

To better illustrate the type of features in each SDOH database, we manually map each feature to one of the five SDOH domains (Figure 1B). The CHR and SDOHD features are predominantly of the Healthcare Access and Quality domain. SVI emphasizes the Neighborhood and the Built Environment domain and the Social and Community Context domain more.



(A) Pearson correlation coefficients between basic demographic features and selected features in CHR (top), SVI (middle), and SDOHD (bottom).

(B) Distribution of features in each SDOH database by domain.

Figure 1: Comparison of features in the MIMIC-IV-SDOH databases. SDOHD is the most comprehensive and granular SDOH database of the three. Its features are more correlated with race than CHR and SVI indices. Each database emphasizes a set of SDOH domains more than others.

4 DATA AND METHODS

Our primary goal is to determine how incorporating SDOH in ML models could impact predictions of acute and longitudinal outcomes. Leveraging the newly created MIMIC-IV-SDOH database, we assess the impact from the perspective of classification performance and group fairness. We also provide a preliminary investigation of the possible mechanisms behind the contributions of SDOH to model performance or the lack thereof.

4.1 Data

In this study, we analyze five patient populations in the MIMIC-IV-SDOH database to assess the impact of SDOH across three tasks. MIMIC-IV data comes from a single EHR system in one geographic location, so the variation in the community-level SDOH features might be too low to be informative. Many past studies that used community-level SDOH features with EHR data from a single hospital or region ended with similar conclusions [28]. To examine the generalizability of our finding, we compare the MIMIC-IV cohort to a patient population in the All of Us Controlled Tier Dataset v6 [120] for the task of 30-day readmission. Unlike MIMIC-IV, which comes from a single hospital in Boston, the All of Us dataset contains patient-level data from more than 35 hospitals across the United States. Because of this difference, the variation in the SDOH data in All of Us is much greater than that in MIMIC-IV (Figure B1). In addition, based on the distribution of SDOH features, we note that the patients in MIMIC-IV are on average more affluent and more educated than the patients in All of Us.

4.1.1 MIMIC-IV-SDOH. Our analysis only includes adult ICU patients (i.e. over 18) from MIMIC-IV v2.2 with a hospital length of stay of at least 3 days. The cohort contains 42,665 patients and a total of 54,380 admissions.

Task Definition. We focus on three common classification tasks: (1) in-hospital mortality, (2) 30-day readmission, and (3) one-year mortality. Patients who have expired during a stay are excluded from predictions of 30-day readmission and one-year mortality. For 30-day readmission, we only consider non-elective readmissions.

Patient Population Definition. A recent study suggests that the impact of incorporating SDOH in predictive models varies by subpopulation – vulnerable populations like Black patients and the elderly are likely to benefit more from the inclusion of SDOH [13]. Moreover, several studies have suggested that SDOH are strongly associated with glycemic control [129], as well as diabetic risk, morbidity, and mortality [60]. Diabetic patients also use significantly more healthcare resources compared to patients with other chronic diseases [44]. In fact, they account for 31% of all ICU patients in MIMIC-IV.

Thus, in addition to the cohort of all ICU patients, we evaluate five subgroups:

(1) Diabetic patients
(2) Black diabetic patients
(3) Elderly diabetic patients over 75 years old
(4) Female diabetic patients
(5) Non-English speaking diabetic patients

On average, all five of these subgroups have more comorbidities compared to the general ICU patients (Table B1).

Data Pre-processing. To better understand the contribution of different types of features to model performance, we divide the entire dataset into a total of 15 feature sets (Table 2) and train separate models on each. These feature sets can be broadly classified into three categories: SDOH features alone, EHR features alone, and SDOH features combined with EHR features.

Table 2: Breakdown of feature sets by the type of EHR data contained

EHR Data Type	Feature Set
No EHR Data/SDOH Alone	`CHR`
	`SVI`
	`SDOHD`
Structured EHR Data (Tabular)	`Tabular`
	`Tabular+CHR`
	`Tabular+SVI`
	`Tabular+SDOHD`
Unstructured EHR Data (Clinical Notes)	`Notes`
	`Notes+CHR`
	`Notes+SVI`
	`Notes+SDOHD`
All EHR Data	`All`
	`All+CHR`
	`All+SVI`
	`All+SDOHD`

For the EHR features, we include two different data modalities: tabular data and discharge notes. To enable fair comparison across the three tasks, we use the same tabular features and sections of the discharge notes in all prediction tasks. Tabular features include basic demographics, Charlson comorbidities, labs from the first 24 hours of stay, and risk scores (APSIII, SAPS-II, SOFA, and OASIS). The following sections from discharge notes are included: chief complaint, present illness, medical history, medications on admission, allergies, major surgical or invasive procedure, physical exam on admission, pertinent results on admission, and family history.

Before separating patients into different patient populations, we use median imputation for numerical features before performing standard scaling and constant imputation for categorical features before one-hot encoding. Median imputation is used instead of mean imputation in consideration of skewed data. We also apply principal component analysis (PCA) to reduce the dimensionality of the SDOH data, which is particularly useful as many of the SDOH features are strongly correlated. We retain principal components that explain at least 0.99 of the variance in the data.

Discharge notes are stripped of explicit indicators of in-hospital mortality before being tokenized and lemmatized. Corpus-specific stop words are removed by filtering terms with a document frequency greater than 0.7. Terms with a document frequency less than 0.001 are also removed. Lastly, the notes are converted into a Term Frequency-Inverse Document Frequency (TF-IDF) representation with a vocabulary of size $|V| = 11,751$ words.

4.1.2 All of Us Cohort. Because the All of Us dataset is made up of primarily living participants, we focus on the prediction of 30-day readmission. We only include adult participants who had an in-patient hospital stay between 2014 and 2021. Unlike MIMIC-IV, the hospital stays in All of Us are not limited to the ICU, so these patients have fewer comorbidities on average (Table B1).

We exclude patients who stayed less than 3 days in the hospital and didn't have any lab results in the first 24 hours; these are the same labs used in MIMIC-IV. We have 13,324 patients and 21,555 admissions in the final All of Us cohort, representing all 50 US states but Kentucky. More than 50% of the patients come from the Northeast region.

The All of Us dataset only has 7 community-level SDOH features sourced from the 2017 ACS via a three-digit zip code linkage (subsection A.3). Tabular features in the All of Us dataset are the same as those in MIMIC-IV except for clinical risk scores, which are not available. We apply the same data pre-processing techniques on both datasets. Because the All of Us dataset has no clinical notes, we only train models on three feature sets: (`Tabular`, `SDOH`, and `Tabular+SDOH`).

4.2 Models Benchmarked

We train three types of machine learning models – logistic regression [101], random forest classifier [101], and XGBoost classifier [29] – for each task, patient population, and feature set combination. Each dataset is partitioned into 70:30 train-test splits. To prevent data leakage, no patient appears in both the training set and the test set. Each model is tuned through random hyperparameter search [14] under broad parameter distributions. See subsection A.1 for additional training details.

4.3 Evaluation

4.3.1 Classification Performance. We evaluate the models in terms of three primary metrics: 1) area under the receiver operating characteristic curve (AUROC), 2) area under the precision-recall curve (AUPRC), and 3) expected calibration error (ECE). While AUROC is a standard metric to assess accuracy, we include AUPRC to account for class imbalance and ECE to measure the reliability of the prediction. We also use recall as a secondary metric. While threshold selection is complex, cost-dependent, and application-specific, we use a classification threshold of 0.5 for demonstration purposes. 95% confidence intervals are constructed for all metrics by sampling the test set for 1000 bootstrap iterations [39].

4.3.2 Group Fairness. In addition to classification parity, we evaluate the FPR parity – based on the equality of opportunity definition of group fairness [54].

$$\hat{Y} \perp\!\!\!\perp G \mid Y = 0$$

In other words, the probability of the model predicting a negative outcome is independent of group attribute G, conditional on the outcome Y being a true negative.

We examine the differences in FPR across subgroups defined based on the following attributes: (1) race, (2) age, discretized into four bins, (3) gender, (4) median household income, (5) percentage of workers commuting via public transportation, (6) percentage of the population with educational attainment less than high school, (7) percentage of the population receiving food stamps, and (8) the percentage of non-citizens. The SDOH features are discretized into quartiles.

5 IMPACT OF SDOH ON CLINICAL PREDICTION TASKS

5.1 Impact of SDOH on the General Population

We first examine the impact of SDOH on the general ICU patient population in MIMIC-IV. We find that the inclusion of community-level SDOH in models does not help with predictive performance, measured by AUROC and AUPRC, but can lead to better-calibrated models with a lower FPR. We validate this finding on a more geographically diverse dataset: the All of Us dataset.

5.1.1 No Improvement in Model Accuracy. First, SDOH features alone, without any EHR data, are not predictive of individual patient outcomes. The mean test AUROC of the XGBoost models, the best models in terms of AUPRC, trained on SDOH alone is below 0.60 across all tasks, substantially lower than those trained on tabular EHR features and the TF-IDF representation of discharge notes (Figure 2). This is not particularly surprising as most studies that utilize community-level SDOH have arrived at similar conclusions [27]. One possible explanation is that community-level estimates are either imprecise or biased, especially if the within-community variance of a feature is high. Moreover, when a patient is critically ill, information on their upstream risk factors might not be as useful as their current state of health.

Similarly, combining SDOH with tabular EHR data and discharge notes does not improve the AUROC and AUPRC of the model. Again, this trend is observed in all model classes and SDOH databases. This suggests that the added SDOH features do not provide additional information beyond what is already captured in the EHR. However, SDOH features have some influence on other metrics as such ECE, FPR, and recall. For example, for the task of in-hospital mortality prediction, combining CHR features with all EHR features significantly reduces ECE from 0.11 to 0.03 and FPR from 0.09 to 0.04 (Table B2). Likewise, for the task of 30-day readmission, combining SVI features with all EHR features significantly reduces ECE from 0.39 to 0.35 and FPR from 0.35 to 0.27. However, these improvements are at the expense of a lower recall.

5.1.2 Generalizability of the Finding. Using the All of Us dataset, we validate that our finding generalizes to a more geographically diverse cohort. Unlike MIMIC-IV, which represents critically ill patient stays at a hospital in Boston, the All of Us cohort includes all in-patient stays across the United States, and many patients do not have any comorbidities (Table B1). The AUROC of the XGBoost classifiers for All of Us is lower than that in MIMIC due to the lack of detailed, hourly lab and vitals. The AUPRC is higher for All of Us because the 30-day readmission rate is 18% in the All of Us cohort and only 6% in the MIMIC-IV cohort.

Because the two cohorts are drastically different, a direct comparison of model performance is not meaningful, but we can examine the trend in the added value of SDOH. Consistent with our results in MIMIC-IV, we see no significant performance differences in models trained with tabular EHR data and tabular EHR data combined with SDOH data in the All of Us cohort (Table 3).

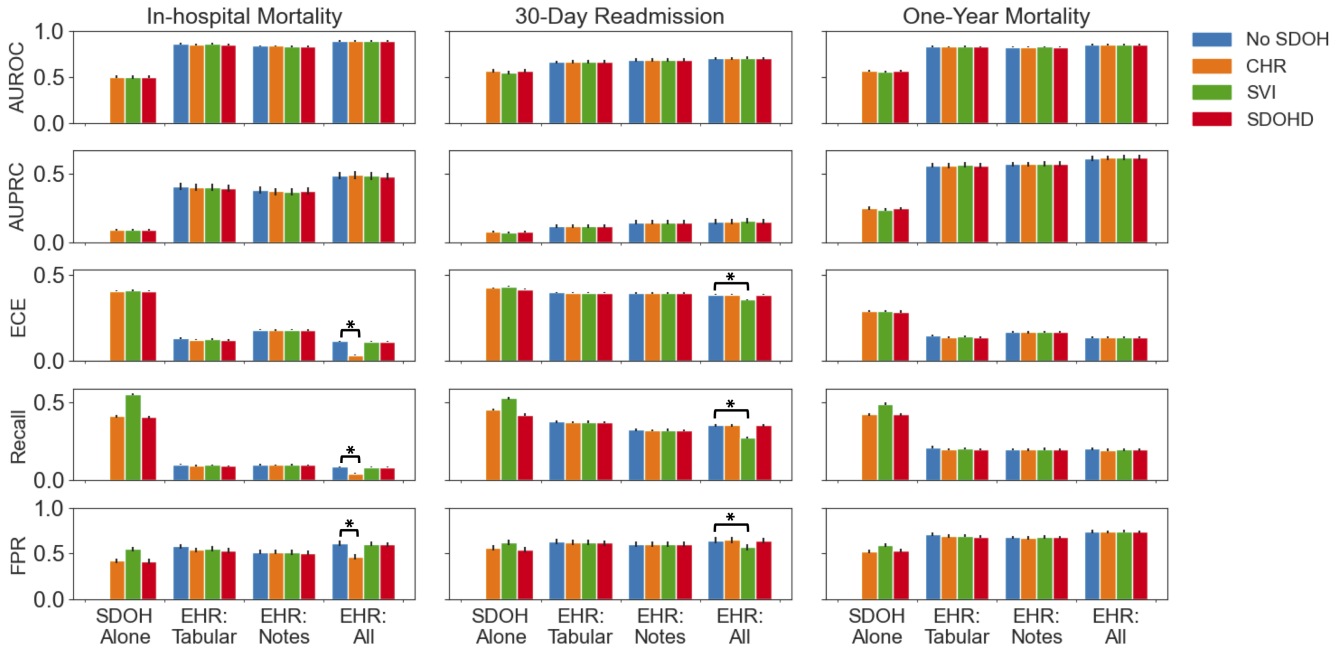


Figure 2: Comparison of the performance of XGBoost classifiers trained on 15 different feature sets to predict in-hospital mortality, 30-day readmission, and one-year mortality in the general ICU population. There are no detectable differences between AUROC and AUPRC of models that do not incorporate SDOH features and those that do. However, when combining SDOH features with all EHR data, we observe significant impacts on ECE, FPR, and recall. We highlight such occurrences with asterisks. The error bars denote the 95% confidence intervals obtained through 1000 bootstrap samples.

5.2 Varying Impact of SDOH on Vulnerable Patient Populations

In this section, we investigate whether including SDOH in predictive models can lead to better performance for specific patient populations. For each task, we compare the best model that incorporates SDOH data to the best baseline model trained on only EHR data.

5.2.1 Limited Improvement in Model Performance in Vulnerable Patient Populations. Similar to the general ICU patients, we find that incorporating SDOH has some impact on model performance in the more vulnerable patient populations. Although predictive performance metrics such as AUROC and AUPRC are largely unaffected, we observe significant improvements in ECE, FPR, or recall in selected models trained on SDOH data. In Table 4, we report the aggregated number of occurrences in which incorporating SDOH features significantly improves or worsens model performance across three prediction tasks. See Table B2 for more granular results.

We find that the added value of SDOH features varies by patient population, prediction task, and the EHR features they are combined with. Even for the same patient population and task, SDOH features are not equally informative or useful. For example, for models trained on all diabetic patients, the only observed performance boost is in recall when CHR features are combined with tabular features. However, the improvement in the recall is at the expense of higher ECE and FPR. In contrast, for models trained on female diabetic patients, incorporating CHR improves model performance in at least one of the three metrics when combined with discharge notes or all EHR data but not tabular EHR data alone.

Table 3: Comparison of model performance for XGBoost classifiers trained with and without `SDOH` for the task of 30-day readmission in MIMIC-IV and the All of Us dataset. In both datasets, the addition of SDOH has no effect on model performance.

Feature Set	MIMIC-IV					All of Us				
	AUROC	AUPRC	ECE	FPR	Recall	AUROC	AUPRC	ECE	FPR	Recall
SDOH	0.57	0.08	0.42	0.42	0.54	0.53	0.21	0.30	0.48	0.50
Tabular	0.67	0.11	0.40	0.38	0.63	0.60	0.26	0.27	0.35	0.47
Tabular+SDOH	0.67	0.11	0.40	0.37	0.62	0.60	0.26	0.27	0.34	0.46

Table 4: Combinations of EHR and SDOH features that influence performance of the best models for each patient population in terms of AUPRC. We report the number of occurrences in which incorporating SDOH features significantly improves or worsens performance in the form of (`# improves/# worsens`) across the three prediction tasks (total number of occurrences is 3). Significance is evaluated using a 1000-sample bootstrap hypothesis test at the 5% significance level. Values in green denote performance boosts while values in red denote decline in performance.

Patient Population	Metric	Tabular			Notes			All		
		CHR	SVI	SDOHD	CHR	SVI	SDOHD	CHR	SVI	SDOHD
All Diabetic	ECE	0/1	0/0	0/0	0/0	0/0	0/1	0/0	0/0	0/0
	FPR	0/1	0/0	0/0	0/0	0/0	0/0	0/0	0/0	0/0
	Recall	1/0	0/0	0/0	0/0	0/0	0/0	0/0	0/0	0/0
Black Diabetic	ECE	1/0	0/0	0/0	0/0	1/0	0/1	0/0	0/1	0/1
	FPR	1/0	0/1	0/0	0/0	1/0	0/1	0/0	0/1	1/0
	Recall	0/1	1/0	0/0	0/0	0/0	0/0	0/0	1/0	0/0
Elderly Diabetic	ECE	0/0	2/0	0/0	0/0	0/0	1/0	0/0	0/0	0/0
	FPR	0/0	1/0	0/0	0/0	0/0	0/1	0/0	0/0	0/0
	Recall	0/0	0/0	0/0	0/0	0/0	1/0	0/0	0/0	0/0
Female Diabetic	ECE	0/0	0/0	0/0	1/0	0/0	0/0	0/0	0/0	0/0
	FPR	0/0	0/0	0/0	1/0	0/0	0/0	1/0	0/0	0/0
	Recall	0/0	0/0	0/0	0/1	0/0	0/0	0/0	0/0	0/0
Non-English Speaking Diabetic	ECE	0/0	1/0	1/0	0/1	0/0	0/0	0/0	0/0	1/0
	FPR	0/0	0/0	0/0	0/1	0/0	0/0	0/0	0/0	0/0
	Recall	0/0	0/0	0/0	0/0	0/0	0/0	0/0	0/0	0/0

This varying effect of the inclusion of SDOH by patient population precisely captures why SDOH should be collected and incorporated in analyses. Although individuals in a neighborhood are exposed to the same community-level SDOH, they have varying social needs [3]. Incorporating SDOH into predictive models may be helpful to identify patients with specific needs and reduce health disparities associated with poor social conditions [2, 7, 27].

6 SDOH AS FAIRNESS AUDIT CATEGORIES

A 2014 report by the National Academies of Medicine (NAM) argued that the integration of SDOH into the EHR would better enable healthcare providers to address health disparities [31]. Extending on a previous study on the integration of SDOH features and model fairness in patients with heart failure [80], we conduct a thorough audit of FPR parity in all ICU patients using SDOH features in addition to protected attributes such as race, age, and gender. To enable evaluation based on SDOH features, they are binned into quartiles, and the bin edges are documented in subsection A.2.

In Figure 3, we report the FPR of classifiers with the highest AUPRC for 30-day readmission prediction. We focus on the models trained on all EHR data (`All`) and all EHR data combined with the most helpful SDOH features (`All+SVI`) across different subgroups. See Figure B2 for the other two prediction tasks.

6.1 SDOH Features Enable More Granular Audits

In this setting, a high FPR indicates that the model is overdiagnosing or falsely claiming that the patient is high-risk, which has both medical and economic costs [61]. A high FPR disparity means that members of a protected subgroup would not be given the correct diagnosis or appropriate intervention at the same rate as the other patients.

An audit of the FPR based on protective attributes confirms findings from prior work that algorithms exhibit biases against underserved patient populations [114, 136, 137]. We find that patients who are older, Black, or female have higher FPRs. (Figure 3). These differences are among the most commonly reported findings in health disparities research; often, these studies stop there without connecting the observed disparities to mechanisms of systemic biases that drive downstream adverse health outcomes [79]. This is partially due to the lack of additional information on the patients beyond basic demographics.

The fairness audit based on SDOH features provided additional insight and raised more questions. We find that the FPR is elevated for patients residing in communities where the median household income is low, a larger proportion of individuals commute to work using public transit, and a larger proportion of individuals did not complete high school (Figure 3).

We hypothesize that the FPR disparity is a result of bias propagation, which has been suggested by previous studies [1, 114]. While future work is needed to validate the hypothesis, one interpretation of the FPR disparity between patients in quartiles defined based on the percent of workers commuting via public transit is that patients in the fourth quartile likely do not own a car and hence have higher transportation barriers and limited access to healthcare [32, 35, 46, 94, 118, 122]. Additionally, a lower household income and lower educational attainment could represent socioeconomic and linguistic disparities in access to care [25, 35, 50, 122].

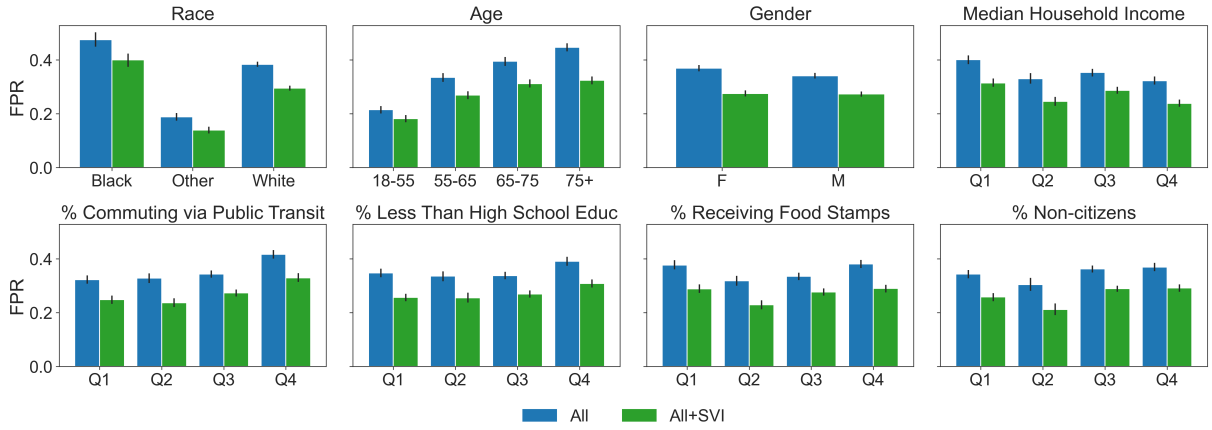

Figure 3: Comparison of the FPR of XGBoost classifiers trained on all EHR data (A11) and all EHR data combined with SVI features for 30-day readmission prediction in all MIMIC-IV ICU patients. FPR is reported for subgroups defined by race, gender, age, and five SDOH features, which are binned into quartiles. The bin edges are documented in subsection A.2. The error bars denote the 95% confidence intervals obtained through 1000 bootstrap samples.

7 DISCUSSION

7.1 The Need for Better Data

Overall, our analysis validates previous findings that community-level SDOH features do not improve the accuracy of clinical prediction tasks [28] in both a multi-year cohort and a geographically diverse cohort. We expect individual-level SDOH to be better predictors of outcomes, as prior studies that incorporated them all reported significantly improved performance [6, 95, 119]. However, this data are not readily available. For example, although individual-level SDOH can be extracted from participant surveys in the All of Us dataset, less than 15% of the participants have completed the SDOH survey. Moreover, the survey responses were collected only once for each participant, so these survey-based SDOH features may not accurately reflect the lived experience of the respondents beyond the period the survey was conducted. In light of our findings, we call for further efforts to standardize the routine collection of SDOH data and integration into EHR.

The healthcare system plays a vital role in collecting, using, and sharing actionable SDOH data [96]. To facilitate this effort, providers and operations staff across care settings should focus on actions that enhance the standardization and integration of SDOH data. Organizations such as the Office of National Coordinator for Health IT (ONC), the Joint Commission, and Health Level Seven International (HL7) are all leading efforts to further SDOH interoperability and standards [99, 109]. It should also be a focus to provide sufficient training and education for the staff who are collecting and encoding the data from the patients while adhering to cultural competency, privacy, and confidentiality standards [87].

As the research community awaits access to the more granular EHR-SDOH data, we hope the MIMIC-IV-SDOH database will serve as a starting point for studies on the relationship between community risk factors and patient outcomes and those looking to understand the needs of vulnerable subpopulations.

7.2 On More Actionable Audits

Despite spending a higher percentage of our GDP on medical care expenditures than other developed countries, health outcomes in the United States are among the worst for developed countries [98]. Numerous studies have confirmed the potential of AI in improving health outcomes, but very few tools that were developed have actually helped [9, 132]. A promising direction forward is to look beyond the clinical walls and understand the conditions that affect the health of the people upstream [86].

The growing evidence around the association between SDOH and health outcomes calls for targeted action, but there is a lack of consensus on what interventions would work [86]. Progress in evidence-informed policymaking requires a commitment to enhancing our current understanding of how SDOH affect different populations and ways to measure the effectiveness of interventions targeting specific SDOH domains. Thus, community-level SDOH features are essential for evaluating and monitoring health disparities [108].

By evaluating fairness using intersectional social identities, we could better account for the socially constructed nature of protected attributes such as race and gender. Capturing SDOH provides information on the social processes that created health disparities in the first place [25, 52, 79]. Audits of biases from the lens of SDOH are also more actionable because these features are not social constructs but modifiable factors that can be addressed [108]. Consider transportation, which is one of the SDOH features we used in the fairness audit. Surveys and audits have identified transportation barriers as one of the leading causes of missed or delayed medical appointments, especially in the elderly and those in rural areas [57, 118, 122]. Health insurance and healthcare delivery organizations are addressing the issue through partnerships with popular ride-share companies to provide non-emergency medical transportation (NEMT) services [104, 124]. These programs have decreased costs [105] and the frequency of urgent care visits [100].

The development of this intervention would not be possible without an understanding of the underlying SDOH and the population affected.

7.3 Future Work on SDOH and Health Predictions

While our work shows that the inclusion of SDOH has minimal impact on three common EHR prediction tasks, they could be more helpful in other tasks and patient groups. Specifically, we did not include any phenotype prediction tasks. Given the associations between SDOH and chronic diseases [6, 30], it is possible that SDOH features are good risk predictors for specific comorbidities. In addition, SDOH could be important to account for in the estimation of treatment effects, which several studies have done using the MIMIC database but without SDOH data [65, 75, 139]. Likewise, although our study utilized three different model classes, they are all relatively simple. Neural networks could potentially uncover more underlying relationships between SDOH and health outcomes [140].

Regardless of the predictive value of SDOH, it is a good idea to account for them in analyses for more granular benchmarking and evaluation of fairness. For example, MIMIC-IV-SDOH can be mapped to MIMIC-CXR, a large database of chest radiographs with radiology reports. There have been many works that focus on group fairness in the field of medical imaging [113, 114, 136], which the inclusion of SDOH could contribute to.

8 CONCLUSION

This work advances our understanding of the impact of SDOH on health prediction. First, we develop a new EHR-SDOH dataset by linking a popular EHR database, MIMIC-IV, to public community-level SDOH databases. This dataset can be used to uncover underlying trends between community health and individual health outcomes and provide more benchmarks for evaluating bias and fairness. Second, we demonstrate that incorporating SDOH features in certain vulnerable subgroups can improve model performance. The value of adding SDOH features, however, is dependent on the characteristics of the cohort and the prediction task. Third, we highlight that algorithmic audits conducted through the lens of SDOH are more comprehensive and actionable. However, the lack of access to high-resolution, individual SDOH data is a limitation of the study. To address this, future work should focus on collecting individual-level SDOH features and accounting for them in analyses to address patient needs better and promote health equity.

ACKNOWLEDGMENTS

This project is supported by the National Institute of Biomedical Imaging and Bioengineering (NIBIB) of the National Institutes of Health (NIH) under grant number R01-EB017205.

We would also like to acknowledge the All of Us Research Program, which is supported by the National Institutes of Health, Office of the Director: Regional Medical Centers: 1 OT2 OD026549; 1 OT2 OD026554; 1 OT2 OD026557; 1 OT2 OD026556; 1 OT2 OD026550; 1 OT2 OD 026552; 1 OT2 OD026553; 1 OT2 OD026548; 1 OT2 OD026551; 1 OT2 OD026555; IAA #: AOD 16037; Federally Qualified Health Centers: HHSN 263201600085U; Data and Research Center: 5 U2C OD023196; Biobank: 1 U24 OD023121; The Participant Center: U24 OD023176; Participant Technology Systems Center: 1 U24 OD023163; Communications and Engagement: 3 OT2 OD023205; 3 OT2 OD023206; and Community Partners: 1 OT2 OD025277; 3 OT2 OD025315; 1 OT2 OD025337; 1 OT2 OD025276. In addition, the All of Us Research Program would not be possible without the partnership of its participants.

Finally, we would like to thank Hammaad Adams, Aparna Balagopalan, Hyewon Jeong, Qixuan (Alice) Jin, Intae Moon, Vinith Suriyakumar, Yuxin Xiao, Haoran Zhang, Dana Moukheiber, Lama Moukheiber, and Mira Moukheiber for their valuable feedback and constructive review of this work.

A ADDITIONAL INFORMATION ON MODEL TRAINING AND DATA PRE-PROCESSING

A.1 Model Training

Due to the class imbalance in all the prediction tasks, we use AUROC for model selection during hyperparameter tuning. The distributions of parameters sampled during the randomized search for logistic regression (`lr`), random forest (`rf`), and XGBoost (`xgb`) classifiers are as followed:

```
lr_param_grid = {
  "C" : [1e-5, 1e-4, 1e-3, 1e-2, 0.1, 1, 5],
  "solver" : ["liblinear"],
}

rf_param_grid = {
  "n_estimators": [50,100,200,500],
  "max_depth": scipy.stats.randint(2, 10),
  "min_samples_split": scipy.stats.randint(2, 10),
  "min_samples_leaf": scipy.stats.randint(1, 10),
}

xgb_param_grid = {
  "n_estimators": [50,100,200,500],
  "max_depth": scipy.stats.randint(2, 10),
  "learning_rate": (0.01,0.05,0.1,0.2,0.3),
  "min_child_weight": scipy.stats.randint(2, 10),
  "colsample_bytree": [0.5,1],
  "subsample" : [0.3,0.6,0.9],
  "reg_alpha" : scipy.stats.randint(0, 10),
  "reg_lambda": scipy.stats.randint(0, 10),
}
```

A.2 Binning SDOHD Features

The quartile bin edges for SDOH features used in the fairness audit are as followed:

(1) Percentage of non-citizens:
0, 0.32, 1.09, 2.54, 30.58
(2) Median household income in dollars:
10446, 60698.5, 74902, 92381, 250001
(3) Percentage with less than high school education:
0, 4.04, 6.79, 11.64, 67.49
(4) Percentage of households receiving food stamps:
0, 4.15, 6.85, 12.1, 78.43
(5) Percentage of workers taking public transit:
0, 4.74, 10.5, 20.44, 77.61

A.3 SDOH Features in the All of Us Dataset

The community-SDOH features used include the following:

(1) Percentage of households receiving food stamps
(2) Percentage of the population with at least a high school diploma
(3) Median household income
(4) Percentage of the population with no health insurance
(5) Percentage of the population in poverty
(6) Percentage of houses that are vacant
(7) Deprivation index

B ADDITIONAL FIGURES AND TABLES

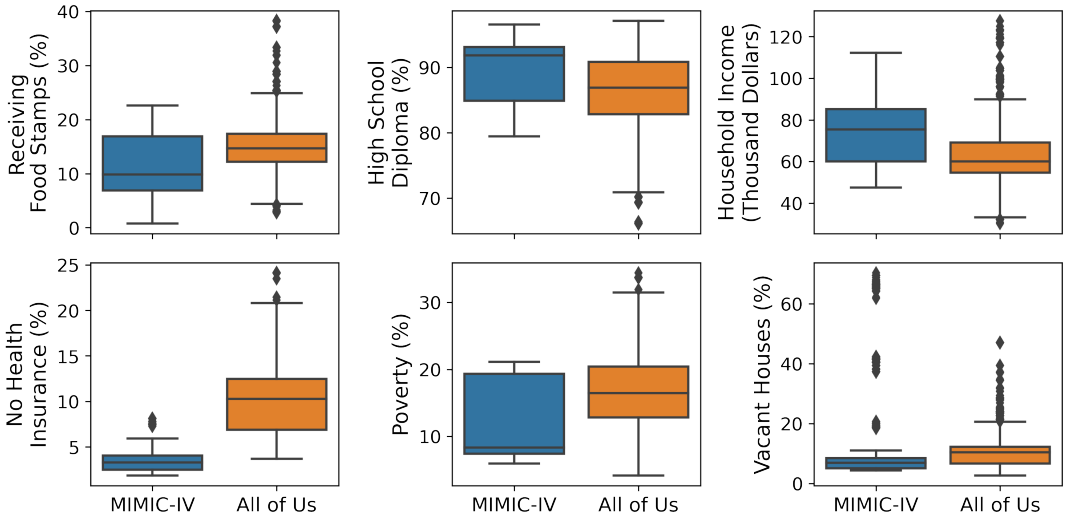

Figure B1: Comparison of selected SDOH features between the MIMIC-IV and the All of Us patient cohorts. Because the All of Us dataset is more geographically diverse, the variation in its SDOH data is much greater than that in MIMIC-IV.

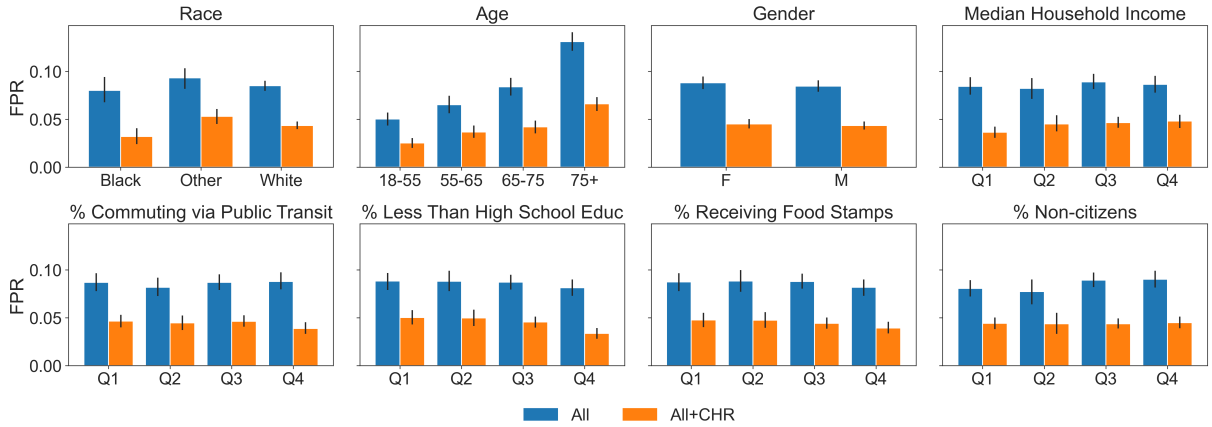
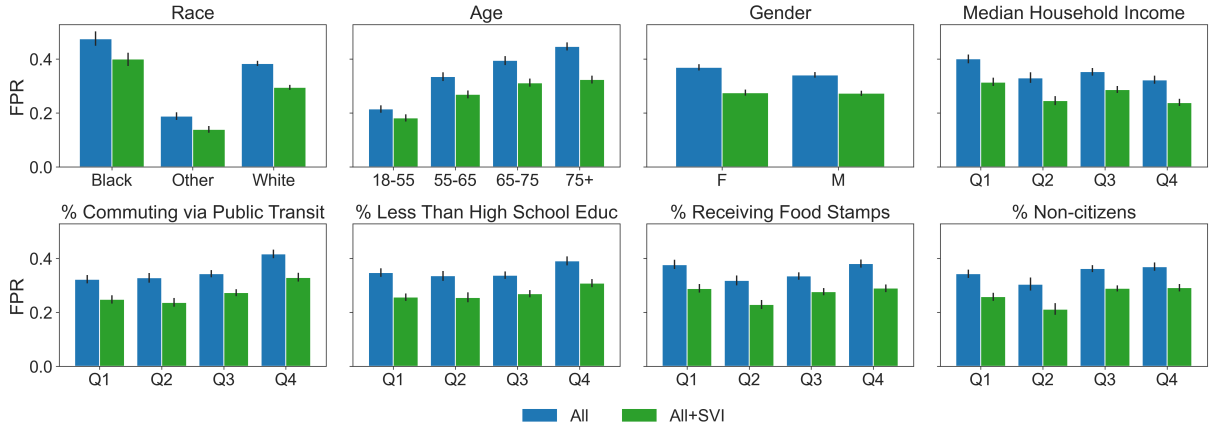
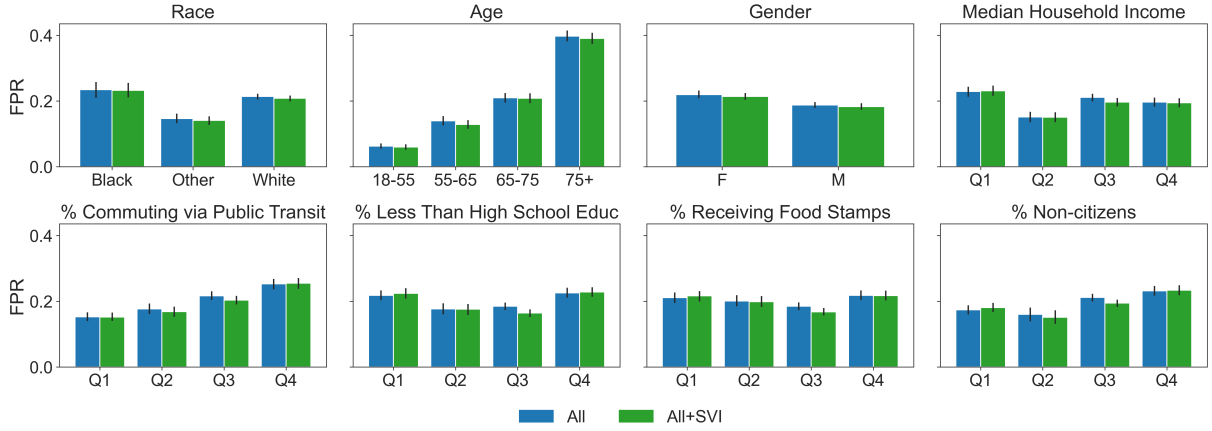


(A) All ICU Patients: In-hospital Mortality



(B) All ICU Patients: 30-Day Readmission



(C) All ICU Patients: One-Year Mortality

Figure B2: Comparison of the FPR of XGBoost classifiers trained on all EHR data (`All`) and all EHR data combined with best SDOH features for the three tasks in all MIMIC-IV ICU patients. FPR is reported for subgroups defined by race, gender, age, and five SDOH features, which are binned into quartiles. The bin edges are documented in subsection A.2. The error bars denote the 95% confidence intervals obtained through 1000 bootstrap samples.

Table B1: Charactertics of the MIMIC-IV and All of Us cohorts. The MIMIC-IV cohort has six patient populations: all ICU patients, diabetic patients, black diabetic patients, elderly diabetic patients, female diabetic patients, and non-English speaking diabetic patients. The All of Us cohort contains all in-patient hospital stays. *N* is the number of patients in each group.

Attribute	Subgroup	MIMIC-IV						All of Us
		All ICU (N=42,665)	All Diab. (N=12,651)	Black Diab. (N=1,710)	Elderly Diab. (N=4,520)	Female Diab. (N=5,251)	Non-English Speaking Diab. (N=1,675)	All Inpatient (N=13,324)

Table B2: Comparison of the performance of models trained with and without SDOH feature to predict in-hospital mortality, 30-day readmission, and one-year mortality for the six patient populations. The evaluation is done only on the best model in terms of AUPRC for each feature set category and task. In general, incorporating SDOH features has a limited impact on model performance. Values in bold indicate significantly better performance compared to the baseline model trained without SDOH, evaluated using a 1000-sample bootstrap hypothesis test at the 5% significance level.

Patient Group	Feature Set	In-hospital Mortality					30-Day Readmission					One-Year Mortality

ABSTRACT

One of the core goals of responsible AI development is ensuring high-quality training datasets. Many researchers have pointed to the importance of the annotation step in the creation of high-quality data, but less attention has been paid to the work that enables data annotation. We define this work as the design of ground truth schema and explore the challenges involved in the creation of datasets in the medical domain even before any annotations are made. Based on extensive work in three health-tech organisations, we describe five external and internal factors that condition medical dataset creation processes. Three external factors include regulatory constraints, the context of creation and use, and commercial and operational pressures. These factors condition medical data collection and shape the ground truth schema design. Two internal factors include epistemic differences and limits of labelling. These directly shape the design of the ground truth schema. Discussions of what constitutes high-quality data need to pay attention to the factors that shape and constrain what is possible to be created, to ensure responsible AI design.

1 INTRODUCTION

Advances in applications of Artificial Intelligence (AI) in the medical domain promise to improve efficiency, promote accuracy and bring cost savings across many areas of medical subspecialty, yet there are also many concerns about ethics and responsibility in the deployment of these technologies [16]. The idea of responsible AI has been extensively discussed in the literature and received much attention from both commercial entities and regulatory bodies [15, 47]. There is considerable agreement that high-quality training data is key to the development of responsible AI systems [28]. Yet research shows that the creation of high-quality data also tends to be an undervalued step in the development of machine learning systems [57, 58].

The process of dataset creation is typically broken down into three steps - data collection, data pre-processing and cleaning, and finally, data annotation[1, 50]. This is especially so in the medical domain where high-quality training data is obtained through a

range of annotation practices such as data quality enhancement [10], generating labels using Natural Language Processing models [23], deriving image labels from medical documentation [34], and following labelling guidelines and principles focusing on fairness and inclusion [36, 59]. This paper investigates the factors that affect the creation of high-quality medical datasets demonstrating that the preparatory work involved in the design of ground truth schema used in data annotation is an important preceding step that tends to be overlooked in the literature. Following the work of Mueller and colleagues [49], we define the ground truth schema as a collection of relational labels and metrics, as well as their definitions and examples that are used during data labelling.

Recent research on the creation of training datasets [21] has discussed annotation activities as a matter of power relations in projects crowdsourced in the Global South [41, 42, 45], the social design of labelled data by domain experts [49], and annotation process recommendations [19]. While understanding data annotation is important, data design work begins before the first data points are labelled. Data is always designed and constructed through situated and emergent processes [18, 49] as domain experts, data scientists, other stakeholders, and diverse political interests imprint their values on the data. However, little is known about the preparatory work necessary to produce high-quality data [31]. Accounts of decisions that shaped the datasets are rarely documented and get dismissed as soon as the data creation work concludes [58], thus become impossible to inspect in the future [49, 51, 61].

In this article, we consider **what factors affect the design of medical datasets prior to data annotation.** We ground our findings in ethnographic research conducted across three organisations developing medical AI for (I) screening chest x-rays, (II) supporting the diagnosis of lung and pancreatic diseases (III) automating patients-to-clinical trials matchmaking. We explore the decisions made by medical professionals, data scientists, designers, and other relevant stakeholders in their quest to create medical AI datasets in highly constrained environments. Our data include approximately 50 hours of observations, interviews with 46 medical professionals, data scientists, and designers, as well as observation notes, email communication, reports, and artefacts. We followed a grounded theory approach [9]that led us to identify and define factors that influence the design of the ground truth schema that underpins the production of high-quality training data.

Our contribution is twofold. First, we identify five factors, three external and two internal, that influence medical dataset creation by affecting data collection, ground truth schema design, and data annotation stages (see Fig. 1). The external factors condition the medical dataset creation processes by determining the data collection and shaping the possibilities for the design of ground truth schemas:

- Regulatory Constraints
- Context of Creation and Use
- Commercial and Operational Pressures

The internal factors define the negotiations between the medical and technical domains:

- Epistemic Differences
- Limits of Labelling

Second, we show how these factors affect the final shape and quality of the resulting medical datasets. While we define each factor separately for analytical purposes, the factors are interrelated and affect each other, structuring the limits of responsible data creation approaches. We argue that these factors condition the stages that precede data labelling and mediate the design of what is aspired to be responsible AI.

2 RELATED WORK

While the idea of responsible AI has received much attention from both commercial entities and regulatory bodies, concerns about the quality of data and the challenges in the creation of quality data are increasingly in focus. The now-emerging guidelines list several data-related challenges as key obstacles that hinder the path towards responsible AI: skewed data (issues that originate during data collection), tainted data (issues that stem from labelling e.g. hidden stratification [52]), or limited features (an inadequate number of features represented in data) [4]. There is broad agreement that dataset creation processes deserve greater attention, despite scholars repeatedly pointing to a strong bias against data work [14, 57, 58].

2.1 How datasets are created and annotated

In computer science, dataset creation is often seen as an activity constituting a step in the larger development processes of ML-based systems [1, 11, 26, 50, 65]. However, scholars have also discussed the dataset creation process on its own merits. For example, Hutchinson drew parallels between software development and dataset creation practices by sharing conceptual stages like requirement analysis, design, implementation, testing, and maintenance[31]. Similarly, increased focus can be observed in the medical area, where researchers describe in greater detail the creation of publicly available medical datasets [8, 13, 33, 35, 40, 66]. Typically, dataset creation is described as a process that spans all activities related to work on medical data, collected under the umbrella of data collection, data cleaning and processing, and data annotation.

Data annotation is one of the most researched aspects of dataset creation. Data annotation or labelling usually happens as part of the curation or preparation step of larger data science projects, following data acquisition and cleaning, and preceding feature engineering [1]. These activities are usually iterative and highly collaborative. Linguistic scholars and Natural Language Processing researchers [19, 30, 63] offer guidance on how to carry out data labelling. They distinguish three focal points: the creation and improvement of an annotation guide [19], schema [63], or manual [30]; the labelling performed by trained annotators; and the adjudication of the annotated data.

In this paper, we use the terms data labelling and data annotation interchangeably and understand them as the action of assigning and adjudicating predefined labels to concrete data points. When considering this step alone, there is a multitude of decisions that need to be taken to complete it. Scholars have pointed to data annotation activities as a site of political struggle, challenges to the labour conditions, as well as the stage in dataset creation that can result in adverse downstream outcomes for trained models. For example, Schumann et al. [59] and Hanley et al. [24] demonstrate how the design of categories (or labels) can reinforce harmful stereotypes and exclude underrepresented groups of people. Badly annotated

data can reduce the performance of AI models [10, 23, 34, 47, 54] and perpetuate exclusion and inequality [36, 59].

In the medical domain, data annotation challenges can be compounded by the requirements for specialised knowledge and training. Despite initiatives like the Unified Medical System [38], the clinical meaning of labels can be unclear [51], and medical knowledge remains difficult to capture for computer use. Li and colleagues [37] explored the inter- and intra-rater agreement between six radiologists of different experience levels when labelling chest x-rays. In some cases, even the experienced radiologists reached only a moderate level of agreement with themselves [39]. This could occur due to not following the best medical practices when labelling data, due to resource constraints [57] or because of the disconnect between the practices of labelling and the actual usage of medical data in regular practice [51].

What much of this research points to is the fact that labelling and annotation as practices are heavily reliant on the creation of annotation guides and schemas [19]. Yet, despite the growing interest in the creation of datasets, current discussions tend to omit and overlook the pre-labelling activities and their potential impact on the quality of the resulting training data [67].

2.2 The design of the ground truth schema

Many scholars investigated the dynamic and situated work of domain experts, data scientists, designers, and other stakeholders engaged with data [25, 48, 57, 60]. For example, Muller and colleagues investigated how domain experts label data, highlighting that the ground truth contained in datasets is a human contribution resulting from improvised and iterative adjustments to principled design processes [49]. Discussing the design of ground truth schema implies that ground truth captured in medical AI datasets is not an objective representation of reality but is a result of a situated design process [6]. In other words, data is never raw [22], instead, all data is actively constructed [3, 43, 53]. Feinberg emphasises the importance of recognising the subjectivity involved in dataset creation and the need to consider the potential biases and limitations inherent in choices that stem from the social and organisational context in which data is produced [18].

Researchers who investigate AI datasets suggest that access to all of the "subtle design decisions" made during the dataset creation, is vital to ensuring a high-quality labelling process [17, 51] and thus high-quality datasets. However, documenting design decisions in data science work is not common [53, 56, 68]. To address this gap, researchers developed a range of documentation frameworks to support the accountability, use, and maintenance of complex datasets [2, 44]. These frameworks range from general purpose and qualitative - Datasheets for Datasets [20], NLP-focused - Data Statements [5], quantitative - Dataset Nutrition Label [27], to fairness focused - data briefs [17] and accountability [31]. Some of these tools [17, 20, 31] include a query for the origin of the labels, but most do not pay much attention to the pre-labelling activities involved in annotation schema creation.

While the existing scholarship has problematised the stage of the data labelling and the power relations and conditions affecting the data annotation work [49], little is known about the stages preceding the data labelling. Particularly, how these stages influence the final shape of medical datasets. We explore the collaborative and situated work of medical professionals, data scientists, and designers that takes place before the labelling stage, within the design stage proposed by Hutchinson et al. [31] or the preparatory work proposed by Fort [19].

3 METHODOLOGY

We investigated three organisations in the Global North developing medical AI-based systems that engaged in the medical dataset creation processes. We focused on the work conducted before the data annotation task by participants described in Table 3).

3.1 Research context and data collection

3.1.1 ORG I. was an interdisciplinary collaboration between academia, business, and the public healthcare sector, aiming to create AI-based chest x-ray prioritisation software for global use. The project's first step was designing the ground truth schema for labelling chest x-rays, which is the process investigated in this study.

Our engagement in ORG I spanned May 2021 to Feb 2023. During that time, we conducted participatory observations of the design process of the ground truth schema. The working group developing the system was based in a Northern European country (Table 3.1). Additionally, a feedback group comprising medical professionals from the Northern European country and an East African country provided feedback on the schema (Table 3.2). We participated in fifteen working group meetings ranging from 26 minutes to 2 hours and 12 minutes in length. Additionally, we conducted twelve interviews and observed external medical professionals evaluating and providing feedback on the intermediate results of the design work. Additional material included observation notes, meeting summaries from other participants, a work progress report, email communication, and produced artefacts - a labelling guide and the ground truth schema.

3.1.2 ORG II. was a large tech company in Western Europe with part of the business involved in the development of complex medical devices. We primarily engaged with sections of the company that focused on the development of AI-based diagnostic tools and systems for oncological radiology.

Our work with ORG II was split into a preliminary exploratory period online from February to May 2022 and in situ participant observations and semi-structured interviews conducted in June 2022 in a Western European country. Due to the size of the organisation, we employed snowball sampling. In ORG II, we conducted thirteen semi-structured interviews with experts (Table 3.3), with an average duration of 65 minutes.

3.1.3 ORG III. was a mid-size start-up in Western Europe that aimed at developing an AI-based platform for matching patients with advanced clinical trials for new drug and experimental procedure development. The company primarily dealt with two data sources. First, they collected data from medical practitioners and their patients. Second, they collected data from public registries in the EU and US and pharmaceutical companies about clinical trial requirements or experimental treatments. Their goal was to match the patients with unmet medical needs and their physicians with the requirements of BioPharma companies that need to enhance drug development and recruit participants for clinical trials.

Table 1: List of participants, their simplified positions, and experience levels. Respectively in ORG I (working group), ORG I (feedback group, participants 10-14 were located in the northern European country, and participants 15-21 were located in the East African country), ORG II, and ORG III.

Our engagement with ORG III spanned February to May 2022. The preliminary period involved online semi-formal meetings and interviews from February to April 2022. In situ ethnographic research was conducted during May and June 2022 at the headquarters of ORG III in Western Europe. We conducted participant observation by joining the daily stand-up sessions of the engineering department and shadowing the workflow of the AI team experts leading the data labelling process for the match-making platform. In total, we interviewed 13 participants (Table 3.4).

3.2 Data analysis

The main focus of our analysis was to identify factors affecting medical dataset creation. We analysed decisions made during the design work, tensions and misunderstandings that needed to be reconciled, looking both outside and within the organisations where the design work took place. We explicitly decided to explore the wider socioeconomic factors that condition the medical dataset creation and influence the final AI-based systems even before the first label is annotated.

Data analysis relied on techniques of grounded theory and situational analysis [9, 12]. First, we conducted line-to-line open coding, coming up with 850 initial codes. We then reflexively proceeded to thematic coding, in an iterative manner, discussing the themes and patterns emerging in our three sites of ethnographic inquiry. During this step, we designed visual maps to lay out the human, technological, and discursive dynamics of the organisations under study [12]. Second, we conducted axial coding to reflexively group the available themes into dimensions. Finally, we assessed these dimensions against the codes and situational maps, converging on the five final factors (regulatory constraints, context of creation and use, commercial and operational pressures, epistemic differences, and limits of labelling).

3.3 Positionality statement

Our qualitative data was obtained from three health-tech organisations in the Global North. The analysis was shaped by the following standpoints. First, we differentiated our roles in studying the three organisations. Researchers in ORG I had the dual position of the expert who on the one hand, designed the labelling software whilst they conducted participant observation and semi-constructed interviews in order to study the process of the ground truth schema design. Researchers working with ORG II and ORG III employed ethnographic methods as a research approach without having a prior engagement with the organisations. Second, we are researchers currently working for Northern European institutions. Third, we have mixed epistemic backgrounds in computer science and law and policy. Finally, we emphasise the situatedness of our research, which focuses on the development of medical AI at the specific loci of our studied organisations. We acknowledge that the factors we identify as defining the medical dataset creation bear the geographical and epistemic limitations of the Northern European context. On this note, we acknowledge that the divide between Global North and Global South we make below has been problematised by scholars in human geography and decolonial studies as a limiting one, reinforcing stereotypes and reducing the polyphony of southern standpoints [29, 64]. For this reason, we use this divide in this paper to (I) acknowledge the limitations of our standpoints in a northern institution and the privilege of our funded projects; (II) tackle assumptions about data universalism [46] by showing the particularities of the northern context in medical datasets creation and their effect on the intended use of such data in different contexts.

4 FINDINGS: FIVE FACTORS THAT INFLUENCE MEDICAL DATASET CREATION

The datasets used for medical AI benefit from the impression that they are a result of an age-old medical practice that is seamlessly transitioning to the digital age, unaffected by external influences, and focused on the pursuit of medical excellence. However, the reality is often different. Our ethnographic data suggest that even before medical professionals have had the chance to annotate or make their first label, many critical design decisions have been made, which frame the labelling space, thus limiting the extent to which medical professionals can use their expertise.

Our analysis challenged our initial understanding of the dataset creation process drawn from the literature. Our data made clear that the preparatory work should be conceptualised as a crucial stage in dataset creation taking place before data labelling because it defines what becomes captured as ground truth within a training dataset. This is the step where the ground truth schema is designed, which, when applied to an unlabelled dataset through expert annotation, embeds the intended ground truth within it.

Regulatory Constraints
• Extent of Collected Data
• Predetermination of Purpose
Context of Creation and Use
• Geographic context of use
• Demographic context of production
• Linguistic context
Commercial and Operational Pressures
• Business model and organisation scalability
• Competition and health tech market
• Intended future use within healthcare type

Table 2: External factors and their dimensions

We identified five factors that influenced the creation of medical datasets in the organisations we studied. Three of these factors were external to the activities directly involved in pre-labelling activities. External factors defined and delineated the limits and possibilities for labelling activities. Two internal factors on the other hand affected the negotiations around what needed to be labelled and how the labelling was to proceed through the design of the schema. Below we describe each factor and demonstrate how they affected the final shape of the medical datasets focusing on the data collection and ground truth schema design stages.

It is important to note that the organisations and processes examined in this paper were largely driven by data scientists as the owners of the dataset creation process, with representatives of other domains contributing to the dataset creation activities. As a result, data science as an epistemology dominated the design work by primarily embedding data scientists' perspectives, inadvertently compromising other domain-based practices and understandings. As datasets in our research were created for the purpose of AI development, the power distribution was uneven, leaving little room for misconceptions from data scientists to be challenged and addressed.

4.1 External factors: defining the ground truth schema design space

Despite the best intentions of the experts engaged in the medical dataset creation process, many of their decisions and actions were structured by different external factors. We identified three such factors - **Regulatory Constraints, Context of Creation and Use**, and **Commercial and Operational Pressures** - that shaped the space of medical dataset creation and thus influenced the final shape of the datasets themselves even before the labelling could begin (Table 2). Each factor consists of several distinct features. We describe these below in detail.

4.1.1 Regulatory constraints. The medical data space is highly controlled through a variety of local, national, and international regulatory constraints. This was particularly challenging for the data collection step of the process. We observed two areas where compliance with regulatory standards affected the creation of medical data: **the extent of the collected data** and **the predetermination of purpose**. Experts in all of the organisations we studied were concerned about compliance with diverse standards that intersected with their work on medical dataset creation. These standards originated from European binding legislative acts, international standard organisations, or industry standards. GDPR, the main legal standard for data protection in the European Union, was the most prominent example of a binding legislative act, regulating the conditions under which personal data is collected and processed. The industry and international organisations imposed, among others, ISO 2700013001, HIPAA, and Good Medical or Good Manufacturing Practices. In ORG III, a data scientist (P39) listed 21 unique regulations they felt they needed to consider. As a larger and more mature organisation, ORG II also had internal ethics boards, which at times imposed even stricter interpretations. However, these standards and limits legitimised the data collection and processing activities.

Constraints on data collection. While experts in all organisations were striving to create what they saw as high-quality data, complying with relevant regulatory standards required concessions from all participants. For data scientists, the regulatory constraints delimited what data was available for collection, at times inadvertently introducing bias in different ways. For example, P26, a data scientist from ORG II, explained: *"what is the data that we are allowed to use, especially if you look at ... bias ... people will want to look at bias and, and see if ... their product was fair to all, some demographics, and [we are] just not able to use the data because of privacy issues or GDPR"*. Similarly, in ORG II, the contractual agreement with a single local hospital, on the one hand, provided a controlled supply of high-quality data, on the other hand, reduced data representativeness: *"we have a strong relationship with them. How do you expect that the data is not going to be biased right?"* (P24). While ORG II was able to create highly detailed and structured training data for their models, this data was clearly not representative of populations that would eventually encounter the resulting technologies.

Limitations imposed on data collection could compromise the resulting datasets in ways that created challenges for subsequent data creation steps. For example, participants of ORG I could collect only chest x-rays and their linked radiological reports. Privacy concerns here also resulted in the loss of the chronological links between the images during data collection. This selection significantly diverged from the usual assortment of data available to radiologists in clinical practice, introducing challenges at the later stages of medical dataset creation, such as schema creation and annotation.

Regulatory standards and contractual agreements determined the purpose and context of use. Data protection regulations have recently focused intently on the purpose of use as one area of emphasis, tied to notions of data minimisation and data subject notification. Companies in our research had to negotiate the legal basis for their data collection with contracted data providers such as hospitals. For example, GDPR and contractual agreements with a local hospital bounded ORG II to use the collected data within the predefined purpose and context. Deviations from the initially stated purposes and context of use required new agreements that could be obtained only through significant time and resource investments. As a product owner (P22) explained the process of collecting data from the local hospital, *"maybe the new study that we want to do has a slightly different scope and it's not covered by the original contract, then we need to make a new contract"*. ORG I encountered a similar predicament where the data collection phase was negotiated based on what the data scientists believed to be a necessary and sufficient dataset given the available resources and legal constraints of local regulations. By the time domain experts explained that the dataset was lacking important data dimensions, it was too late.

4.1.2 Context of creation and use. The context of production and the context of use influenced the creation of medical datasets. In our studies, each medical dataset was created for a specific intended use that was embedded in the collected medical data, e.g., clinical trial repositories, hospitals, and patients. These sources cover specific geographical populations, which has consequences for the final medical dataset. We identified three dimensions where that influence was prevalent: **the geographic context of use, the demographic context of production**, and **the linguistic context** (Table 2).

The geographic context of use affected the selection of labels. While medicine strives to deliver replicable results that generalise across populations, the ground truth schemas are designed to serve specific needs in specific contexts. Some of them are defined by the intended use of the future AI-based systems in the geographic context, in which they are going to be used. In ORG I, the project group designed the first version of the ground truth schema based on local data from a Northern European country. As a result, the first version of the schema captured the locally prevalent conditions well but missed conditions relevant within the countries of intended use, which were almost never encountered locally. To account for that, direct and indirect input from medical professionals from the East African country was collected and incorporated into the schema during joint design work, as seen in this exchange between a radiologist and an ML engineer.
"So if you wanted that in the hierarchy, it could be there." (P1)
Is it aortic unfolding? Because I clearly remember this sentence from [the East African country] reports, "aortic unfolding due to chronic hypertension" (P2). Yet despite having a broader ground truth schema, the same project also struggled to ensure enough examples of common medical conditions across expected countries of use available for annotation, since the data was originally only collected from one country.

The demographic context affected representativeness concerns In both ORG I and ORG II, data in medical datasets were collected from a single country, which had several consequences. For example in ORG II, the data was predominantly collected from a single local hospital, where ORG II had a contractual agreement. Not only was this problematic due to a more homogeneous patient population, but the collected medical imaging data originated on machines from the same producer. This created many concerns since imaging machines from different manufacturers often produce slightly different artefacts in their output. Yet the information about which machines were used to produce the images was rarely included in the resulting dataset.

Similarly, due to the characteristics of the population embedded in medical datasets, experts worried about how portable the resulting AI models would be. As a usability designer (P25) from ORG II noted, *"you can have all sorts of differences in patient demographics ... and you cannot just apply a model that you train on population A to population B"*. However, despite the designers' and data scientists' awareness, a senior radiologist from the East African country emphasised that *"in the [developing world]*[1] *we are usually consumers, not producers of tech. We may find ourselves hitched to tech that doesn't serve our needs"* (P15). When evaluating the ground truth schema, the same medical professional elaborated, *"I've done this for 10 years since my graduation. I've never seen certain diseases like cystic fibrosis, but whenever I read the books, there's a lot of stuff about cystic fibrosis [prevalent in the Global North],"* which highlights the effect of local ground truth schemas on the transferability of the final AI-based systems.

Linguistic context and local understanding of medical terms challenged the application and transferability of the ground truth schemas. The design of ground truth schemas included naming the labels, defining and organising their relations, and providing examples. However, medical concepts are not always used in the same way across different countries. In ORG I when discussing the naming convention for a chest x-ray finding, one radiologist noted *"I know that it's not proper, but [in the Northern European country] they use 'infiltrat' as a synonym of consolidation ... I think the direct translation consolidation would be 'consolidering' but they don't use that, they use 'infiltrat'... I think maybe our infiltrate is broader"* (P1). As a result, a presentation of infiltration by an AI-based system could be understood differently by medical professionals from different countries. To account for that, data scientists and medical professionals evaluated the ground truth schema against English translations. In ORG III, which operates globally, the data scientists and designers recounted a similar challenge of re-translating medical terms during the data annotation process. The limitations of the locality of medical terms prohibited the aspiration of designing a ground truth schema that can operate universally. As a UX designer (P40) remarked: *"there are also challenges around that because different cultures will refer to different diseases in different ways. It's global and we re-translate some of our stuff into different pages. We also have to consider localisation, how you turn this medical term into a layman term, but that's also relevant in like different countries as well."*

4.1.3 Commercial and operational pressures. The three organisations each had a different business model and exhibited different relations to the market and the public sector. This often determined the availability of the resources (human and material) allocated for dataset creation and affected the organisations' ability to collect data and design the ground truth schema. We identified three dimensions of commercial and operational pressures (Table 2): **business model and scalability of the organisation, the competition in the health tech market**, and **intended future use within the healthcare type**.

The business model and scalability of the organisation determined the amount of collected and labelled data. Every investigated organisation represented a different business model. ORG I intersected with the public sector, whilst ORG II and III were situated entirely in the private sector. The business models of the organisation determined the way in which data was collected. The business model of ORG III relied on providing free use of the AI-based platform to patients but also providing paid services to BioPharma by enrolling patients into clinical trials. To do that, ORG III collected data from the public clinical trial registries in the EU and US, as well as patient medical information. Such data collection was heavily dependent on the organisation's scalability, as well as the "fine" balance between the data requested by their BioPharma clients and the data that could have been collected. As a data scientist (P38) explained: "sometimes it's difficult to decide what kind of data you collect, right? Or what patients. (...) there's a balance between what's actually feasible to collect and what will give us the highest chance of getting as much data as possible. So those

[1] edited to avoid pejorative language

I think are tricky decisions." These conditions affected how much data was finally collected, hence, the ideal of representativeness of the created dataset was compromised.

In ORG I, the budget allocation for the data annotation process played a vital role in the amount of data possible to be labelled by medical professionals. Due to the high cost of labelling by experienced medical professionals, ORG I had to cap the maximum number of labelled images. This cap limited the number of distinct labels that could be annotated in the created dataset and remained statistically significant. "We have a limited budget for the test data that we can collect because we need several radiologists board-certified possibly to look at images" (P3). The limited resources defined the amount of data that was possible to be annotated, putting ORG I at a competitive disadvantage: "What the [competitors] do (...) there is no way we can reach what they do. They have 127 findings and they use a hundred plus radiologists to annotate, and they annotated 800,000 images each image by three radiologists. So the scale is completely different" (P2).

Market standards and industry competition affect the design of the ground truth schemas. Since all organisations under study operated in the health tech sector, the experts engaged in the processes of designing ground truth schemas had to both consider existing state-of-the-art solutions and methods, as well as address market competition. In ORG I, the choice of a specific machine learning model architecture was dictated by the industry standard. However, this choice had consequences for the label needs during the design of the ground truth schemas. At the same time, addressing market competition influenced the work on the ground truth schema design, as seen here, "so this is [a competitor's system] and this is their output. they ... split consolidation and nodules, which at this stage of the hierarchy we are not doing. And so I was wondering why we're not doing it" (P2). In this organisation competition directly influenced the design work.

Due to the large size of ORG II, the matter of competition fed to internal business processes whose results other experts relied on during the dataset creation, as explained by a product owner (P22), "it's a combination of ... alignment with the business priorities and that is also strongly driven by customer requests and customer demands. So that is actually very important ... try to find the alignment". Finally, market competition created time pressures that could structure and limit how data creation had to be organised: "if you want to validate something properly, it costs time. If you want to validate across domains, it costs time. And we are often in very competitive domains where being fast to market or, or fast at the FDA is also important. So there are some time trade-offs, need to be made there." (P27).

The intended use and the type of healthcare system affected the content and the level of detail of the ground truth schemas. Visions of future intended use permeated the design work on the ground truth schemas. The imagined intended use of a future AI-based system factored into decisions about the validity of label choices. Imagined use did not fit in with current domain-specific practices and resulted in confusion and concerns during the design of the ground truth schema. Consider the following discussion between a medical professional and data scientists from ORG I about the implication of different intended uses of the future system for the selection of labels.

We have two priorities, one is decision support. So it might be easy for you to see the mass, so that won't help you. But there's also the pre-screening - prioritisation. So that might be relevant to detect mass prematurely, right? (P3)

So if you use it for like a warning, a prioritisation, it can be useful, but for detection... we can see a mass. It's not difficult to find (P1).

Epistemic Differences
• Miscommunication between domains
• Misapprehension of medical practice
• Misapprehension of medical knowledge
Limits of Labelling
• Domain expert buy-in
• Onboarding to the labelling task
• Labelling hardware and software
• Similarity to the clinical practice

Table 3: Internal factors and their dimensions

Medical AI-based systems in our organisations were designed to operate across the world within public or private healthcare systems. Yet medical systems in different countries operate differently based on public values, profit, incentives, and conventions. The design decisions during dataset creation are a product of all these components. The dependency on the healthcare type was well captured by a data scientist from ORG I when discussing the level of detail of the ground truth schema, *"if it was in the US where you actually pay, then from a business point of view, you really wanna find everything. First of all, you don't get sued, and secondly, you can make a lot of money by treating them. But here it's very different, right? Because it's a public system and you only treat things that are necessary, that need to be treated, right?"* (P4). These concerns manifested in debates about what could and needed to be annotated as expert annotators infused the values of their local system into data creation activities.

4.2 Internal factors: designing the ground truth schema

While external factors were key in shaping what data was collected and made available for annotation and highlighted the importance of local considerations and their implication for the resulting datasets, two internal factors drove debates, discussions, and disagreements that affected the ground truth schema and the resulting datasets. These were **Epistemic Differences** and **Limits of Labelling** (Table 3). The effort going into the creation of medical datasets as training data had two purposes that sometimes came into conflict. First, medical datasets were seen as a means of capturing the current state of medical knowledge and the tacit knowledge of medical professionals who focused on medical practice and clinical usefulness. Second, the same datasets served computer scientists as complex input data to solve problems through mathematical operations, where consistency and accuracy were in the spotlight. These two perspectives, while not opposing, often prioritised distinct qualities of the same datasets.

4.2.1 Epistemic differences. While in ORG II and ORG III, we engaged with relatively homogeneous teams within each company, in ORG I, our research process was focused on supporting the data creation process by working together with the data science and

radiologist teams. As such, in ORG I, we were able to observe first-hand how teams with domain expertise often disagreed on what constituted legitimate knowledge as they discussed what was worth annotating and how things ought to be annotated. We consider three sources of epistemic differences that affected the final design of the ground truth schemas (Table 3), communication challenges within the teams, misapprehension of medical practice, and misapprehension of medical knowledge. Within these dimensions, team members from different domains expressed diverging priorities, values, and understanding of concepts, which needed to be reassured and negotiated.

Communication challenges within teams. The three organisations involved stakeholders from different backgrounds, such as health, data science, and design. All of these brought their own traditions, meanings, and domain knowledge that needed to be shared, translated, and understood by other parties for worthwhile collaboration. It is no secret that interdisciplinary teams must spend time finding common ground before they can work together productively [7]. In our research, we observed how medical professionals, designers, and data scientists constantly translated and explained concepts from their respective domains to maintain a shared understanding. For example, at the beginning of the study in ORG I, medical professionals designed labels based on their, at times naive assumptions of machine learning capabilities, such as when they included two medical concepts under the same label, *"but couldn't that be, if you put nodule, mass in the same category, couldn't you just program it, later on, to say that if the thing that they have marked nodule/mass is over I think ... five millimetres or something, you call it a mass"* (P1), which was not possible given the collected data and was later clarified through a joint discussion. Similarly in ORG II medical professionals had to explain to data scientists that to detect some types of cancer it is necessary to look at more than just the organ in question, and that doctors need to use other information, such as the condition of bile ducts or the blood flow around the organ, affecting data collection and subsequent labelling set up.

Misapprehension of medical practice. Across the organisations the expectations for the quality of the datasets were closely aligned with concepts such as consistency or bias. This focus was clearly visible when discussing the goal of the labelling task in ORG 1. In the pursuit of consistent and unbiased data, data scientists initially framed labelling as a *"different task"* to clinical work: *"We need to know what's in the image and we need it without them being biased towards looking for only stasis"* (P6). As a result, the labelling task did not provide what was seen by the data scientists as "extraneous and potentially biasing" information, such as the background information of a patient. However, situating the labelling task further away from the medical practice affected the quality of the input medical professionals could provide, impairing the ability of medical professionals to use their knowledge. As one senior radiologist (P10) noted: *"Asking a radiologist to categorise something on a picture only without getting any information on the patient. Is like asking a surgeon to look at the scars on a patient and having him tell you what kind of surgery that patient had"*.

The pursuit of objective and unbiased labels isolated labelling from what data scientists saw as extraneous, potentially biasing information. Yet this transformed the work of the radiologists into a new task that was incompatible with medical practice. To deliver the expected results in this new unfamiliar process, radiologists attempted to reconstruct their medical practice by drawing from their tacit knowledge or, simply, guessing: *I have to create something about the patient myself, which is, [or] might not be true. And I then describe the picture from there...* (P10).

Misapprehension of medical knowledge. Specific data was needed to train AI models that provide clinically useful functionalities. However, due to the misapprehension of practice, the assumptions about what clinical knowledge was possible to extract from the clinical data provided were also, at times, flawed. As the schema went through iterative rounds of design, we observed how both sides struggled to understand why particular data was requested or why a particular request seemed to be difficult to fulfil. For example, in ORG I, radiologists were asked to assign one of three possible values as a patient's general state based solely on a single chest x-ray, so that relevant cases could be later prioritised using the resulting AI system. This task proved to be particularly problematic to radiologists who do not use such metrics in their daily practice, so they had to develop a range of new approaches to assign them, like *"I chose to interpret it from the view that it could be the worst situation"* (P12) or *"I think it was mostly a gut feeling"* (P11). In the end, the radiologists produced the kind of data that data scientists expected to see as labels. However, what these labels actually captured diverged from the original intention.

4.2.2 Limits of labelling. Finally, we turn to the mechanics of labelling itself that affected the final design of the ground truth schema. We observed schema design and testing in situ directly in ORG I, while in ORG II and ORG III, our data come from post-hoc interviews. We find that four features affected the final design of the ground truth schema (Table 3), domain expert buy-in, onboarding to the labelling task, clinical practice familiarity, and labelling hardware and software. These dimensions manifested when evaluating the labelling processes. Unlike the *Epistemic Differences*, where data science was the defining domain, the *Limits of Labelling* emerged as medical professionals confronted the intermediate results of the epistemic negotiations discussed above. These limits altered what kind of data was collected and affected the quality of the labelling.

Domain expert buy-in. Our data showed that domain expert buy-in was crucial and required concessions on the type and amount of collected data. Some ML models require specific types of annotated data, such as *"what we're asking them is for each patient to go through 500 images and for each image to annotate [...] at pixel level"* (P21). Not only are such tasks typically outside of the scope of clinical practice but are also mentally challenging. For example, when P1 was asked to oversee the labelling process performed by external radiologists, they recalled: *"I think that he [a senior radiologist] opened the program, saw how difficult it was, and just closed it and just never had the energy to start it again"* (P1). Monetary compensation turned out to be a necessary but not sufficient strategy in ORG I for recruiting medical professionals with high expertise to annotate data.

Once the experts agreed to annotate data, **limited training for the labelling task reduced the chance for a "shared mindset".** Additional metrics were a relevant part of the ground truth schemas. These metrics usually included concepts not used in daily clinical practice. In ORG I, the medical professionals were supplied with

written guidelines to boost common understanding and were briefly introduced to the labelling task. However, some annotators referred to the guidelines only when in doubt: *[the labelling software worked] right out of the box ... I didn't really read this part because it was not necessary* (P12). Not knowing the exact guidelines, medical professionals relied on an intuitive understanding of the metrics and labels, which often resulted in discrepancies between the annotators as they attributed different meanings.

Hardware configuration and user interface of the labelling software affected the quality of the annotations. These challenges were observed to a greater extent in ORG I, as to assess medical data like CT scans and x-rays, radiologists usually use diagnostic displays. Thus, when they annotate on a *"non-diagnostic screen, you miss details ... maybe small, smaller changes would be missed ... we don't annotate them because we cannot see them"* (P13). Similar comments were shared during the evaluation of the labelling software, medical professionals marked the location of findings using touchpads, which resulted in frustration and low precision.

Labelling software design could have influenced the final quality of the medical dataset to an even greater extent if not caught during the evaluation. Labelling medical data requires "[a] professional tool that could do the job in a very efficient way" (P21). However, the design of this software could have influenced radiologists in ORG I to overreport radiological findings per x-ray during an evaluation period, *"...maybe it's an interface. Maybe they forgot the normal button was there because they only saw the [labels]"* (P1).

The overreporting was not solely caused by the labelling software. **Expectations and habits influenced what medical professionals noticed in medical data.** For example, a radiologist who reported on an evaluation of the ground truth schema in ORG I reported, *"I told my participants that there would be some normal, but they have not marked any of them normal or I can't find them"* (P1). This phenomenon was later explained by a senior radiologist who pointed to the expectation of labelling a dataset with findings and the fact that when the ratio of abnormal to normal cases is skewed, radiologists tend to overreport to remain on the safe side, *"that's [why] they thought they saw something that was not there"* (P6).

5 DISCUSSION

In the creation of high-quality training data, our research shows that the design of ground-truth schema is a crucial but often overlooked step. We highlight five factors that represent external and internal constraints that directly affect the quality of the resulting medical datasets. The external constraints condition the data collection process, affecting this way the design of the ground truth schema, while the internal constraints strongly affect the resulting ground truth schema and can lead to disagreements and debates among domain experts, predominantly data scientists and medical professionals.

5.1 Conditioning the data collection

Our findings demonstrate that the regulatory constraints, along with the geographical, demographic, and linguistic context of creation and intended use, and the organisations' scalability crucially affect the amount and type of data that was possible to be collected by the organisations we studied. In this sense, specific data quality metrics were already compromised since the first stage of the medical datasets creation. For example, in ORG I and II the geographical and demographic distribution of the collected data reflected not only how much data was possible to be collected by the contractual agreements in place but also manifested a lack of representativeness, given the regional and local source of data collection.

In ORG III, the aspirations for creating datasets of global coverage stumbled upon the linguistic contextuality of medical terms, which proved to become an issue during the ground truth schema design for the match-making platform. Similarly, in ORG I, the geographical, demographic, and linguistic context of the medical data collection shaped the type of the collected data, such as that when the experts came to decide on how to design the ground truth schema, dilemmas did not only concern the different understanding of the same medical terms across countries and continents but also possible omissions of local lung diseases. In this sense, the aspiration of designing "transferable" ground truth schemas proved to be both dependent and limited by the standards that regulate the data collection and the context of its collection.

A further insight that emerged in our studies was that the business models and scalability of each organisation affected differently its capacity to collect data. For example, ORG I, being a small-size start-up, having however the public sector involved in its entity, had easier access to timely data (x-ray images of multiple years) from regional hospitals. Yet, the organisation's limited scalability defined the amount of data that was possible to be labelled by medical professionals. In Org III, a similarly small-size start-up, the data collection from both public registries and patients was shaped by the organisation's availability of resources. The constraints were imposed on the recruitment of data scientists designing the platform's ground truth schema and medical professionals who assisted the patients in submitting their medical information into an appropriate and structured format. On the other hand, in ORG II, due to its large size and scalability, the limitations of the data collection were shaped by market demands. This was reflected in the need to collect quality data, i.e., particularly structured, consistent, and contextual medical images from a controlled environment (the contracted local hospital). This push for one type of quality reduced another, in this case, the representativeness of the acquired data.

So far, scholarship has defined and treated data acquisition as a particular step in the data creation process, existing in a vacuum [1, 11, 26, 50, 65]. Very little is known about how this step influences the stages that precede the data labelling, eventually affecting the shape of the final medical dataset. Our studies show that regulatory constraints, the context of data creation and use, and the business models and scalability of the organisations, crucially affect the extent and the type of data that is possible to be collected and processed.

5.2 Conditioning the ground truth design

Within this context, we identified the design of the ground truth schema as a crucial stage of medical dataset creation. In our studies, the externally imposed constraints shaped the amount and type of data that reached the stage of designing ground truth schema. This has implications for scholarly discussions that focus on developing documentation frameworks that support the responsible and informed use of complex datasets [2, 5, 20, 31, 44]. We showed that

the decisions taken during the design of the ground truth schemas were foundational to the succeeding stages of dataset creation. We argue that in this stage, experts do not deal with ideal conditions, but there are inherent limitations which we conceptualised as epistemic differences and limits of labelling. We further argue that the external constraints influence how these inherent limitations manifest in situated collaborative domain settings.

The amount and type of data that reach the ground truth schema design is already shaped by the necessity of organisations to comply with regulatory standards. This has led the experts from ORG I and II to work with data that had limited representativeness from the start, further affected by the predefined purpose of use and geographical, demographic, and linguistic context for its collection and use. These had implications for the negotiations between data scientists, designers, and medical professionals on what "makes sense" to be labelled.
