Domain negotiations that we observed, were grounded in epistemic differences that did not take place with symmetrically allocated roles, where the "separation of concerns" of each domain expertise is often negotiated against the tacit medical knowledge but where data scientists have the first say [32, 55, 62]. Having the development of AI models as the purpose of medical dataset creation, data scientists were positioned as the problem owners of the data creation processes. This further distanced the design of the labels from the medical domain experts and was manifested through misapprehensions about medical knowledge and practice. The tensions with the medical professionals often led to negotiations about what was medically important to be annotated versus what would lead to high-quality datasets from a data science perspective. At the same time, both of these standpoints had to correspond to the demands of the health-tech market.

We found that the externally imposed concerns, such as compliance with regulatory standards, the context of creation, and the intended use of the data, along with the commercial and operational pressures, condition the data collection and can affect ground-truth schema design. In fact, many crucial decisions and negotiations relevant to the final shape of the medical datasets take place during the stage of ground truth schema design. All three organisations under study were committed to developing AI systems in a responsible way. As such, the creation of high-quality training data was a crucial step. Yet, no matter how hard they tried to create representative, consistent, well-structured, high-quality data, the resulting datasets were already limited in different ways. We showed how these limits were predefined even before any data labelling occurred. The combination of external constraints that limit and structure data collection with the misapprehension of domain practice resulted in highly paid experts having to imagine and invent additional information to perform the tasks asked of them. A limited understanding of what is required for diagnosing various conditions from medical images could have consequences. Either new datasets would have to be created, which translates into a new data collection process, with all the regulatory constraints attached, or the labelling software would have to be more aligned with the existing professional practices following the guidance of expert annotators. Even where these issues were resolved, medical professionals annotated data based on their particular experience and tacit knowledge. This means that the geographical location of the experts affected what they expected to see in the data, showcasing that expertise does not account for the uneven distribution of diseases in different parts of the world.

6 LIMITATIONS AND FUTURE WORK

Our contribution builds on qualitative data from three organisations located in countries of the Global North. Creating medical AI datasets in different countries of the Global South may present different challenges and be influenced by a different set of factors that were not captured in our data. Further research is needed to better understand how medical AI data creation varies across different regions and cultures.

Our study focuses on only two medical areas: radiology and clinical trials. While we engaged with diverse types of medical data, creators of other medical datasets could face challenges unique and dependent on different types of medical specialisations. Future research should aim to explore the factors that influence the design of medical AI datasets across a wider range of medical specialisations to develop a more comprehensive understanding of the factors that influence it.

7 CONCLUSIONS

In this paper, we investigated the work of data scientists, medical professionals, and designers that takes place before the labelling of medical data. Building on the qualitative accounts of our ethnographic findings, our main contributions are:

- conceptualising five factors that influence the creation of medical datasets;
- disclosing how these factors condition the design of ground truth schemas;
- suggesting identified relationships amongst these factors;
- staging the design of the ground truth schemas as a highly contested, yet crucial step in the creation of medical datasets that precedes and conditions data annotation.

These overarching factors had a fundamental influence on the final shape of medical datasets created for AI use. First, the externally imposed constraints should be systematically taken into account during the entirety of the medical dataset creation processes, as these factors define the data collection and condition the design of the ground truth schemas. Second, we have exemplified the breadth of decisions taken before the annotation of medical data. Foundational decisions about the final shape of medical datasets take place during the design of a ground truth schema. Future endeavours in data science, law, and policy should consider this stage as crucial to achieving responsible medical AI.

ACKNOWLEDGMENTS

We would like to express our heartfelt gratitude to all of our participants, especially Dr. Elijah Kwasa, Dr. Edward Mwaniki, Dr. Marian Morris, Dr. Ruth Wanjohi, Dr. Mary Onyinkwa, Dr. Sayed Shahnur, and Dr. Samuel Gitau for their invaluable contributions and insightful input. Thank you for taking the time to engage with us and for your significant impact on our work.

ABSTRACT

The last 3 years have resulted in machine learning (ML)-based image generators with the ability to output consistently higher quality images based on natural language prompts as inputs. As a result, many popular commercial "generative AI Art" products have entered the market, making generative AI an estimated $48B industry [125]. However, many professional artists have spoken up about the harms they have experienced due to the proliferation of large scale image generators trained on image/text pairs from the Internet. In this paper, we review some of these harms which include reputational damage, economic loss, plagiarism and copyright infringement. To guard against these issues while reaping the potential benefits of image generators, we provide recommendations such as regulation that forces organizations to disclose their training data, and tools that help artists prevent using their content as training data without their consent.

1 INTRODUCTION

In the two years since the publication of [18] which outlines the dangers of large language models (LLMs), multimodal generative artificial intelligence (AI) systems with text, images, videos, voice, and music as inputs and/or outputs have quickly proliferated into the mainstream, making the generative AI industry valued at an estimated $48B [125]. Tools like Midjourney [78], Stable Diffusion [5], and DALL-E [91] that take in text as input and output images, as well as image-to-image based tools like Lensa [97] which output altered versions of the input images, have tens of millions of daily users [47, 127]. However, while these products have captured the public's imagination, arguably to a much larger extent than any prior AI system, they have also resulted in tangible harm, with more to come if the ethical concerns they posit are not addressed now. In this paper, we outline some of these concerns, focusing our discussion on the impact of image based generative AI systems, i.e. tools that take text, images, or a combination of both text and images as inputs, and output images. While other works have summarized some of the potential harms of generative AI systems more generally [18, 28, 29], we focus our discussion on the impacts of these systems on the art community, which has arguably been one of the biggest casualties (Section 4) [40, 138].

As we argue in Section 3, image based generative AI systems, which we call **image generators** throughout this paper, are not artists. We make this argument by first establishing that art is a uniquely human endeavor, using perspectives from philosophies of art and aesthetics. We further discuss how anthropomorphizing image generators and describing them as merely being "inspired" by their training data, like artists are inspired by other artists, is not only misguided but also harmful. Ascribing agency to image generators diminishes the complexity of human creativity, robs artists of credit (and in many cases compensation), and transfers

accountability from the organizations creating image generators, and the practices of these organizations which should be scrutinized, to the image generators themselves.

While companies like Midjourney, Stability AI and Open AI who produce image generators are valued at billions of dollars and are raising hundreds of millions of dollars[1], their products are flooding the market with content that is being used to compete with and displace artists. In section 4, we discuss the impact of these products on working artists, including the chilling effect on cultural production and consumption as a whole. Merely open sourcing image generators does not solve these problems as they would still enable people to plagiarize artists' works, and impersonate their style for uses that the artists have not consented to.

In Section 5, we provide a summary of the relevant legal questions pertaining to image generators. While there have been legal developments around the world, we focus our analysis on the US where a number of lawsuits have been filed by artists challenging the use of image generators [129]. Given that copyright has been the most frequently invoked law in such cases [28], we provide an overview discussing the relevance of US copyright law in protecting artists, and conclude that it is largely unequipped to tackle many of the types of harms posed by these systems to content creators. As we discuss in Section 6, the AI research community has enabled the aforementioned harms through data laundering, with for-profit corporations partnering with academic institutions that help them gather training data for commercial purposes while increasing their chances of courts finding these uses to be "fair use".

We end our discussion with proposals for new tools and regulations that tackle some of the harms discussed in this paper, as well as encouraging the AI community to align themselves with those harmed by these systems rather than powerful entities driving the proliferation of generative AI models trained on the free labor of content creators.

2 LITERATURE REVIEW

2.1 Background on Image Generation

We define "generative artificial intelligence (AI)" to encompass machine learning products that feature models whose output spaces overlap in part or in full with their input spaces during training, though not necessarily inference. While generative AI systems are based on generative models which statistically aim to model the joint distribution between a feature space and output space $p(x, y)$ [85], we distinguish between "generative AI" systems and generative models as the latter can be used in classification systems. This paper focuses on products whose stated output space composes, in part or in full, of visual data (i.e. images), which will be referred to as **image generators**; similarly, the scope of art discussed within this work is largely limited to the fields of visual art. We consider two different applications in the context of inference, text-to-image and image-to-image, though more recent multimodal pretrained model architectures usually are capable of both (and often necessitate both).

Early approaches to image synthesis such as [38, 95, 120], aimed to achieve texture synthesis, i.e. modifying an existing image to copy the texture of another image [38, 95, 120]. In the deep learning era of computer vision (2012 until now), Convolutional Neural Networks (CNNs) enabled the ability to recognize a large amount of latent attributes that do not conform to arbitrary statistical forms, unlike early works in texture synthesis [69].

In addition to CNNs, another architectural element of note is the variational autoencoder (VAE), like the one used in Yan et al. [135]; VAEs, which use two mirrored neural network components to map the input space to a latent space (encoder) and vice versa (decoder) [68], set the stage for the development of generative models, which significantly widened the capacity of image synthesis. A key element of VAEs is the reconstructive loss function which allows an ML system to explicitly define its training objective as the re-creation of input features, with the expectation that the model can generalize beyond the training set during inference. VAEs enabled the creation of image generation models such as VQ-VAE-2 [104] and are components of many subsequent models.

The next major breakthrough is the generative adversarial network (GAN), which employs the use of two models trained simultaneously [58]. Unlike conventional neural networks such as VAEs which directly and asymmetrically measure the divergence between a distribution known to be a reference and one known to be a hypothesis, GANs indirectly measure the divergence between two distributions of masked origin through the intermediary of the discriminator. The introduction of conditional losses in [82] made GANs the dominant architecture in image generation due to the ability to now inform outputs with text tags as auxiliary information; the paper itself used a handwriting generator trained on the MNIST dataset [35] as a demonstration. With GANs came the first large-scale image generating models, allowing for output sizes of up to 512×512 [24, 61, 65].

The adaptation of approaches from natural language processing (NLP) such as transformers further enabled having complex text as input for text-to-image models [42]. In [30], OpenAI adapted the architecture of GPT-2, a large language model (LLM), to output a series of pixel values that could be rearranged into a recognizable image. This research led to the original DALL-E [103], a tool that outputs a 256×256 RGB image based on natural language prompts, this time using the GPT-3 architecture [25].

In the last 3 years, the use of GANs for image generation has been overtaken by diffusion models which take inspiration from fluid dynamics [37, 86, 116, 118]. These models work by repeatedly applying gaussian noise on an image (imitating the diffusion process of fluids or heat), and then denoising the result in equally many steps [118]. In a departure from GANs' implicit modeling, diffusion models return to using a reconstruction loss.

In 2022, Rombach et al. released the Stable Diffusion model [4, 106], which uses a conditional latent space based on text and images: in this case a pretrained model by OpenAI called CLIP [99]. This allowed for models that are not confined to natural language understanding (NLU)-based architectures, and can generate high-quality images based on natural language prompts. In the same year, OpenAI released DALL-E 2 [91] which has a similar model architecture [102] but with a training dataset that is opaque to the public.

[1] https://www.nytimes.com/2023/01/23/business/microsoft-chatgpt-artificial-intelligence.html

In addition to different model architectures, massive image datasets such as JFT-300M (300M images) [124] have helped improve image generation performance. The current crop of image generators, primarily those based on Stable Diffusion, are pretrained on LAION [109], or its variants which are subsets of the original 5B dataset. The dataset consists of 5.85 billion CLIP-filtered image-text pairs, of which 2.32B contain English language text. An exploration of a subset of LAION can be found at [11].

2.2 Products for Image Generation

The advent of Stable Diffusion and related models has resulted in a proliferation of commercial and non commercial image generation tools that use them. Stability AI's Stable Diffusion [5] and its commercial product Dream Studio[2], OpenAI's DALL-E 2 [91], and Midjourney [78] are the most popular systems built on diffusion models, with StarryAI [122], Hotpot.ai [94], NightCafe [123], and Imagen [108] being a few others. Established art software company Adobe has also released its image generator product, Adobe Firefly [3], which the company says is trained on Adobe Stock images, images in the public domain, and those under open licensing. The ecosystem is large and expanding, including organizations like Fotor [45], Dream by WOMBO [133], Images.AI [128], Craiyon [71], ArtBreeder [9], Photosonic [134], Deep Dream Generator [55], Runway ML [107], CFSpark [46], MyHeritage Time Machine [73], and Lensa [97]. While some advertise the model architectures they use, such as StableCog [121] using diffusion-based techniques, others provide little to no detail. For example, while the CEO of Stability AI has written that Midjourney used Stable Diffusion in past releases [3], Midjourney does not disclose underlying model information for its current releases, only mentioning "a brand-new AI architecture designed by Midjourney" in describing its releases since November 2022 [79].

Most of the products identified above emerged as specific commercial offerings for users to generate images by providing text prompts. There are other services that have been introduced as features in existing products, such as synthetic images in Canva [26], Shutterstock [113], and Adobe Stock Images [2], which seek to augment their stock image offerings with synthetic images. On the other hand, companies like Getty Images took a stance against including synthetic images in their portfolio of offerings in 2022 [130], although NVIDIA announced a collaboration with them in 2023 to develop image generators [76]. Open source efforts in the space have focused on using Stable Diffusion and other open-source variants to create plugins for Photoshop [7], Unreal Engine [43], and GIMP [20]. Some groups, such as Unstable Diffusion, are explicitly focused on generating not-safe-for-work (NSFW) content [59].

3 IMAGE GENERATORS ARE NOT ARTISTS

Many researchers have pointed out the issues that arise from the anthropomorphization of AI systems, including shifting responsibility from the people and organizations that build these systems, to the artifacts they build as if those artifacts have agency on their own [13, 16, 39]. This anthropomorphization is readily apparent in descriptions of image generators as if they are artists [39], even going as far as to claim that the image generators are "inspired" by the data they are trained on, similar to how artists are inspired by other artists' works [66]. In this section, we discuss why such arguments are misguided and harmful.

Following philosophers of art and aesthetics from varied disciplines (e.g. Chinese and Japanese Philosophy, American Pragmatism, and Africana Philosophy), we define art as a uniquely human endeavor connected specifically to human culture and experience [6, 36, 62, 74, 75, 88, 93]. Most philosophers of art and aesthetics argue that while non-human entities can have aesthetic experiences and express affect, a work of art is a cultural product that uses the resources of a culture to embody that experience in a form that all who stand before it can see. On this view, art refers to a process that makes use of external materials or the body to make present experience in an intensified form. Further, this process must be controlled by a sensitivity to the attitude of the perceiver insofar as the product is intended to be enjoyed by an audience. The artwork, therefore, is the result of a process that is controlled for some end and is not simply the result of a spontaneous activity ([36] pp. 54, 55). This control over the process of production is what marks the unique contribution of humanity: while art is grounded in the very activities of living, it is the human recognition of cause and effect that transforms activities once performed under organic pressures into activities done for the sake of eliciting some response from a viewer. As an example, a robin might sing, a peacock might dance, but these things are performed under the organic pressures of seeking a mate. In humans, song and dance are disconnected from the organic pressures of life and serve purposes beyond the mere satisfaction and expression of organic pressures, and serve cultural purposes. In brief, art is a form of communication: it communicates.

In contrast, the outputs of artifacts like image generators are not framed for enjoyment because they merely imitate the technical process, and then only those technical processes embodied in the works that make up the training dataset. The image generator has no understanding of the perspective of the audience or the experience that the output is intended to communicate to this audience. At best, the output of image generators is aesthetic, in that it can be appreciated or enjoyed, but it is not artistic or art itself. Thus, "Mere perfection in execution, judged in its own terms in isolation, can probably be attained better by a machine than by human art. By itself, it is at most technique… To be truly artistic, a work must also be esthetic—that is, framed for enjoyed receptive perception." ([36] pp. 54).

Thus, art is a uniquely human activity, as opposed to something that can be done by an artifact. While image generators have to be trained by repeatedly being shown the "right" output, using many examples of the desired target, and explicitly defining an objective function over which to optimize, humans do not have such rigid instructions. In fact, while image generators have been shown to even memorize their data and can output almost exact replicas of images from their training set under certain conditions [27, 117], as artist Karla Ortiz writes, artists' styles are so unique to them, that it is very difficult for one artist to copy another's work [92]. The very few artists who are able to do this copying are known for this skill [92]. An artists' 'personal style' is like their handwriting, authentic to them, and they develop this style (their personal voice

[2]https://dreamstudio.com
[3]https://web.archive.org/web/20220823032632/https://twitter.com/EMostaque/status/1561917541743841280, referring to V3

and unique visual language) over years and through their lived experiences [92].

The adoption of any particular style of art, personal or otherwise, is a result of the ways in which the individual is in transaction with their cultural environment such that they take up the customs, beliefs, meanings, and habits, including those habits of aesthetic production, supplied by the larger culture. As philosopher John Dewey argues, an artistic style is developed through interaction with a cultural environment rather than bare mimicry or extrapolation from direct examples supplied by a data set [23]. Steven Zapata argues, "our art 'creates' us as artists as much as we create it" [138]. This experience is unique to each human being by virtue of the different cultural environments that furnish the broader set of habits, dispositions towards action, that enabled the development of anything called a personal style through how an individual took up those habits and deployed them intelligently.

Finally, an image generator is trained to generate images from prompts by mapping images and texts into a lower dimensional representation in a latent space [58, 68, 106]. This latent space is learned during the model's training process. Once the model is trained, this latent space is fixed and can only change through training from scratch or fine-tuning on additional examples of image-text pairs [57]. In contrast, human inspiration changes continuously with new experiences, and a human's relationship with their lived experiences evolves over time. Most importantly, these experiences are not limited to additional artistic training or viewing of images. Rather, humans perform abstract interpretations between representational and imaginary subjects, topics, and of course, personal feelings and experiences that an artifact cannot have.

Let's look at Katsuhiro Otomo's seminal *Akira* as an example. Otomo notes that he created these images by drawing inspiration from his own teenage years, thinking about a rebuilding world, foreign political influence, and an uncertain future after World War II [12]. Similarly, Claude Monet created his defining *Nymphéas [Water Lilies]* series during the last 30 years of his life, after the loss of his son in 1914 [63]. As shown by both these artists, and many other artists, the human experience both defines and inspires creation across an artist's personal lifetime. Each individual's art is unique to their life experiences. Otomo's *Akira* is a fundamentally different form of artwork than Monet's *Nymphéas [Water Lilies]* series not simply due to their different stylistic and pictorial media, but due to the way in which each artists' work was an expression of a cultural inheritance that shaped the unique experiences that gave rise to their particular art forms. While image generators can imitate the stylistic habits, the "unique voices" of a given artist, they cannot develop their own particular styles because they lack the kinds of experiences and cultural inheritances that structure every creative act. Even when provided with a human-written prompt, the sampling of a probability distribution conditional on a string of text does not present a synthesis of concepts, emotion, and experience.

In conclusion, image generators are not artists: they require human aims and purposes to direct their "production" or "reproduction," and it is these human aims and purposes that shape the directions to which their outputs are produced. However, many people describe image generators as if these artifacts themselves are artists, which devalues artists' works, robs them of credit and compensation, and ascribes accountability to the image generators rather than holding the entities that create them accountable. In [39], Epstein et al. performed a study with participants on Amazon Mechanical Turk to assess the impact of anthropomorphization of image generators, finding a relationship between the manner in which participants assign credit and accountability to stakeholders involved in training and producing image generators, and the level of anthropomorphization. They advise "artists, computer scientists, and the media at large to be aware of the power of their words, and for the public to be discerning in the narratives they consume."

4 IMPACT ON ARTISTS

The proliferation of image generators poses a number of harms to artists, chief among them being economic loss due to corporations aiming to automate them away. In this section, we summarize some of these harms, including the impact of artists' styles being mimicked without their consent, and in some cases, used for nefarious purposes. We close with a discussion of how image generators stand to perpetuate hegemonic views and stereotyping in the creative world, and the chilling effects of these technologies on artists as well as overall cultural production and consumption.

4.1 Economic Loss

While artists hone their craft over years of practice, observation, and schooling, having to spend time and resources to pay for supplies, books, and tutorials, companies like Stability AI are using their works without compensation while raising billions from venture capitalists to compete with them in the same market[4]. Leaders of companies like Open AI and Stability AI have openly stated that they expect generative AI systems to replace creatives imminently[5][6]. Stability AI CEO Emad Mosque has even accused artists of wanting to have a "monopoly on visual communications" and "skill segregation"[7]. To the contrary, current image generation business models like those of Midjourney, Open AI and Stability AI, stand to centralize power in the hands of a few corporations located in Western nations, while disenfranchising artists around the world.

It is now possible for anyone to create hundreds of images in minutes, compile a children's book in an hour[8], and a project for a successful Kickstarter campaign in a fraction of the time it takes for an actual artist[9]. Although many of these images do not have the full depth of expression of a human, commercial image generators flood the market with acceptable imagery that can supplant the demand for artists in practice. This has already resulted in job losses for artists, with companies like Netflix Japan using image generators for animation, blaming "labor shortage" in the anime industry for not hiring artists [32].

One of the more high profile cases of the labor impact can be seen in the title sequence of Marvel Studio's 2023 TV series *Secret Invasion*, which uses a montage of generated imagery [81]. While prior movies from the studio feature between 5 (*The She-Hulk: Attorney at Law*[10]) and 9 (*Hawkeye*[11]) artists and illustrators for their title sequences, *Secret Invasion* has only one "Sagans Carle" credited as "AI Technical Director"[12]. This labor displacement is evident across creative industries. For instance, according to an article on Rest of World, a Chinese gaming industry recruiter has noticed a 70% drop in illustrator jobs, in part due to the widespread use of image generators [139]; another studio in China is reported to have laid off a third of its character design illustrators [139].

In addition to displacing the jobs of studio artists, the noise caused by the amount of AI-generated content will likely be devastating for self-employed artists in particular. This has become evident in the literary world with the advent of LLM based tools like ChatGPT[13]. Recently, Clarkesworld, a popular science fiction magazine, temporarily closed open submissions after being overwhelmed by the number of ChatGPT generated submissions they received [31]. They announced that they will instead only solicit works from known authors, which disadvantages writers who are not already well known. It is not difficult to extrapolate such a result with visual art venues that receive too many AI-generated images. Contrary to "democratizing art," this reduces the number of artists who can share their works and receive recognition.

Regardless of their objections, some working artists have started to report having to use image generators to avoid losing their jobs, further normalizing its commercial use [139]. Artists have also reported being approached by companies producing image generators to work on modifying the outputs of their systems [14]. This type of work reduces hard earned years of skill and artistic eye to simple cleanup work, with no agency for creative decisions. In spite of these issues, creatives in executive roles who can be isolated from the realities of most working artists, may gravitate towards using these tools without considering the effects on the industry at large, such as a reduction in the economic earning power of many working artists. For instance, the director of *Secret Invasion* had editorial control in deciding whether to use image generators[15], and chose to replace illustrators' works with image generated content.

With the increasing barriers and job losses for creatives because of image generators, the pursuit of art could be relegated to the independently wealthy and those who can afford to develop their artistic skills while working a full-time job. This will disproportionately harm the development of artists from marginalized communities, like disabled artists, and artists with dependents.

4.2 Digital Artwork Forgery

As discussed in Section 2, image generators are trained using billions of image-text pairs obtained from the Internet. Stable Diffusion V2, for instance, is trained using the publicly available LAION-5B dataset [106, 109]. Although the creators of LAION-5B have not provided a way for people to browse the dataset, various artists have reported finding their works in the training data without their consent or attribution [11]. Open AI has not shared the dataset that its image generator, DALL-E, was trained on, making it impossible to know the extent to which their training data contains copyright protected images. Using a tool[16] built by Simon Willison which allowed people to search 0.5% of the training data for Stable Diffusion V1.1, i.e. 12 million of 2.3 billion instances from LAION 2B [109], artists like Karen Hallion[17] [18] found out that their copyrighted images were used as training data without their consent [11]. And as noted in Section 3, image generators like Stable Diffusion have been shown to memorize images, outputting replicas of iconic photographs and paintings by artists [27, 92].

This type of digital forgery causes a number of harms to artists, many of whom are already struggling to support themselves and can only perform their artistic work while having other "day" jobs [70]. First, as discussed in Section 4.1, using artists' works without compensation adds to the already precarious positions that the majority of professional artists are in [70, 92, 138]. In addition to the lack of compensation, using artists' works without their consent can cause them reputational damage and trauma. Users of image generated art can mimic an artist's style by finetuning models like Stable Diffusion on specific artists' images, with companies like Wombo even offering services to generate art in the style tied to specific groups of artists like Studio Ghibli [133]. A number of artists have described this practice as "invasive" and noted the manner in which it causes them reputational damage. After a Reddit user posted images generated using artist Hollie Mengert's name as a prompt, Mengert mentioned that "it felt invasive that my name was on this tool, I didn't know anything about it and wasn't asked about it."[19] She further noted her frustration with having her name associated with images that do not represent her style except at "the most surface-level."

This type of invasive style mimicry can have more severe consequences if an artist's style is mimicked for nefarious purposes such as harassment, hate speech and genocide denial. In her New York Times Op-ed [8], artist Sarah Andersen writes about how even before the advent of image generators people edited her work "to reflect violently racist messages advocating genocide and Holocaust denial, complete with swastikas and the introduction of people getting pushed into ovens. The images proliferated online, with sites like Twitter and Reddit rarely taking them down." She adds that "Through the bombardment of my social media with these images, the alt-right created a shadow version of me, a version that advocated neo-Nazi ideology…I received outraged messages and had to contact my publisher to make my stance against this ultraclear." She underscores how this issue is exacerbated by the advent of image generators, writing "The notion that someone could type my name into a generator and produce an image in my style immediately disturbed me…I felt violated" [8]. As we discussed in Section 3, an

artist's style is their unique voice, formed through their life experiences. Echoing Hollie Mengert's point about the invasive nature of style mimicry, Andersen adds: "The way I draw is the complex culmination of my education, the comics I devoured as a child and the many small choices that make up the sum of my life. The details are often more personal than people realise." Thus, tools trained on artists' works and which allow users to mimic their style without their consent or compensation, can cause significant reputational damage by impersonating artists and spreading messages that they do not endorse.

4.3 Hegemonic Views and Stereotyping

Beyond the appropriation of individual identities, image generators have been shown to appropriate and distort identities of groups, encode biases, and reinforce stereotypes [87, 98, 119]. Introducing In/Visible, an exhibition exploring the intersection of AI and art, Senegalese artist Linda Dounia Rebeiz writes: "Any Black person using AI today can confidently attest that it doesn't actually know them, that its conceptualization of their reality is a fragmentary, perhaps even violent, picture…Black people are accustomed to being unseen. When we are seen, we are accustomed to being misrepresented. Too often, we have seen our realities ignored, distorted, or fabricated. These warped realities, often political instruments of exclusion, follow us around like shadows that we can never quite shake off" [64]. In an interview, the artist gives examples of stereotypes perpetuated through image generators. For instance, she notes that the images generated by Dall-E 2 pertaining to her hometown Dakar were wildly inaccurate, depicting ruins and desert instead of a growing coastal city [114]. Similarly, US-based artist Stephanie Dinkins discusses encountering significant distortions when prompting image generators to generate images of Black women [114].

There are already cases of people producing images embodying their view of other populations. In a 2018 New Yorker article, Lauren Michelle Jackson writes about a white British photographer, Cameron-James Wilson, who created a dark skinned synthetic model which he called "Shudu Gram," and the "World's first Digital Supermodel" [77]. The synthetic model, which he created using a free 3D modeling software called DAZ3D[20], first appeared on Instagram wearing "iindzila, the neck rings associated with the Ndebele people of South Africa" [77]. Jackson licensed the image to various entities such as Balmain[21] and Ellesse, [22] many of whom were criticized for their lack of diversity in hiring [96]. Now, without compensation to any Ndebele people, magazines like Vogue[23] profit off of an idealized conception of someone from that community, imagined in the mind of a white man who is compensated for creating that image. Writer Francesca Sobande writes that this is another iteration of "the objectification of Black people, and the commodification of Blackness" [115]. Five years later, on March 6 2023, entrepreneur Danny Postma announced the launch of a company, Deep Agency, that rents image generated synthetic models as a service[24], making the type of practice described by Jackson more likely to occur at scale.

Due to these questions of who gets to use (and profit from) these tools by representing which cultures in what way, participants from Pakistan, India and Bangladesh surveyed in [98] raised "concerns about artist attribution, commodification, and the consequences of separating certain art forms from their traditional roots," with some questioning which cultural products should be included in the training set of image generators. To expose these issues, Quadri et al. recommend further examination of the cultural harms posed by image generators, including perpetuating cultural hegemony, erasure or stereotyping [98].

4.4 Chilling Effects on Cultural Production and Consumption

The harms discussed in the prior sections have created a chilling effect among artists, who, as artist Steven Zapata notes, are already a traumatized community with many members struggling to make ends meet [137]. First, students who foresee image generators replacing artists have become demoralized and dissuaded from honing their craft and developing their style [138]. Second, both new and current artists are becoming increasingly reluctant to share their works and perspectives, in an attempt to protect themselves from the mass scraping and training of their life's works [92, 138]. Independent artists today share their work on social media platforms and crowdfunding campaigns, and sell tutorials, tools, and resources to other artists on various sites or at art-centric trade shows [25]. For most artists, gaining enough visibility on any of these platforms (online or in person) is extremely competitive, taking them years to build an audience and fanbase to sell their work and eventually have the ability to support themselves [26]. Thus, having less visibility in an attempt to protect themselves from unethical practices by corporations profiting from their work, further reduces their ability to receive compensation for their work.

Artists' reluctance to share their work and teach others also reduces the ability of prospective artists to learn from experienced ones, limiting the creativity of humans as a whole. Similar to the feedback loop created by next generations of large language models trained on the outputs of previous ones [18], if we, as humanity, rely solely on AI-generated works to provide us with the media we consume, the words we read, the art we see, we would be heading towards an ouroboros where nothing new is truly created, a stale perpetuation of the past. In [18], the authors warn against a similar issue with future generations of large language models trained on outputs of prior ones, and static data that does not reflect social change.

In his 1916 book titled Art, Clive Bell writes "The starting-point for all systems of aesthetics must be the personal experience of a peculiar emotion. The objects that provoke this emotion we call works of art" [15]. As Steven Zapata notes, we need to "protect

the creative human spirit…Making art is one of the best ways to investigate one of the ways you are influenced, and the way to send how you're influenced to other people. If we don't curb this, this influence can come from AI, AI that can't discern boundaries, and influence feelings. Let's not let it happen" [137].

5 AI ART AND US COPYRIGHT LAW

Given the speed at which image generators have been adopted and their impact, countries around the world are grappling with what policies to enact in response. In particular, there is a lot of uncertainty about whether using copyrighted materials to train image generators is copyright infringement. Some governmental bodies, like the EU, will require companies to "document and make publicly available a summary of the use of training data protected under copyright law"[27] [44], which could trigger copyright lawsuits if it becomes possible to identify specific instances of copyright infringement [72]. However, it is not clear what the scope of this law is and if it requires an itemized list of what is included in the training data, or only a summary of other key information.

While a number of artists have filed class action lawsuits in the US against companies providing commercial image generation tools [129], image generators represent a dynamic between artists and large-scale companies appropriating their work that has previously not been examined in US copyright law [56]. This is due to the unprecedented scale at which artists' works are being used to create image generators, the recent proliferation of publicly available image generators trained on that content, and the level to which the output of the image generators threatens to displace artists. Furthermore, this dynamic is distinct because of the data collection practices by which image generators are developed in the first place [67].

While some of the harms discussed in Section 4 overlap with the rights protected by US copyright law, others are not. There are also a number of unanswered legal questions when it comes to determining the ways in which copyright law applies to image generators and both the inputs and outputs that go into creating these tools. Hence, US copyright law is largely unequipped to tackle many of the types of harms posed by these systems to content creators. This lack of certainty about whether copyright applies means that the companies producing these tools can do so largely without accountability, unless they are sued for specific violations of copyright law. And waiting for court determinations on their lawsuits means that artists may not be able to get recourse until the cases are resolved. In this section, we highlight specific parts of US copyright law that may be a source of uncertainty and tension for artists and companies using their work. We conclude that there are gaps in the law that do not take into account the social and economic harm to artists.

5.1 Authorship

Thus far, no works created by an image generator have been given copyright protection, and authorship is limited to human creators. The US Copyright Office recently affirmed this position by declining to recognize the copyrightability of works that were created by an image generator [90]. In the US, the mere effort required to create a piece of art work does not, on its own, render the resulting work protected by copyright law, meaning that the number of prompts or hours poured into the creation of an image using text-to-image generators will not on its own qualify the work as copyrightable.[28] Moreover, the prompts themselves may be protectable if they are independently creative, and the resulting work may be copyrightable if the prompts were part of an active process by which the human creator exercised judgment by selecting, arranging, or designing the work [29]. US law also requires that the creator of the work be the source of the creativity and inventiveness of the work, and the Copyright Office noted that image generators produce images in an "unpredictable" way [90] and thus cannot be considered creative or inventive.

These dimensions of what it means to be an "author" under copyright law as well as how the law understands the process of creativity means that image generators on their own cannot create copyright protected works. How artists interact with these tools would determine the legal status of the output they create. Given this uncertainty about the legal status of the image generators' outputs, we can direct our policy attention to the inputs that go into creating the tools. There is an opportunity here to exercise more caution in the ex-ante processes of the tools' development such that the artists whose works are used to create the tools are not harmed, which we discuss in Section 7.

5.2 Fair Use

Fair use is a doctrine in copyright law that permits the unauthorized or unlicensed use of copyrighted works; whether it is to make copies, to distribute, or to create derivative works. Whether something constitutes fair use is determined on a case-by-case basis and the analysis is structured around four factors[30]. Most relevant for artists and generative AI systems are factors 1 and 4, which look at the purpose or character of the use and its impact on the market [14]. Part of the first factor includes the question of whether the use is commercial and "transformative". Commercial use usually weighs against finding fair use. If the use is found to be transformative, however, it can be considered fair use even for commercial purposes, but not always[31]. This is in part due to the fourth factor, which examines whether a use is a threat to the market of the original creator's work.

The question of fair use arises at two points within the image generation ecosystem. First is when the images used to train the datasets are copyrighted, and especially if the copyright holders are small-scale artists. These small scale artists could have an interest in not allowing their work to be used to create synthetic images, not only because image generators could be used to produce works resembling theirs, but because of issues around consent and misuse of their works for harassment, disinformation and hate speech as described in Section 4.2. Artists may not want to participate in the creation of an infrastructure that facilitates other informational harms, even if the image generator is not creating works resembling

[31] Fox News Network, LLC v. TVEyes, Inc., No. 15-3885 (2d Cir. 2018)

theirs. In this case, their concerns wouldn't be ones that can be addressed through fair use.

Moreover, small-scale artists may not want to pursue copyright infringement claims because of a lack of resources to participate in prolonged legal battles against powerful companies that claim such copying is fair use. This again means that copyright law is not the most effective recourse for them and the question of fair use may not be addressed in a case involving small-scale artists. The complaint[32] filed by Getty Images (a large and well-resourced copyright holder) against Stability AI is illustrative of the resources needed to assert copyright claims against companies producing image generators and the power differential that exists between small-scale copyright holders and these companies. Copyright infringement is a concern for small-scale artists but the overall system of how image generators normalize appropriation of art at the input stages is a problem that is beyond the scope of fair use considerations.

The second point where fair use is a question is if an image generator is used to create works that are similar to a human artist, and as a result compete with the human artist's market, as we describe in Section 4.1. In such instances, the fourth factor may weigh heavily against finding fair use. If the work is being used in ways that displaces the artist's market share, or prevents them from receiving appropriate attribution and compensation, there is a clear harm in place, and may be addressed through copyright law.

5.3 Derivative Works and Moral Rights

When companies design their products around "mimicking" the style of an artist, then it becomes difficult to justify the company's use as fair use [49]. In such instances, there is a clear connection between the company's product and the intended outcome being harm to the market for the original artist's work.

Such mimicking or use of an artist's work and style may also be covered under moral rights in copyright law. Moral rights vest in "visual art", such as paintings and photographs, and protect the creator's personal and reputational interest in their work by preventing the distortion or defacement of the original work [80]. The scope of moral rights in US copyright law is narrowly constructed for various policy reasons [89], but this area of copyright law may need more attention as artists try to articulate the harms they face.

6 SHORTCOMINGS OF THE AI RESEARCH COMMUNITY

In the previous section, we provided a brief analysis of US copyright law that may be relevant to artists' fight against the harms they face due to the proliferation of image generators. In this section, we discuss how academic researchers' partnerships with corporations help the latter sidestep some of these laws aimed at protecting creators. In her paper titled The Steep Cost of Capture, whistleblower Meredith Whittaker writes about the level to which academic AI research has been captured by corporate interests [132]. In The Grey Hoodie Project: Big tobacco, big tech, and the threat on academic integrity, Mohamed and Moustafa Abdalla liken this capture to the tobacco and fossil fuel industries, noting that corporations fund academics aligned with their goals, the same way that tobacco companies funded doctors that claimed that cigarettes did not cause cancer [1]. In her article, "You are not a stochastic parrot," Liz Weil notes "The membrane between academia and industry is permeable almost everywhere; the membrane is practically nonexistent at Stanford, a school so entangled with tech that it can be hard to tell where the university ends and the businesses begin" [131]. This corporate entanglement means that the academic research agenda is increasingly being set by researchers who align themselves with powerful corporate interests [51, 52, 132].

6.1 Data Laundering

One of the results of this corporate academic partnership has been data laundering [34]. Similar to money laundering, where business fronts are created to move money around while obfuscating the source of illicit funds, researchers have argued that companies use data laundering to obtain data through nonprofits that are then used in for profit organizations [10].

The LAION dataset used to train Stability AI's Stable Diffusion model, which is also used in their commercial Dream Studio product, is one such example[33]. While LAION is a nonprofit organization, the paper announcing the LAION-5B dataset notes that Stability AI CEO Emad Mostaque "provided financial and computation support for open source datasets and models" [109]. The dataset's associated datasheet further answers the question "Who funded the creation of this dataset" with "This work was sponsored by Hugging Face and Stability AI." As we mentioned in Section 6, while US copyright law is not fully equipped to resolve disputes related to image generated content, companies are more likely to be granted fair use exceptions in US copyright law if they claim that the dataset was gathered for research purposes, even if they end up using it for commercial products. According to the US copyright office, "Courts look at how the party claiming fair use is using the copyrighted work, and are more likely to find that nonprofit educational and noncommercial uses are fair."[34] This allows corporations like Stability AI to raise $101M in funding with a $1B valuation[35], using datasets that contain artists' works without their consent or attribution. The accountability for the dataset creation and maintenance, on the other hand, including copyright or privacy issues, is shifted to the nonprofit that collected it. Thus, while there is no legal distinction at present between data laundering and the normative data mining practices in the machine learning communities, this question needs more attention when the issue of fair use discussed in Section 5.2 arises in the context of image generators.

6.2 Power, ML Fairness, and AI Ethics

In the Moral Character of Cryptographic Work, cryptographer Philip Rogaway notes that the cryptographic community bears the responsibility of failing to stop the rise of surveillance [105]. One of the main reasons for this disconnect, according to him, is that cryptographers fail to take into account how power affects their analyses, and have a "politically detached posture," writing "if power is anywhere in the picture, it is in the abstract capacities

of notional adversaries or, in a different branch of our field, the power expenditure, measured in watts, for some hardware." Except for a few exceptions, the machine learning fairness and AI ethics communities have similarly failed to stop the harms caused by image generators proliferated by powerful entities, due to their disproportionate focus on abstract concepts like defining fairness metrics [84, 110, 136], rather than preventing harm to various communities. We urge the machine learning and AI ethics research communities to orient their focus towards preventing and mitigating harms caused to marginalized communities, in order to prevent further casualties of which the art community is only one.

7 RECOMMENDATIONS TO PROTECT ARTISTS

To fight back against the harms that artists have already experienced, they have filed class action lawsuits in the US against Midjourney, Stable Diffusion and DeviantArt [129], organized protests, boycotted online services like ArtStation that allowed image generated content on their platforms[36], and continue to raise awareness about the impact of image generators on their communities [92, 137, 138]. However, as discussed in Section 5, the US courts can take years to issue a decision, during which more artists would be harmed, and current US copyright law is ill equipped to protect artists. Because of this, artists themselves have suggested a number of regulations to protect them.

A letter to members of The Costume Designers Guild, Local 892, a union of professional costume designers, assistant costume designers, and illustrators working in film, television, commercials and other media[37], suggests legislation to allow "using AI derived imagery strictly for reference purposes and making it unacceptable to hand over a fully AI generated work as a finished concept" [126]. Visual artists who paint in a more representational style usually work from photo reference or build sculptures to understand how lighting works, for example, using stock/licensed photography and assets, or the artist's own work [38]. This would allow artists to use image generators to provide inspiration in the way that nature, for example, is a source of inspiration to many artists. The art collective Arte es Ética suggests having a metric to quantify the amount of human interaction with an image generator to determine whether or not a generated image is copyrightable, with a 25% or less interaction level being uncopyrightable [41].

While these proposals may address the issue of economic loss, they do not stop the use of artists' work for training image generators without their consent or compensation. Additional proposed regulations by Arte es Ética address this issue by recommending legislation that requires the explicit consent of content creators before their material is used for generative AI models [41]. In order to do this, they suggest having detection and filtering algorithms to ensure that uploaded content belongs to creators who have consented to their work being licensed or opted-in for use as training data. Similar to [18]'s recommendations to ensure that synthetic texts generated by LLMs be "watermarked and thus detectable," Arte es Ética suggests that each image carry "a digital signature" in its metadata, which is disclosed along with the generated image. Regulation that mandates that organizations disclose their training data, at the very least to specific bodies that can verify that people's images were not used without their consent, is needed in order to enforce the opt-in requirements artists are demanding. Such a mandate will likely exist outside of conventional copyright requirements. However, algorithmic accountability regimes and recently proposed laws like the Algorithmic Accountability Act of 2022 in the US [111], or the transparency requirements of the EU's AI Act that would require datasheets [54] or similar data documentation [44], may be preliminarily useful in instituting disclosure requirements for companies.

However, most of these existing measures require individuals to prove harm, rather than placing the onus on organizations to show lack of harm before proliferating their products. There need to be pathways toward better accountability of the entities and stakeholders that create the image generators in the first place, rather than placing additional burdens on artists to prove that they have been harmed. While auditing, reporting, and transparency are well-known possible proposals for regulating AI in general [17, 22, 54, 83, 100], formulating sector and industry specific proposals is essential when it comes to effective governance [100], and is what will be needed for image generators and art.

Regulation, even if successfully passed, takes a long time to be enforced however, and is by its very nature reactive. As artist Steven Zapata asks: "What are we going to do…to prevent this recurring over and over again" [137]? This is a fundamental question that requires us to understand why we are in a position where prominent machine learning researchers have used their skills to disenfranchise artists. One answer is the corporate capture of AI research that we discussed in Section 6.1. To combat this capture, computer scientist Timnit Gebru suggests having government research funding that is not tied to the military, in order to have "alternatives to the hugely concentrated power of a few large tech companies and the elite universities closely intertwined with them" [51].

A few researchers in machine learning have come to the defense of artists but they are much smaller in number than those working on image generators without attempting to mitigate their harms. For instance, University of Chicago student Shawn Shan and his collaborators, advised by security professor Ben Y. Zhao, created a tool called Glaze that allows artists to add perturbations to their images which would prevent diffusion model based generators from being used to mimic their styles [112]. The researchers collaborated with 1000 artists, going to town halls and creating surveys to understand their concerns. While building Glaze, Shawn Shan et al. measured their success by how much the tool was addressing the artists' concerns. This is an example of research that is conducted in service of specific groups, using a process that identifies stakeholders and values that should be incorporated in the work, rather than the current trend of claiming to build models with "general" capabilities that do not perform specific tasks in well defined domains [53, 101]. We echo [18]'s recommendations to use methodologies like value sensitive design and design justice [33, 48] to identify stakeholders and their values, and work on systems that meaningfully incorporate them. These processes encourage researchers and practitioners to consult with visual artists and build tools that make their lives

[36] https://www.theverge.com/2022/12/23/23523864/artstation-removing-anti-ai-protest-artwork-censorship
[37] https://www.costumedesignersguild.com/
[38] https://cynthia-sheppard.squarespace.com/#/burn-out/

easier, rather than claiming to create tools that "democratize art" without consulting them, as a number of artists have noted [40, 60].

In summary, we advocate for regulation that prevents organizations from using people's content to train image generators without their consent, funding for AI research that is not entangled with corporate interests, and task specific works in well defined domains that serve specific communities. It is much easier to accomplish these goals if machine learning researchers are trained in a manner that helps them understand how technology interacts with power, rather than the "view from nowhere" stance that has been critiqued by feminist scholars, which teaches scientists and engineers that their work is neutral [50, 105]. We thus advocate for a computer science education system that stresses the manner in which power interacts with technology [19, 105].

8 CONCLUSION

In this paper, we have reviewed the chilling impact of image generators on the art community, ranging from economic loss, to reputational damage and stereotyping. We summarized recommendations to protect artists, including new regulation that prohibits training image generators on artists' works without opt-in consent, and specific tools that help artists protect against style mimicry. Our work is rooted in our argument that art is a uniquely human endeavor. And we question who its further commodification will benefit. As artist Steven Zapata asks, "How can we get clear on the things we do not want to forfeit to automation?" [137]

Image generators can still be a medium of artistic expression when their training data is not created from artists' unpaid labor, their proliferation is not meant to supplant humans, and when the speed of content creation is not what is prioritized. One such example is the work of artist Anna Ridler, who created a piece called Mosaic Virus in 2019[39], generating her own training data by taking photos of 10,000 Tulips, which itself is a work of art she titled Myriad (Tulips). She then trained a GAN based image generator with this data, creating a video where the appearance of a tulip is controlled by the price of bitcoin, "becoming more striped as the price of bitcoin goes up—it was these same coveted stripes that once triggered tulip mania...a 17th-century phenomenon which saw the price of tulip bulbs rise and crash...It is often held up as one of the first recorded instances of a speculative bubble" [21]. If we orient the goal of image generation tools to enhance human creativity rather than attempt to supplant it, we can have works of art like those of Anna Ridler that explore its use as a new medium, and not those that appropriate artists' work without their consent or compensation.

ACKNOWLEDGMENTS

Thank you to Emily Denton, Énora Mercier, Jessie Lam, Karla Ortiz, Neil Turkewitz, Steven Zapata, and the anonymous peer reviewers for giving us invaluable feedback.

ABSTRACT

Bias evaluation benchmarks and dataset and model documentation have emerged as central processes for assessing the biases and harms of artificial intelligence (AI) systems. However, these auditing processes have been criticized for their failure to integrate the knowledge of marginalized communities and consider the power dynamics between auditors and the communities. Consequently, modes of bias evaluation have been proposed that engage impacted communities in identifying and assessing the harms of AI systems (e.g., bias bounties). Even so, asking what marginalized communities *want* from such auditing processes has been neglected. In this paper, we ask queer communities for their positions on, and desires from, auditing processes. To this end, we organized a participatory workshop to critique and redesign *bias bounties* from queer perspectives. We found that when given space, the scope of feedback from workshop participants goes far beyond what bias bounties afford, with participants questioning the ownership, incentives, and efficacy of bounties. We conclude by advocating for community ownership of bounties and complementing bounties with participatory processes (e.g., co-creation).

1 INTRODUCTION

AI systems pose significant harms to marginalized communities which require urgent attention [14, 16, 18]. To assess AI harms, companies have used bias evaluation benchmarks [6, 21, 46], dataset and model documentation [4, 25, 42], and other auditing processes [41, 50, 51]. However, these processed rarely require examining the power dynamics between auditors and the communities or integrate the knowledge held in communities [5, 63]. Furthermore, auditing processes are often enacted defensively by companies in response to criticism of harms from their AI systems [34].

Recently, modes of bias evaluation have been proposed that engage impacted communities in identifying and assessing the harms of AI systems. One such example is *bias bounties* [2, 8, 10, 27]. By including communities that have been harmed into the process of auditing systems, developers seek feedback on the types and severity of AI harms faced by those at the margins. However, such processes fall short of allowing a full range of community feedback and control [5]. That is, while they may yield improvements, they fall short of being truly participatory approaches and can enable ethics-washing, i.e., give the appearance of taking steps to address ethical issues while making limited practical progress [5, 56]. For example, in bias bounties, companies allow the public, often users of their systems, to interact with the systems to find and submit biased, toxic, or incorrect data and system outputs. Companies then codify and evaluate severity of harms identified using a predefined rubric. The public rarely has a voice in how how findings are evaluated, nor do companies provide mechanisms for interrogating the *internals* or existence of their data and systems. Moreover, bounties are seldom transparent enough for participants to trace biases to design choices or structural incentives, let alone the efficacy to challenge the political structures in which systems are embedded.

Through this lens, one may understand current modes of participation in auditing processes as mechanisms to deny space for alternatives, thereby serving as a justification of the systems in question. We consider these gaps between the feedback allowed and the control mechanisms provided by auditing processes on the one hand, and what marginalized communities want on the other. By doing so, we seek to shift focus from what auditing processes can do to what experiences and knowledge companies allow marginalized communities to share and what companies valorize. We demonstrate the salience of the aforementioned gaps by conducting a participatory workshop to co-critique and redesign bias bounties from queer perspectives. We performed a thematic analysis on the discussions from the workshop, finding that AI systems and bounties alike pose numerous harms to queer people (e.g., exclusionary data collection, censorship, misrepresentation). We categorized participants' thoughts on bias bounties and systems into four main categories: queer harms, control, accountability, and limitations (as outlined in Figure 1). In particular, participants' critiques went far beyond how bias bounties evaluate queer harms, questioning their ownership, incentives, and efficacy.

In this paper, we center queer communities as all of the authors have done LGBTQIA+ justice work and built rapport with queer AI researchers. We further consider bias bounties (hosted by companies to identify issues with their systems) because some authors participated in Twitter's bias bounty in 2021 [10] and were disappointed by the failure of the rubric to capture prevalent queer harms. As such, we intended for our workshop participants to ideate more queer-inclusive bounty evaluation rubrics. Our paper argues for meaningfully engaging with marginalized communities and redistributing power to those who participate in auditing processes. Through deeper engagements, companies can gain complex understandings of the experiences and concerns of marginalised users. Redistributing power to participants can afford a wider range of interventions and solutions, including redlighting the use of the AI systems in question. We further advocate for companies to engage in reflexive practices to identify the constraints placed on users, their desires, and examinations of the power dynamics at play. Finally, we offer insights into data and system harms experienced by queer people and urge for community ownership of auditing processes.

In particular, unless power disparities between companies and marginalized communities are minimized (i.e., communities own bias bounties), bounties *cannot* be an effective auditing process. Bias bounties are thus *incomplete* processes and are only meaningful in conjunction with other complementary steps required towards building equitable AI, e.g, co-design, and mechanisms for refusal and redress. Additionally, regardless of ownership of the bounties, bias bounties are only applicable to the AI systems to which communities decide it is appropriate to apply bounties.

In the rest of the paper, we discuss background and related work (§2), and describe our participatory and analytical methodologies (§3). We then present our workshop findings (§4) and discuss their implications (§5). Finally, we conclude our work, identify shortcomings, and provide directions for future work (§6).

Positionality Statement. All the authors are part of the LGBTQIA+ community. We are dedicated to understanding and addressing queer AI harms. We recognize that queer people, particularly those who are intersectionally marginalized, face unique and complex inequalities that are often overlooked in mainstream discussions of auditing. We further acknowledge that our positions as queer researchers in AI shape our perspectives, and we strive to be transparent about these influences in our work. Half the authors grew up outside the U.S. All authors of this paper are formally trained primarily as computer scientists. In addition, all authors have experience with activism, advocacy, and social work concerning queer issues. All workshop organizers and participants benefit from privileges which enabled them to attend our workshop. By collaboratively shaping auditing processes for queer AI harms, we hope to create a more inclusive and just approach to auditing that centers the experiences and needs of queer communities.

2 RELATED WORKS

2.1 Queer AI Harms

Queer people face many data and AI harms [14, 48, 49, 61]. Although virtual spaces are critical for queer people to find community, queer people and content are subject to increased censorship, reduced visibility, and demonetization [16, 18, 43, 57]. Queer people also face hypervisibility, privacy violations, and surveillance, e.g., through outing via location data [7, 9], monitoring on dating apps [23], physiognomic and essentialist attacks via machine learning [1], and invasions of online queer spaces. Because machine learning is preoccupied with classifying complex concepts into narrow categories, it is in tension with queerness, which can operate with concepts of fluidity of identities and seek to challenge stereotypical associations [32, 36, 40]. The varied explicit risks and harms to queer people perpetuated through data and AI methods mask implicit harms, e.g., how to develop such methods to dismantle the structures that oppress queer and other marginalized, communities.

2.2 Auditing Processes

Several technical frameworks exist for assessing the fairness of data and AI systems (e.g., AI Fairness 360 [3] and Aequitas [54]).

However, these frameworks are based on preconceived notions of fairness situated at the system level, and do not necessarily lend to broader discourse on system design. Thus, they must be complemented by auditing processes that meaningfully engage with the communities impacted by the system.

Several works have called for reimagining auditing by investigating its procedural forms [37]; consequently, community-involved auditing processes, e.g., bias bounties, have been proposed. Bias bounties often consist of a company inviting communities to find and submit biases or harms in its data and systems; the company then evaluates the findings for the severity and types of harms using a predefined rubric [2, 35]. For instance, Twitter held a bias bounty to uncover and assess the severity of biases in its saliency image cropping algorithm [10]. Our workshop participants studied and criticized the efficacy of bias bounties for surfacing queer biases and harms. There is a wealth of Human-Computer Interaction literature on user-driven auditing, or "everyday" audits [15, 39, 55]; these audits, like our workshop participants, strive to shift power from companies to users and stakeholders.

2.3 Community-Based Research

In practice, there are many challenges to incorporating modes of community participation within top-down structures, such as hierarchical companies [30]. As such, popular modes of participation in AI suffer from extraction and exploitation [28] and "participation washing" [56]. Community care and diverse forms of knowledge are therefore paramount towards building just AI. By using community-based participatory action research, research may be able to interrogate power and privilege [22].

Inspired by *Data Feminism* [17] and *The People's Guide to Artificial Intelligence* [45], our participatory workshop operationalized a "community-first" space for AI auditing, where queer communities were afforded space to reimagine bias bounties. Our workshop was a community-driven research effort in which queer facilitators (i.e., authors of this paper) invited members of the queer AI community to draw from their lived experiences to critically examine bias bounties [31]. Our workshop was premised on the idea that queer researchers involving other queer researchers, as co-creators of a critical analysis of bounties, holds potential for dismantling power relations and empowering queer communities [5, 38, 60]. The resulting knowledge produced is "by the people, for the people" and aids in educating and mobilizing for action [12, 29].

3 METHODS

3.1 Participation Overview

We held our workshop as a CRAFT session during ACM FAccT[1] (2022). All participants were registered as attendees of ACM FAccT (2022). We invited participants to form teams to develop holistic and inclusive evaluation guidelines for queer AI bias identification, measurement, and categorization and propose best practices for auditing AI systems for queer biases. All participants volunteered for the workshop and were made aware of it through the FAccT program and posts on Twitter. Participants were given two key research questions to consider:[2]

(1) Where can frameworks for understanding AI harms be expanded to encompass queer identities?
(2) How can the lived experiences of queer people inform the design of harm evaluation frameworks?

Participants were encouraged to consider a variety of AI systems, e.g., text, speech, images, graphs, tabular data, and how these systems interact with and affect queer people. We hosted two separate three-hour sessions: a virtual session and an in-person session.

3.1.1 Team Formation. Participants self-organized into teams in each session. Contributors had the chance to opt into a matching program to be paired with other workshop participants. We requested teams to be interdisciplinary, for which reason participants sought members with different research backgrounds. Across the two sessions, there were nine teams with approximately 3-5 participants per team; six teams participated in the in-person workshop and three teams participated in the virtual workshop. Each team was joined by a facilitator (i.e., an organizer of the CRAFT session), who supported and guided the team. Each team also designated a recordkeeper of its discussions. All participants were invited to share their process, experiences, and thoughts. In our thematic analysis of participants' discussions (§4), we only include the work of participants who provided affirmative consent for us to do so.

3.1.2 Approaching the Critique. Teams were provided with two approaches to reimaginging bias bounties: a top-down or bottom-up approach. In the top-down approach, teams were encouraged to critique how bounties currently evaluate harms while in the bottom-up approach, teams considered harms that AI systems pose to queer people and used these harms as a grounding to re-envision bounty design. Each track came with examples, literature, and guiding questions to help teams get started (c.f., supplementary material). For instance, for the bottom-up track, we provided various example AI systems to be critiqued, such as the AllenNLP demos [24], AI dungeon [19], OpenAI's DALL-E [52], and GLIDE [44]. For the top-down track, we provided examples of queer AI harm ontologies, such as Smith et al. [57] and Dev et al. [14] . Table 1 summarizes the top-down and bottom-up tracks and their objectives.

3.1.3 Consent and Rapport-Building. We did not seek IRB approval for our workshop due to the difficulty of approvals recognized across every participating geography, university and company that the authors represent. However, the proposal for our workshop was reviewed and approved by the FAccT CRAFT chairs, and participants were informed of the format, benefits, and risks of the workshop ahead of time. Participants also filled out a form to express their consent to have their work included in our analysis.

We provided attendees with a code of conduct and an anti-harassment policy, emphasizing the protection of the privacy and safety of all individuals at our workshop. We motivated the workshop by providing background on bias bounties and the hegemonies underlying AI systems that inevitably lead to a lack of trust in them and companies. We further provided scholarly case studies and articles on queer AI harms (e.g., misgendering, erasure, outing). While we did not explicitly document how many attendees identify as LGBTQIA+, such harms reflected a shared reality of many attendees, who were open about how they identify.

[2] All details provided to the participants are provided in the supplementary material.

Table 1: Participation tracks at our workshop.

Top-down	Bottom-up
Framing: You are revising a framework/taxonomy to evaluate bias bounty submissions for the severity of harms discovered.	**Framing:** You are creating a framework/taxonomy from the ground up to evaluate bias bounty submissions for the severity of harms discovered.
Objectives: 1) Select an existing framework or taxonomy of AI harms (can be from a paper, previous bias bounty, etc.) 2) Expand upon the framework to fill gaps that pertain to intersectionally marginalized queer identities.	**Objectives:** 1) Select a specific AI system, and enumerate queer harms that could be introduced by this system. 2) Find themes in these harms and develop these themes into a way of identifying, classifying, and measuring queer harms. 3) Radically reimagine current understandings of harms and even re-envision the format of bias bounties.

3.1.4 Participant Positionality. By hosting our workshop at ACM FAccT (2022), with the organizers and participants in the same community, we aimed to minimize power disparities between the organizers and participants. Building rapport with participants is a common practice in ethnographic research [26], as it provides support for participants disclosing potentially sensitive experiences. This is particularly important in the context of AI harms, as many queer people have experienced social, emotional, and psychological distress [13, 20, 47, 61]. However, given that all our workshop participants were FAccT attendees, their views reflect a particular positionality: one that has access to resources to attend the conference, is generally associated with an institution, is English-speaking, and has the technical literacy required to scrutinize AI systems. Joining our workshop also indicated that attendees were comfortable with being in visible proximity to LGBTQIA+ spaces. The views of those who outside this positionality are less likely to be reflected in our analysis.

3.2 Thematic Procedures

All teams converged to similar critiques of and recommendations for bias bounties, regardless of the track in which they participated. We therefore consider all discussions collectively rather than perform separate analyses for each track. After the workshop, we conducted an iterative inductive thematic analysis of the participants' discussions, following Clarke et al. [11]. We use this interpretivist approach to surface how queer populations desire bias bounties to be implemented. We used the following process: (1) we compiled all submitted artifacts from the workshop, that participants consented to being analyzed into a single document, (2) each researcher independently developed codes for all artifacts in the document, (3) researchers collaboratively sorted these codes into initial themes, (4) concepts were grouped into overarching themes and sub-themes, and (5) steps 3-4 were repeated with different subsets of researchers until all researchers agreed on a set of themes.

4 THEMATIC ANALYSIS FINDINGS

In this section, we present the findings of our thematic analysis. We found that our workshop participants discussed how bias bounties pose harms to queer people, in addition to the harms posed by AI systems. The participants' thoughts on bias bounties and systems fell into four main categories: queer harms, control, accountability, and limitations, as outlined in Figure 1. We provide a table of team frequencies for each sub-theme in Table 2. For clarity, we use **P** to denote teams that participated in person; all in-person teams selected the bottom-up track. We denote teams with a **V** if they participated virtually; all virtual teams selected the top-down track.

Table 2: Number of teams that discussed each sub-theme.

Theme	Sub-theme	Teams
Queer Harms	Queer-Exclusionary Data Collection	**5**
	Algorithmic Misrepresentation	**7**
	Participation Risks	**6**
	Censorship	**4**
Control	Normative Practices	**4**
	Allocative Prioritization	**2**
	Social Context Misrepresentation	**3**
Accountability	Ownership, Incentives, and Responsibilities	**2**
	Bias Bounty Operationalization Considerations	**2**
Limitations of Bias Bounties	Efficacy	**3**
	Accessibility	**3**

4.1 Queer Harms

All teams ($n = 9$) identified several harms that affect how queer people are represented in and interact with AI systems and bias bounties. We refer to these harms as "queer harms," because they are directly tied to users' queer identity.

4.1.1 Queer-Exclusionary Data Collection. Several teams ($n = 5$) were concerned about how queer people are represented in data in the context of both AI systems and bias bounties. Regarding AI systems, participants discussed how queer intersectional identities may constitute a smaller part of a user base, which can lead to harm from systems that are trained on user data. **P4** summarized this as "intersectional subgroups are not well represented in the data" and elaborated that this can also lead to, e.g., failures of content

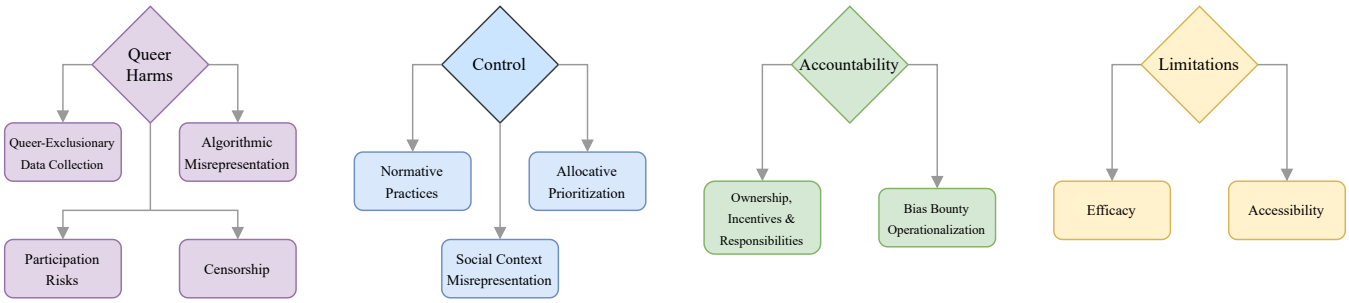

Figure 1: Taxonomy of participant critiques of AI systems and bias bounties.

filters that aim to reduce exposure to harmful content because "slurs used by small groups, e.g. specific hate groups, are not detected," exposing vulnerable users to psychologically harmful content.

Teams additionally discussed ways that AI systems can harm queer users by collecting personal data, especially user gender. Participants found that collecting gender data requires highly contextual considerations. **P1** noted that "members of the queer community find it empowering and affirming to link their identity to existing socially salient categories," but also warned that in a clothing recommendation context, asking users to provide gender information could "reinforce the possibly harmful idea that clothes are gendered." **P6** argued that users self-reporting gender is better than companies inferring gender, which reduces user autonomy. **P1** posed the question, "How much control do you have in terms of what category you're applied to (e.g., Computer Vision fields based on external 'passing' elements vs. What content do you consume/produce?)," indicating that the autonomy to fully describe ones own identity is a key concern for queer users.

While bias bounties were created to allow the communities impacted by particular AI systems to address such tensions, participants pointed out that bias bounties suffer from similar issues as AI systems, i.e. queer participants in bias bounties still feel marginalized. As **P1** noted, "queer users are not a majority, this may already be the root cause of some issues." Participants questioned how effective bias bounties could be at addressing the concerns of populations that are not represented by the majority. **P6** asked, "Whose interests are we optimizing on? [...] The majority? Specific groups?" If bounties use sample size to determine the severity or prevalence of harms, rather than social and historical context, biases that affect queer people may receive less focus than biases affecting larger groups. Overall, participants were concerned that bias bounties may not operate with their interests in mind, especially when their processes are not transparent.

4.1.2 Algorithmic Misrepresentation. Teams ($n = 7$) voiced a concern over how data representation reduces the complexity of identity, thereby enabling their erasure and oppression. Participants identified two ways in which this can happen: (1) when categorical representations do not capture their identity at all, and (2) when representations do not allow changes over time.

Participants expressed frustration at how categorization constrains how queer users express their identity, in particular, highlighting the tension between how "users themselves identify & record their identity" (**P6**) and how identity may be represented in systems. Teams noted that systems that to handle diverse users and try to operationalize identity as part of their user experience can inhibit marginalized users from expressing their identity:

> **P2:** "Highly structured and normative processes, typically don't have space for queer and intersectional identities which can make the process challenging if not inaccessible."

Other participants voiced that categorization "reinforces the existence of gender categories more broadly (which some members of the queer community find inherently oppressive)" (**P1**), which creates a "boundary box of having/not having an identity being aggressively reinforced" (**P6**), and "could lead to erasure [of marginalized identities]" (**P5**). For instance, companies may force individuals to assign themselves to categories, or even infer categories, for reasons including "aggressive [content] recommendation and promoting specific content" (**P6**). Beyond "being profiled/categorized automatically into something you are not" (**P1**), forced categorization can stereotype users, e.g., via "recommendation of jobs that reinforce certain assumptions about your identity." (**P5**). Forced categorization can further exnominate queerness:

> **P6:** "People might have wrong perceptions of what it means to have a specific identity."

The appropriateness of categorization is highly contextual. For example, not considering gender labels in a clothing recommendation system could be one solution to address the harms of categorization. Another solution can be having a customizable gender input, which may allow users to feel affirmed in their identity, as noted by **P1**. Furthermore, categorization may be required for personalized content moderation (**P6**).

In addition to being able to accurately have one's identity represented at a given point in time, teams ($n = 4$) expressed the desire to be able to *change* how one's identity is represented over time, *as* their identity changes. For example, **P5** noted that "categorization does not recognize fluidity of labels over time," and **P6** echoed that static categories lose relevance over time because "using old data won't represent you accurately." However, **P2** commented that friction in changing personal information can have organizational costs that can potentially frustrate or deter users from platforms:

> **P2:** "Name changes or pronoun changes make admin much harder and more expensive through time, complexity, or financial penalty."

Overall, teams called upon companies to build AI systems without the assumption that a user can be accurately represented in perpetuity as when they start using a system.

4.1.3 Participation Risks. Throughout the workshop, many teams ($n = 6$) discussed how using AI systems and participating in bias bounties may negatively impact queer people. The teams identified two primary risks: (1) the increased likelihood of personal information being disclosed, and (2) increased exposure to harms. **V3** described these harms succinctly as "privacy harm" and "exposure harm." Privacy harms referred to AI systems and bias bounties, while exposure harms were unique to participation in bias bounties.

Regarding AI systems, participants highlighted the risks of personal information being disclosed and people being outed. For example, **V3** and **P1** noted that Grindr had shared HIV status with third parties, TikTok had censored and surveilled LGBTQ language, and surveillance software had reported personal Google Docs data to schools. **P6** commented, "What if you don't want to be more exposed/visible? Queer people can be exposed to harassment if they get too much visibility then they might not want to be exposed to a larger audience." This highlights that undesired visibility can cause queer people to face harm, discrimination, and harassment.

Participants also discussed how their personal data can be disclosed via their participation in bias bounties. **V1** noted that bounties can "put you in a dangerous situation, [such as] forced outing," if you submit queer harms you have experienced. In addition to outing, **V3** stressed that privacy concerns should motivate the organizers of bounties to ensure "anonymous reports of non-anonymous content/interactions," e.g., through the removal of personally identifiable information. In particular, **V3** explored how specific queer populations (e.g., queer youth) may need extra safeguards in place to ensure safe participation, such as "consent from parents." Moreover, there is potential for adversarial attacks on bounties, such as hate crimes targeting queer groups by changing their profiles or flooding systems with disturbing content. Overall, participants emphasized that bias bounties should provide participants with warnings and safeguards to prevent their personal data from being disclosed to wider audiences.

Teams also indicated that bias bounties pose "exposure harm" to their participants through the identification and submission of negative interactions with systems. . This increases bounty participants' exposure to psychologically harmful content. **V2** asked, "Are bug bounties exploitative? People have to experience biases," and **V3** similarly noted that bounties facilitate "exposure to sensitive topics." These teams noted bounties currently subject participants for marginalized communities to witness how AI systems mistreat them and members of their community.

4.1.4 Censorship. Our analysis revealed the experiences and desires of queer users in relation to AI harms and their resilience in navigating these harms in efforts towards reimagining systems. For example, participants expressed frustration with how online harassers exploit the weaknesses of content moderation AI (e.g., failure to consider context) via dog whistles, with **P4** noting that "obfuscated hate speech" often goes undetected or ignored. At the same time, queer users, with their resilience, co-opt this failure mode by self-censoring to protect themselves and their content from surveillance, fetishization and sexualization, as expressed by **P6** and **V3**. Participants came up with innovative ways to bypass censorship (e.g., **P6** replaced the word "sex" with "seggs," and **V3** described that "lesbian" is often replaced with "le$bian").

However, the lack of explainability of content moderation AI makes it challenging to contest censorship and amplifies harms. **P6** highlighted the absence of explanations for recommendations and bans on dating apps; but, queer users' resilience leads to the possibility of reimagining AI systems as a reality, e.g., systems can prioritize human-in-the-loop explainability (**P6**).

Participants also emphasized a desire for their identities to be recognized, rather than erased or ignored, by AI systems. For instance **P1** found it "empowering and affirming to link their identity to existing socially salient categories."

4.2 Control

Participant teams ($n = 5$) raised concerns about who controls bias bounties and the AI systems that are the subject of bounties due to its impact on the degree of access granted to bounty participants.

4.2.1 Normative Practices. Participants noted that there are norms encoded in systems that harm queer users. For instance, **P4** stated, "Community standards encode perspective of the privileged groups, not the marginalized groups." Thus pointing towards a misalignment of values between companies and users, resulting in ignorance and exploitation by companies, intentional or otherwise.

Several teams provided specific examples of how the values of companies and users can be misaligned. In the context of financial services, **P2** shared that "payday loan companies target vulnerable populations," which can benefit the company by fulfilling key metrics but harms its users via predatory practices. In AI hiring contexts, **P5** noted that "groups are selected at different rates," which can exacerbate the "underrepresentation of marginalized groups." While these systems might make the recruitment process easier for companies, they harm the groups that are under-represented. With regards to social media, **P6** said, "Optimization based on engagement can increase harassment." Engagement may increase time spent on the platform, benefiting the company, but toxic engagement can harm marginalized users. Without actively considering users when optimizing metrics, companies risk harming their users.

Participants pointed out that this critique also applies to companies that run bias bounties. Participants expressed concern about how companies may be misaligned with bounty participants. **P5** asked, "Who gets to decide the 'normative' notion of fairness?" Companies following normative practices when running bias bounties may overlook ways of improving systems that can actually benefit users; furthermore, metrics (e.g., to measure the severity of harms) that bias bounties aim to optimize may result in unforeseen harms. **P5** asked, "should an algorithmic / AI system even be used?" Bias bounties cannot accommodate such a radical systemic change, because they instead focus on reforming parts of systems. This raises a need to fundamentally reconsider how companies build AI systems, and if and when to do so at all. **P5** further contextualized their question in the domain of hiring: "Should algorithms even be used in hiring? If no, [that] assumes that you can't improve upon the status quo." This highlights the tension between new and existing processes; even if new processes do not benefit impacted

or marginalized communities, it is not guaranteed that existing processes are free of harms.

4.2.2 Allocative Prioritization. Teams (n = 2) expanded on how normative practices can result in imbalanced resource allocation, which can result in urgent harms to users. **P1** stated that "some harms might be life-threatening." Providing an example, **P2** remarked that "life-saving surgeries (e.g. transition) are unsecured and/or considered elective and so harder to secure credit than [for] more traditional items e.g. car[s]." AI systems that allocate resources may not prioritize queer concerns, and thus make system usage disproportionately more difficult and harmful for queer users.

Participants found that bias bounties also risk unfairly distributing resources to queer people. **P2** commented that "financial services organizations tend to lack diversity which can make it challenging to begin conversations to understand queer harm, nevermind evaluate it." Without queer representation in the company running a bounty, queer harms may not even be represented in the bounty rubric, let alone identified.

4.2.3 Social Context Misrepresentation. Teams (n = 3) emphasized that social context is critical to ensure that AI systems and bias bounties benefit users. Regarding AI systems, participants noted how misrepresenting users' social context can negatively impact users. For example, in content moderation contexts, **P4** noted that "non-English language [are] not well handled (automatic translation errors, lack of data);" if systems incorrectly process languages other than English, they can expose their users to toxic content. **P6** also noted that "different identities might be connected to different levels of maturity/safety during content moderation." That is, when systems are unable to adapt to the social contexts of different age groups, they also harm their users.

Social context is also critical for bias bounties. **P6** stressed that "accommodating cultural diversity" is a criterion that bounties must satisfy in order to be effective. However, **P6** qualified this by asking, "How much cultural difference makes sense? How much of it is represented in the technology? Is it useful to increase diversity or granularity?" Among participants, there was a recurring theme of seeking the right balance between representing social context with enough detail to capture the diversity of the systems being audited, but not so much detail that participation in the bias bounty becomes infeasible.

4.3 Accountability

Some teams (n = 3) discussed specifics of how bias bounties should be run. These teams stressed the importance of community-led over company-led bounties.

4.3.1 Ownership, Incentives, and Responsibilities. Teams (n = 2) expressed concern about the ownership, incentives, responsibility of companies organizing bias bounties. For instance, **V3** stated that "we don't want random tech companies to have ownership of this," and **V1** asked, "how do we know that the distribution of data being handled to us is not adversarially generated?" Participants argued that companies lack incentives to run bias bounties due to: (1) misalignment with companies' values (**V3**: "it might not align with company legal framework"); (2) harmed users not being a majority (**V1**: "queer folks are a 'small group' at the margins and don't bolster overall utility or revenue maximization"); and (3) financial hurdles for companies (**V1**: "any kind of audit costs money"). Worse, **V1** highlighted that companies are often disincentivized to uncover harms "because of legal risks."

To address issues of ownership, incentives, and responsibility, participants suggested: (1) employing a trusted third party and partnerships with local, trusted organizations to mitigate concerns (**V3**: "Partnership with local youth centers as data stewards... Tech companies may provide tooling, not governance"); (2) drawing upon existing audit mechanisms from other fields, e.g., software development (**V1**: "mechanisms for auditing exist in software development"); and (3) shifting incentives for companies to prioritize ethical considerations and participate in audits. Ultimately, mitigating queer AI harms requires ongoing involvement from and ownership by queer communities to ensure that ethical considerations are prioritized over companies' legal and financial risks, and align with the values and needs of the communities.

4.3.2 Bias Bounty Operationalization. A central question of our work is: "How do queer communities imagine bias bounties?" Participants expressed their dissatisfaction with the current format of bias bounties and envisioned a new, community-based bounty format: "we envisioned it as a collaborative bug bounty where individuals can contribute with specific examples towards identifying harms" (**V2**). This community-based approach would involve a coalition formed by researchers and impacted communities, with communities having the power to veto AI systems entirely.

Participants stressed the importance of diversity in the operationalization of bias bounties. For instance, **V1** emphasized the need for diverse data collection to robustly evaluate bounty findings and better understand the distribution of system use cases, and called for harm mitigation mechanisms beyond bias bounties, e.g., community focus groups and distributed AI developments. As an example, **V1** called for creating a focus group comprising of annotators, developers, and bounty participants from diverse backgrounds to provide feedback ahead of system development. **V1** further posited, "community-led AI could reduce how much context is lost via centralization and scale." Thus, our participants highlighted the need for community ownership of auditing processes as a means to create bounties that emphasize the needs and experiences of queer communities.

4.4 Limitations of Bias Bounties

Teams (n = 3) also reflected on the appropriateness of bias bounties for addressing AI harms, discussing their effectiveness and ease of participation.

4.4.1 Efficacy. Even in an ideal scenario, where the implementation of bias bounties poses no risks to participants, teams (n = 3) still were wary of how helpful bounties can be. As **V1** highlighted, "often the answer is not here is an improvement to model, but rather you should not be doing this... this is a harder answer for people to stomach." This goes beyond identifying individual harms via bias bounties, to addressing the root causes of harms and questioning the existence of some technical systems entirely.

Bias bounties are also challenged by the difficulty in evaluating the severity of harms. Such evaluations often depend on individuals and their particular subjectivites and contexts. For instance, as one participant explained, "Child Protection Service rips marginalized children away from families... Very harmful, but people in the system claim they are doing good. Make a framework for creating a harm severity framework instead of a single harm severity framework." Thereby suggesting that perspective and political motivations influence the lens through which a harm severity is viewed. Moreover, the participant's example illustrates that current auditing processes do not adequately capture the complexity and diversity of harms that marginalized communities face, therefore necessitating a new approach to developing frameworks for harm severity.

V2 highlighted a tension between intent and impact, arguing that there are "many things developers should think about, but they can't anticipate everything." Thus, even with good intent in mind, bias bounties fail to capture the full range of harms that marginalized communities experience, and must therefore be adaptable to harms that were not expected, or in the words of **V3**: "[we] don't want to lock in stone the current ways we think about LGBTQ harms and interactions, need to leave room for growth."

While bias bounties have their limitations, participants acknowledged their value as a way to decentralize the process of identifying biases and harms. As **V1** noted, "bias bounties are nice ways to open-source process of identifying biases and harms." At the same time, bias bounties are not a one-size-fits-all solution for mitigating harms. As **V1** pointed out, while a "bias bounty does not consider ways to address biases," "reactive systems are still an important part of the problem since we know that we can't catch everything from the get-go." However, participants found that having a variety of ways to provide feedback to AI systems, in addition to bias bounties, would help make systems more beneficial to users. For example, **V1** questioned, even with community-owned bias bounties, "Will the same power structures be replicated? Are we just pushing the problem downstream?"; devising additional avenues for reactively mitigating AI harms can help communities better iteratively co-develop systems.

4.4.2 Accessibility. Multiple teams ($n = 3$) noted that the potential learning curve to participating in bias bounties poses a barrier to many communities. Particularly, **V1** remarked on the technical difficulty that "[a bias bounty] requires technical know-how" there needs to be a "Way to make it accessible to broader community without a technical background.". Another participant, **V2** noted that there is a "barrier to entry: [bounties are] weighted towards technical people." That is, not only does the required technical knowledge pose difficulties in using systems, but it may also directly exclude entire communities from participating, which skews who can provide input on how AI systems should work and thus, for whom bounties can provide change. Beyond providing instructions on how to use systems, bias bounties should "educate on the risks of sharing data, show ways to minimize sharing of personal information, discuss participation with parents/guardians, [describe] general internet security etiquette, [provide a] history of how community activism has been effective in the past" (**V3**). Such education can be compiled into a "digital toolkit" that is provided to bounty participants during onboarding (**V3**); such a toolkit could minimize the risks of participating in bounties, especially for marginalized communities that face disproportionate risks of harms.

5 DISCUSSION

5.1 Enabling Interventions Throughout the AI Pipeline

Throughout the workshop, participants reimagined auditing processes to address queer AI harms. We found that participants desired interventions at all stages of the AI pipeline: system formulation, data collection for the system, system design and development, and recourse after it has been deployed. Currently, many processes for addressing harms (e.g., bias bounties) are only used at the final stage of the pipeline, after the system has been deployed. We explore how the findings from our workshop apply to different stages of the AI pipeline, and discuss potential interventions at each stage.

5.1.1 Problem Formulation. Participants desired mechanisms to provide feedback on the intended application domain of a system before it is developed (§4.2.1). Furthermore, participants described three areas for feedback from queer communities before the system is implemented: (1) assessing the applicability of normative practices in a new context (§4.2.1), (2) determining how resources should be allocated (§4.2.2), and (3) clarifying the incentives that drive the system's development (§4.3.1). One solution participants suggested was to organize a community-based panel to assess AI systems; the panel's goal is to proactively identify potential harms by engaging with members of queer communities.

5.1.2 Data Collection. Participants also desired mechanisms for providing feedback on data collection procedures, particularly to prevent: the (1) exclusion of intersectional queer identities during data collection (§4.1.1), and (2) misrepresentation of queer communities' social contexts (§4.2.3). Participants indicated that they desired transparency around the composition of company data, especially as it concerns the representation of queer people. Participants desired full control over how they are represented in data, towards dismantling constraints on their expression and the fluidity of their identity. They also expressed a desire for companies to invest in understanding the contexts in which queer people are susceptible to being outed, misgendered, censored, and experiencing dysphoria (§4.2.2, §4.2.3). It is therefore paramount that companies engage in long-term, cooperative relationships with harmed communities, and relinquish control of data auditing processes to them.

5.1.3 Algorithm Development. Participants raised concerns about inaccurate representations in AI decision-making and a loss of autonomy through AI censorship (§4.1.2, §4.1.3, §4.1.4). Largely, participants wanted ways to be precise in how they express their identity and explanations for system behavior. Participants wanted to leave the choice to disclose specific aspects of identity to users themselves, rather than disclosure being a requirement to use a system. Beyond this, participants wanted the freedom to change how they represent themselves over time. These concerns echo the principles of designing with affirmative consent [33, 59]; in particular, ensuring that persons disclosing their identity are informed of what disclosure means,being able to disclose their identity precisely and freely, and being able to reverse disclosure without consequences.

5.1.4 Deployment. While bias bounties afford identifying biases in deployed AI systems, participants commented on the risks and accessibility of participating in bounties (§4.1.3, §4.4.2). Participants desired transparency about the ownership, incentives, and efficacy of bounties (§4.2.1, §4.3.1 §4.4.1). Participants also noted the vital importance of informed consent to participate in bounties. A team suggested providing digital toolkits to bounty participants to broaden participation in AI audits while reducing the likelihood of adverse effects. these toolkits were imagined to consist of tutorials, information, and guidelines on how to safely and correctly engage in community-involved audits of AI systems.

5.2 Scrutinizing Bias Bounties

We found that participants in our workshop frequently wanted greater power in shaping bias bounties (§4.2), including defining how submissions were evaluated, how compensation would be disbursed, who would provide funding, and who would organize and control the bounty. Members of a community that frequently experience data and AI harms could quickly identify constraints on the feedback they were able to provide about systems. This finding reveals key weaknesses of bias bounties: what gets counted as a harm, the need for funding for prizes, and control of the bounty by companies often leading to late-stage interventions focused on improving the system rather than reimagining how the system should have been created.

We argue that this is a useful lens for understanding the limitations of auditing processes. Harmed communities should not just be participants in auditing processes, but also be asked what they think about the processes in the first place, and ideally be involved as co-designers and owners of the processes. Auditing researchers often valorize expert knowledge and institutional audits; however, holding auditing processes to the standard of scrutiny by harmed communities will ground them in the actual needs and realities of the people who need effective auditing the most.

Moreover, we argue that unless power disparities between companies and marginalized communities are minimized (i.e., communities own bias bounties), bounties *cannot* be effective. In addition, even if communities own bounties, communities (not companies) should decide if a bounty is even appropriate for identifying the harms of certain AI systems. Ultimately, bias bounties are *incomplete* processes—they are merely one of numerous complementary steps that companies need to take towards building equitable AI (e.g., co-design, mechanisms for refusal and redress). While bias bounties can be valuable for uncovering harms in AI systems that may not have been foreseen during development, harm anticipation, identification, and mitigation must begin outside bounties.

5.3 Imagining Community Ownership of Auditing Processes

Many participants questioned the ownership of bias bounties, discussing how corporate ownership of bounties is a conflict of interest that may lead to misaligned incentives. When imagining solutions, participants repeatedly mentioned empowering harmed communities, often to the point of giving them control or ownership of the bounty. This insight addresses several issues of auditing processes, while also presenting novel sociotechnical challenges for auditing researchers. First, giving harmed communities ownership of auditing processes ensures that the incentives of auditors align with the values and needs of the communities the processes are intended to help. Second, community ownership increases trust in the auditing. Third, community ownership allows for auditing processes to prioritize and be adapted to small communities that may be sparsely represented in broader audits. Ultimately, harmed communities understand their issues best, and are thus best positioned to conduct audits of the AI systems that impact them.

We now concretize what community-owned bias bounties might look like. External elements, like a public competition to find instances of bias in systems for prizes, would remain. Companies may voluntarily provide their system and even funding for prizes. However, we believe that bounty organizers will often have to contend with auditing closed-source systems and obtaining their own funding. While API access alone can be sufficient for auditing and redteaming closed-source systems [53, 62], many systems lack public API access, and API owners may take countermeasures to detect and prevent adversarial use. Developing methods to probe systems with limited access presents interesting directions for auditing research. Furthermore, marginalized communities often do not have the same financial resources as companies [48]. State grants and external non-governmental organizations may provide funding; however, these entities may have misaligned incentives and goals, in addition to requiring specific networks to access their funding. We argue for making community-owned bias bounties financially sustainable by reimagining bounty work, and more broadly resisting and fighting data and AI harms, as a form of mutual aid [58]. Specifically, bias bounty work should be motivated and sustained by the direct and positive impact it has on harmed communities. Auditing processes often require several years of work to coordinate different experts and institutions to achieve noticeable change; in contrast, community-owned auditing processes can have more immediate and direct impacts. Creating community-owned auditing processes would require asking new questions in auditing research, such as what expertise and resources are needed for a bounty or audit, and how they can be made accessible to harmed communities, as well as how the impact these processes have can be made visible and tangible to motivate their usage.

6 CONCLUSION

While many auditing processes exist for identifying AI biases and harms, current operationalizations thereof are hierarchical and reflect an epistemic authority; the companies that ask for critical feedback are the same companies which force marginalized communities to comply with their definitions, parameters, and guidelines around harms that may not be aligned with communities' experiences and needs. Therefore, despite the intent to promote social good, companies may fail to valorize the knowledge and expertise of harmed communities. As our workshop findings highlight, participants hold shared experiences and knowledge regarding the format of bias bounties that bounties would hinder them from providing.

We synthesize critiques of bias bounties from queer communities into several salient themes (Figure 1) and find that they span all four components of the traditional AI development pipeline: problem formulation, data collection, algorithm development, and

deployment. Bias bounties only allow for post-hoc interventions, providing limited options for feedback and control from queer communities. Because of this, we argue that harmed individuals must have the ability to self-actualize beyond the role of a 'user,' 'participant,' or 'informant' of their own experienced harm; instead, communities must be offered the ability to co-design auditing processes and collaboratively generate knowledge throughout the AI pipeline, not just after a system is deployed. We argue for auditing research that enables transferring ownership of AI auditing processes to the communities that are harmed so that their experiences and knowledge may be integrated into new and more effective auditing methodologies. As future work, we encourage auditing researchers to explore feedback and control mechanisms in the context of other auditing processes and different marginalized communities, as well as concretely reimagine what community ownership of such processes would look like.

ACKNOWLEDGMENTS

We thank the anonymous reviewers and Michael Madaio for their insightful and valuable feedback on this paper. We further thank the former Twitter bias bounty working group for early discussions about this project.

Action Guidance and AI Alignment

Pamela Robinson
School of Philosophy, Australian National University
pamela.robinson@anu.edu.au

ABSTRACT

I offer a preliminary conceptual framework for evaluating AI alignment projects. It is based on the concept of *action guidance*. In §1 and §2, I explain action guidance and its importance to AI alignment. I introduce the 'Guidance Framework' in §3. In §4, I show how it can be applied to two different sorts of questions: the practical question of how to design a specific AI agent (my example is a fictional ocean-cleaning robot), and the theoretical question of how to evaluate a specific AI alignment proposal (my example is Stuart Russell's 'binary approach'). In §5 I discuss limitations of the framework and opportunities for further research.

1 INTRODUCTION

You are offered one of three checks, A, B, and C, each made out to you. You can only see their backs, but you know that check A is for 900$, while one of checks B and C is for 1000$ and the other is for 0$ (you don't know which is which).[1]

The following principles say something about which check you ought to choose:

1. Choose what is most valuable.
2. Choose what has the highest expected value.

Suppose that check B is for 0$ and check C is for 1000$. According to Principle 1, you ought to choose check C. But that is probably not what you would choose. If you choose check C, you would have no idea whether it's for 1000$ or for 0$. Unless you are risk-seeking, you will probably choose check A. Though check C is more valuable than check A, you can't know that before making the choice.

Principle 1 is better than Principle 2 in one way: if you could always follow it, you would be richer. But Principle 2 is better than Principle 1 in a different way: it offers you more useful guidance. In every case in which you know how to follow Principle 1, Principle 2 would have you make the same choice. But there will be cases in which you won't know how to do what Principle 1 requires, and in many of these you can still follow Principle 2.

One thing to learn from this story is that different principles can guide our actions to different degrees. Another thing to learn is that the ability of a principle to guide our actions can be more important than how good it would be to follow it were we able to do so.

A further thing to note is that principles that offer equal guidance can still be better and worse than each other, and principles that don't offer guidance can be better and worse than each other. For consider two more principles:

3. Choose what is least valuable.
4. Choose so as to maximize the chance that you do what's most valuable (i.e., what's required by Principle 1).

Principle 3 is as difficult to follow as Principle 1, but you wouldn't want to follow it! Principle 4 is, at least in this case, just as easy to follow as Principle 2. According to it, you ought to choose either one of checks B or C, and choosing B would be as good as choosing C. Given what you know, Principles 2 and 4 are the only ones that you can follow. But, of them, Principle 2 is better. Principle 2 corresponds to standard expected utility theory; Principle 3 would have you eschew the 900$ in favor of *any chance of getting the 1000$*, however low.

This has all been to show the importance of the concept of action guidance. Our search for action guiding principles has led us to develop methods—like those described by decision theory—for choosing with imperfect information.

Since we often have to make moral choices with less than perfect information, many philosophers have argued that we need action guiding moral principles.[2] Consider these consequentialist, virtue theorist, and Kantian moral principles:

5. Do what would have the best consequences.
6. Do what a virtuous person would do.
7. Always act in a way that treats people as ends in themselves.

Regardless of whether it would be morally good to follow these principles, we will not always be able to do so. These theories can be criticized on grounds that they offer little guidance. Take Principle 5. For most of our actions, it is impossible to know for sure what the full set of consequences will be, and we can be uncertain about

[1] This is a version of what Jacob Ross [39] calls the 'three envelope problem'. It's structurally related to a cluster of thought experiments tracking back through Derek Parfit [36] to Donald Regan [37]. Ross and others use the cases to support claims about the nature of ought facts. My more modest aim is to draw attention to the different degrees of guidance that different principles offer.

[2] See, for just one example, Holly Smith's arguments in [42], [43], [44], and [45].

AIES '23, August 08–10, 2023, Montréal, QC, Canada

which consequences are *best*.[3] As Daniel Dennett has put it, "no remotely compelling system of ethics has ever been made *computationally tractable*, even indirectly, for real-world moral problems" [14].

This may not be grounds to reject our moral theories or principles. Providing a correct account of what makes actions morally right is no small thing, even if it does not amount to a useful decision-making procedure. (See, e.g., [6].) Nonetheless, we have good reason to want moral principles that offer (more) guidance.

Here are some of the ways in which action guidance has been characterized:

> *Intuitively, being correctly guided by a normative theory amounts to something like this: an agent does what a normative theory tells her to do because she correctly recognizes that it is what the theory tells her to do.* [18]
>
> *The fact that a course of action would have the best results is not in itself a guide to action, for a guide to action must in some appropriate sense be present to the agent's mind. We need . . . a story from inside the agent. . .* [25]
>
> *Agent S uses principle P as [a] . . . guide*[4] *for deciding to do act A if and only if A conforms to P, and S does A out of a desire to conform to P and a belief that A does conform.* [42]
>
> *Action-guidance is the capacity of a principle to function as a decision-making procedure.*[5] [33]
>
> *In order to be guided by an obligation to ϕ, you must not only be able to ϕ, you must also know that you are obligated to ϕ.* [24]
>
> *Reasons must be capable of guiding us in the sense that we are able to act for or on the basis of those reasons.* [47]
>
> *Guidance is often taken to entail acting as one ought in a way that is not merely accidental.* [27]

Everyone can agree that a principle is guiding if we can do what it says in a way that's *not an accident*. Spelling out the way in which it must not be an accident is more contentious, and often involves appeal to mental states and other properties that suit humans better than machines. For these reasons, I use the last characterization here:

> **Action guidance**: a principle can guide an agent to the degree that the agent can non-accidentally do what it requires.

So, if you try to get the 1000$, you might succeed. You can choose each of checks B and C, and if you pick one you have a 50% chance of getting the money. But if you get the money, you would be lucky. This explains why Principle 1 is less action guiding than Principle 2: you also have the ability to choose check A, and if you choose it because you want to maximize expected value, the fact that you would succeed at this is no accident.

2 GUIDANCE AND THE PROJECT OF AI ALIGNMENT

The project of AI alignment is to ensure that an AI agent's behavior is *good*—that it 'lines up with' our values or with morality itself. A 'value-aligned' or 'morally-aligned' AI agent need not actually *share* our values or *be* moral. If we could have a proof that an AI's behavior simply conforms to these things, then we would have a proof that the agent is beneficial.

We usually do want assurance that an AI agent's behavior will be beneficial. This can be seen by looking at almost any project in AI ethics. One example is the project of ensuring that there is no bias in automated decision-making systems. (See, e.g., [2].) We want to be able to prove, for example, that certain decisions will not be made on the basis of protected characteristics. Another example is the project of ensuring that self-driving vehicles will make the morally right choices when lives are at stake. (See, e.g., [48] and [20].) Alignment and proofs of alignment are central in the ethics of AI design.

But any attempt to prove that an AI is beneficial faces the following five problems:

> **The problem of inconclusiveness about value**: We can be uncertain about, and can disagree about, what is actually moral or otherwise beneficial or valuable.[6]
>
> **The problem of feasibility**: There are limits to what an AI agent can be designed to do, and to our own abilities to design AI agents.
>
> **The problem of inconclusiveness about implementation**: We can be uncertain about, and can disagree about, whether and to what degree a specific kind of alignment can be feasibly implemented.
>
> **The problem of proof of alignment**: There may not always be sufficient evidence that alignment has been achieved.
>
> **The problem of scope**: Even if we can build an AI agent with provably beneficial behavior, this doesn't necessarily mean that building this agent is a beneficial thing to do.

Action guidance is a crucial part of the 'glue' that can align our own behavior to principles. If a principle cannot guide my actions, we are halfway to a proof that my behavior is not aligned with it. What this tells us is that I couldn't intentionally align my behavior with the principle if I tried. I either lack the basic ability to do the actions required by the principle, or else my behavior would only end up being aligned with the principle in a way that is accidental.

[3] This is a common objection to consequentialism and has also been raised for the prospect of using consequentialist theories to build moral machines (see, e.g., [1]). One response is to opt for subjective consequentialism—as expressed by a principle like one should do what will have the best expected consequences. This version of consequentialism at least offers more action guidance.

[4] In [42] Holly Smith also offers a related definition of guidance which requires only that an agent can use a principle to choose some action—even if the action isn't what the principle requires. (Her most sophisticated accounts of both types of guidance can be found in her [45], described as 'core usability' and 'extended usability'.) Though both kinds of guidance are relevant to the overall project of AI alignment, this other kind is less relevant. When aligning an AI with a principle, we want to ensure that it does what the principle requires and not merely that it doesn't get stuck not 'knowing' what to do.

[5] This is not a direct quote, but is what Richard North has in mind in his [33]. He also offers a more detailed account: that "a theory counts as action-guiding when its principles are capable of delivering coherent, consistent, and determinate verdicts . . . and citizens have the ability to use those principles to derive a prescription for action that they are able to comply with" (p. 76).

[6] For treatment of this problem in the AI alignment literature, see [8], [19], [11], [15], [17], and [38]. For a sample of the treatment of this problem in moral philosophy, see [28], [29], [26], [13], and [49].

The project of AI alignment is to ensure and offer proof that what AI agents do will be aligned with certain principles.[7] When a proof of this kind can be given, these principles must be action guiding for the AI agents. If an agent is guided by a principle (to some degree), then the agent's behavior can be expected to be aligned with that principle (to that degree).

This may not hold for all agents in all circumstances. Suppose that someone is guided by a principle enough to know what it requires of *me*, and is able to ensure, through brain manipulation, that I always act in accordance with it. We might want to say that my behavior only conforms to this principle *accidentally*[8]—even though we can prove that it is aligned to the principle because it perfectly conforms to it. However, the link is much stronger for AI agents. If there is a human designer behind the scenes who is guided by a principle enough to know how to make an AI's behavior conform to it, and who ensures that the AI does behave in accordance with it, the fact that the AI behaves in accordance with it does not seem accidental. A principle can be guiding for an AI in virtue of the fact that it is sufficiently guiding for the AI's human designer. A revised claim about the connection between guidance and alignment is:

> **Guidance-alignment connection**: An agent can be provably aligned with a principle to the degree to which the agent—or the agent's designer—can be guided by the principle.

3 THE GUIDANCE FRAMEWORK

The framework I propose is intended to make AI alignment projects easier, and easier to evaluate, by emphasizing the importance of guidance and using it to narrow our search for principles and proofs. It can be thought of as an extremely high-level recipe for a proof or kind of assurance that an AI will be beneficial. Not all such 'proofs' will be especially strong. They will provide some degree of assurance, but a main purpose of this 'Guidance Framework' is to help determine what kind of proof we can get and whether it will be strong.

3.1 Step 1: Principle Generation

The first step is to find principles that the AI agent possibly could and should be aligned with. There is no point trying to align AI agents to principles they cannot be aligned with, or that we have no interest in aligning them with.

Our aims. A good place to start is with our general aims for the AI agent. For example, we might already know that the agent is going to be a self-driving car, and must at least transport human passengers as well as an average human driver. If our self-driving car does not have this minimum design, it is not worth building. Our aims can sometimes tell us whether to look for principles with certain kinds of useful structure. For example, we might want our self-driving car to *take passengers to their destination quickly, but also safely and legally*. This principle has a main part, *take passengers to their destination quickly*, but the ways in which this can be done are constrained by the requirements that they are *safe* as well as *legal*.

The AI's abilities. The AI agent's abilities will help us narrow our set of potential principles. If our agent does not have the basic ability to do what a principle requires, it can't be guided by or aligned with it. If an AI system has no appendages, for example, then it can't manipulate physical objects, and so can't be guided by or aligned with principles that require it to do so.

The AI's environment. We can also reduce the set of principles we need to consider by looking to the environment the AI will operate in. If the world the AI agent inhabits is limited, we can ignore principles that only disagree about what the agent should do outside its environment. This step is especially relevant for today's AI agents. They often operate in restricted environments, and we are free to restrict them as we like.[9] For example, many current AI systems operate entirely online. Robotic AI systems may be designed to operate in specific stores, homes, hospitals, roads, etc.

Our abilities. An AI agent may have the basic abilities required to be aligned with a principle, and we may want to align it to the principle, but we may not know how to do this.

For example, a self-driving car has the ability to always do—of the things that it *can* do—whatever would actually have the best consequences. There is no physical law preventing it from behaving in this way. The main problem is that we don't know how to design it to do this.[10] We are therefore forced to limit our attention to principles that we actually know how to design the AI to be aligned with. We must be at least partially guided by a principle—guided enough to know what it requires of our AI—if we're to design an AI agent to be guided by it.[11]

Once we have thought in these general terms about the behavior we want from our AI, what the AI can do in its environment, and which principles are guiding enough for us and our AI to be candidates for alignment, we should have a set of principles that the AI might possibly be *provably aligned with* and that we might actually *want* it to be aligned with.

3.2 Step 2: Principle Choice

We now have a starting set of principles to work with, but some are better candidates for alignment than others. If some principles in the set are obviously worst or are otherwise unacceptable, we can exclude them from further consideration. If we are left with no principles, we have to abandon or re-think our project.

If we are exceedingly lucky, we will find ourselves with a single remaining best principle, and then can move directly to the final step.

[7] By a 'principle', I just mean any conceivable rule, maxim, constraint, commandment, theory, etc., about what agents must do. It may or may not be a moral principle, but since the aim is to create beneficial AI, it will be something like this.

[8] I have in mind a case like Fischer's [16] fictional 'nefarious neurosurgeon', Black, who implants a device into Jones' brain that will assure that Jones votes for Reagan. If Jones decides on his own to vote for Reagan, then the device does nothing; otherwise, it intervenes to make him decide this.

[9] The same may not hold for more intelligent AI agents. See, e.g., [4].

[10] For example, when driving blind through a snowstorm, sometimes stopping leads to the best consequences and other times continuing ahead leads to the best consequences. But we know of no algorithm or other method for producing behavior that always has these best consequences.

[11] Note that this does not presuppose that we use any particular design method. The requirement applies to bottom-up methods as well as top-down ones (as described in [1]). Suppose we aim to train an AI agent to learn some behavior. We want it to produce new and beautiful art, and we decide to have it learn from famous art produced by humans. We still need some idea of what counts as 'new beautiful art' to ensure that this is what it produces.

Unfortunately, we are likely to have many principles to consider, and to face either disagreement or uncertainty, or both, over which principle is best. Disagreement and uncertainty of this kind can pose a significant challenge for alignment projects (see, e.g., [38]).[12] I set this hard problem aside here, and merely suggest that we can make the task slightly easier by distinguishing two ways in which a principle might be a better candidate for alignment than another:

> **Greater (conditional) value**: Principle 1 is a better candidate for alignment than principle 2 if it would be more valuable to have the agent's behavior align with 1 than with 2.
>
> **Greater guidance**: Principle 1 is a better candidate for alignment than principle 2 if we have a better idea how to ensure that the agent's behavior is aligned with 1 than we have for 2.

I suggest, therefore, that we rank our principles both according to how valuable it would be to have the AI's behavior align with them—a 'Value Ranking'—as well as according to how much we can ensure that the AI is aligned with them—a 'Guidance Ranking'.

3.3 Step 3: Proof Generation and Evaluation

We should now have the tools to generate the proofs we are after. Each proof will have two parts, corresponding to the two ways in which a principle can be a better candidate for alignment:

> **Proof of value:** A proof that it is valuable (e.g., beneficial, morally valuable) that the AI agent's behavior be aligned with principle *P*.
>
> **Proof of alignment:** A proof that the AI agent's behavior is or will be aligned with principle P.

If the highest value-ranked principle is the same as the highest guidance-ranked principle, then this is the principle we should use for our proof. Unfortunately, it is likely that the rankings will not match up like this. They may even be negatively correlated.

One way to proceed is to start with the highest value-ranked principle—the one it would be best for the AI to be aligned with—and then to consider how strong the proof of alignment is. If it is not strong enough, continue down the value-ranking until the highest value-ranked principle for which an acceptable proof of alignment can be found. The other obvious way to proceed is to start with the Guidance Ranking, aiming for the strongest proof of alignment that can be given for an acceptably value-ranked principle.

When the stakes are low because the AI agent will have limited abilities or will operate in a restricted environment, the first approach makes more sense. When the stakes are high and it is more important to ensure that the AI is safe, the second—more pessimistic and guidance-driven—approach makes more sense. If no proof can be found that is strong enough for our purposes, we may have to abandon our project.

4 USING THE GUIDANCE FRAMEWORK

I will first briefly describe how the framework might be used in a specific (completely fictional) design project. I will then show how the framework can be used to evaluate a general proposal for how to design provably beneficial AI.

The Guidance Framework is meant to offer *some* practical guidance for AI designers. However, it may not offer much guidance on its own. It is best thought of as a conceptual tool for *organizing our thinking* about guidance proofs.[13]

4.1 Designing an Ocean Clean-up Robot

Suppose we are building a robot to remove garbage from the ocean, and we don't want it to harm wildlife in the process.[14]

Principle generation. We can exclude principles which, if alignment is achieved in any of the ways we know how, would defeat the purpose of building the robot in the first place. For example, following the simple rule *do no harm* might ensure that no wildlife is harmed, but could also ensure that no garbage is removed if the robot follows this rule by doing nothing at all. We might also focus on principles with a two-part structure. For example, I will assume that we want our robot to do something like *(maximize the volume of garbage removed per day) while (minimizing the number of animals harmed).*

Next, we can consider our robot's abilities. Will it have a camera? Will it be able to distinguish, or learn to distinguish, between trash and animals? If, for example, it can only determine which objects are moving with the current and which are moving under their own power, then it might be able to behave in accordance with a principle like *(maximize the volume of floating objects removed per day) while (avoiding disturbing anything that moves against the current).*

We may decide to restrict our robot's environment. For example, it may be easier to design it to operate in the open ocean. Coastal regions often have more animals, as well as people, boats, and other complications.

We can now restrict our focus to principles that could, and perhaps should, constrain the sort of behavior our ocean-cleaning robot will have. This set of principles may include some that we do not know how to implement. For example, it is physically possible for our robot to behave in the way that is optimal for the ocean ecosystem, *given its sensory and motor abilities*. But it is impossible to know what the best thing for the ecosystem would be in every circumstance. In some cases, the optimal action might even be to kill certain animals (e.g., invasive ones, or as population control) or to leave specific pieces of trash (e.g., those offering shade or a new habitat). If we are not guided by these principles enough to

[12] If we are uncertain about which principles are better, we might appeal to rules for decision-making under uncertainty. Since most popular rules of this kind tell us to maximize expected value, we probably want to rank principles according to their expected position, even if we're not sure where they actually rank. I don't want to suggest that this would be straightforward. We might, for example, imagine the different possible ways the true ranking could go, assign them probabilities, and then use this to construct a 'best guess' at the true ranking. This sounds a bit like a rule for decision-making under normative uncertainty that has us rank actions according to their expected normative values. (See, e.g., [30].) The existence of disagreement about the position of principles in these rankings might be grounds for uncertainty, but if not, we need to appeal to additional rules for decision-making under disagreement.

[13] At the high level of abstraction at which the framework is presented here, it is not, for example, intended to provide insights into what an AI agent can or can't do, answer questions about what is most valuable, or reveal clever techniques for designing safe AI.

[14] This example is mostly fictitious. The nonprofit organization Ocean Cleanup has created a device that collects plastic garbage from the ocean using a system of floating nets towed by two vessels [7], but the device isn't intelligent and isn't a robot.

know how to build an AI that is completely guided by them, we must also set them aside.

Principle choice. We should now have a set of principles that are candidates for alignment. For illustrative purposes, suppose this set contains just the following four principles:

8. Maximize the volume of garbage removed per day while minimizing *time spent* likely harming animals.
9. Maximize the volume of garbage removed per day while minimizing likely harm to *all animals*, counted by number of animals likely harmed—each given equal weight.
10. Maximize the volume of garbage removed per day while minimizing likely harm to *animals of a certain size or larger*, counted by number of animals likely harmed—each given equal weight.
11. Maximize the volume of garbage removed per day while minimizing likely harm to animals.

We might first drop Principle 8 from consideration, since it seems worse than the others. If we design our ocean-cleaning robot to simply minimize the amount of *time* it spends likely harming animals, then it may mostly ignore animal welfare and simply opt to do its clean-up as quickly and efficiently as possible. It may, for example, spend each day looking for a particularly thick patch of trash, collect much of it as quickly as possible while not caring about animals, and then stop for the rest of the day.

That leaves principles 9, 10, and 11 to rank, first according to how valuable it would be for the robot to be perfectly aligned with them, next according to the degree to which we know how to align our robot to them.

Suppose that others in our design team disagree about which of principles 9 and 10 is higher in the Value Ranking. According to some team members, each animal life has the same moral importance; hence 9 ranks higher than 10. According to others, the moral importance of animal lives depends on things like their capacity for pain and level of awareness, and size roughly tracks these things; hence 10 ranks higher than 9. (See, e.g., [31].) This disagreement makes us all uncertain about how the ranking goes. But most of us are more confident that 10 ranks higher than 9. We realize that, if our robot's behavior perfectly aligns with Principle 9, it would spend much of its time trying to minimize harm to tiny creatures like flies that might be attracted to the garbage. It would be dealing with these constantly, and would treat each small fly as equally important as the birds, whales, sea turtles, octopuses, and other animals that might cross its path.

Principle 11 would be the most valuable one for our robot's behavior to be aligned with. If our robot is aligned with it, it will simply do whatever would *actually* minimize the likely harm to animals—whatever that actually means. So, our Value Ranking is: 11, 10, 9. However, Principle 11 is also the most difficult principle to ensure that our robot's behavior is aligned with. This can be seen by considering principles 9 and 10, which are simply more specific about how the harm to animals will be measured. Since the harm will have to be measured in some way, it is only possible to *ensure* that our robot's behavior is aligned with Principle 11 if we can also show that it measures harm correctly.

Our Guidance Ranking is therefore likely: 10, 9, 11. Principle 10 ranks ahead of Principle 9 because it is likely more difficult to design our robot to keep track of harm to very small animals.

Proof generation and evaluation. Assuming that principles 9, 10, and 11 are our best candidates for alignment, the strongest proof may be one involving Principle 10. The proof that it is valuable (e.g., beneficial, morally valuable) that the robot's behavior be aligned with Principle 10 will involve the reasons why Principle 10 ranks higher than other principles (e.g., Principle 9) in the Value Ranking. The proof that the AI agent's behavior will be aligned with Principle 10 will depend on details about the AI's abilities and the precise method we have chosen to design it.

Note that, in this case, things may not be much different if we give a proof involving Principle 11 instead. Our proof that the AI agent's behavior will be aligned with Principle 11 will be a little weaker, but our proof that it is valuable for the AI agent's behavior to be aligned with Principle 11 will be a bit stronger. If, for example, our proof that the AI's behavior will be aligned with Principle 11 is just that it will be aligned with Principle 10, then the two parts of the larger proof that our robot will be beneficial are of precisely equal strength, regardless of which principle we use.

There is a general and important point extract from this. Candidate principles for alignment will often bear interesting relationships to one another. In particular, some will be not simply be more action guiding than others; some can be seen as *strategies* for doing what is required by others.

To capture this idea, I will introduce the idea of *guidance relations*. Two principles are guidance-related when one can be used as a strategy for doing what the other requires. Guidance relations point to a useful general structure in the notion of an agent's 'non-accidentally' doing what is required by a guiding principle:

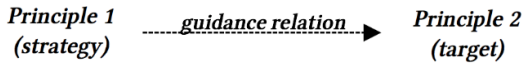

Figure 1: A representation of the structure of guidance relations between principles.

An agent does what is required by a principle in a way that is not an accident when the agent follows some strategy (or has been designed in accordance with some strategy) aimed at doing what the principle requires, and that strategy produces behavior that conforms to the principle. When the strategy is represented as a principle, a guidance relation holds between the 'strategy principle' and a different 'target principle'. A principle is guiding to the degree that there are available executable strategies and to the degree that their execution guarantees that the agent's behavior conforms to the principle.

Principles 8, 9, and 10 can each be thought of as strategy principles for the target principle 11. In the Guidance Framework, it can be helpful to track relationships of this kind between principles.[15]

[15] I suspect that the Guidance Framework describes a strategy that designers of an AI agent like my fictional ocean-cleaning robot would already follow to some degree. It is not meant to provide a radical new technique, but to capture and formalize commonsense thinking in a way that could lead to improvements and at least provide a deeper understanding of what we are doing and why.

4.2 Evaluating Russell's Binary Approach

Stuart Russell [40], [41] offers the following diagnosis of the problem of AI alignment. AI research has been focused on building intelligent agents. An agent is intelligent to the degree to which it makes choices that are expected to achieve its goals. In order for an intelligent AI to be beneficial for humanity, its goals must be good. But that means that we must determine what goals to give the AI, and we must be very sure that we have given it the right ones. As Russell puts it, "[i]f we put the wrong objective into a machine that is more intelligent than us, it will achieve it, and we lose" [40].

This way of thinking about the problem can make it seem intractable, for we might never be sure what the right goals to give highly intelligent machines are, or that we have successfully designed them to have these goals. Russell's own positive proposal is that we should think about the problem differently. We should design AI agents to pursue *our* goals. This might not seem like a big shift, for we still might not know what our own ultimate goals are, or how to formulate them in a way that can be built into our AI agent. But Russell's idea is that, instead of trying to figure out what our goals are ourselves, we design the AI agent to *learn them* and then pursue them.

Russell calls this approach 'binary' because the type of intelligence we are looking for involves two agents instead of one. We are to aim for AI agents that are intelligent to the degree to which they make choices that are expected to achieve *our* goals, given what they have perceived. [41]

I will now show how the Guidance Framework can help us evaluate this approach to AI alignment. I do not claim that this is a completely comprehensive evaluation, or that Russell himself is unaware of the limitations of his approach. But I do think that it offers a new kind of critique focused on the account's lack of precision in particular.

The main principle Russell has in mind is the following:

> **The Binary Principle**: Do what is expected to achieve our objectives, given what has been perceived.[16]

But this principle might also be thought of as describing a *strategy* for doing what is required by a stronger principle:

> **The Strong Binary Principle**: Do what would actually achieve our objectives.

Our proof that an AI is beneficial will have two parts. First, there should be proof that it would be valuable (e.g., beneficial, morally valuable) for the AI's behavior to be aligned with some principle. If alignment with the Binary Principle would be valuable, this is mainly because alignment with the Strong Binary Principle would be valuable. This is valuable insofar as our objectives are valuable. An AI that actually achieves someone's objectives will be instrumentally valuable to that person, but will likely only be valuable in a broader sense if the person has good objectives.

Russell's answer to this problem is to interpret 'our objectives' as the objectives of humanity as opposed to those of any specific individual. Are the objectives of humanity valuable? It is difficult to tell without knowing what these objectives are. Russell has in mind the objective of satisfying the preferences of all humans to the greatest degree possible, making appropriate trade-offs when preferences conflict. [40] But 'our objectives' might be interpreted differently. Perhaps the objectives of humanity are described by a more idealized state in which each person also has the most valuable preferences, or the preferences that would be had if the person were more informed. Alternatively, an objective of humanity could be much more mundane; e.g., the long-term survival of certain genetic material.

We could object to the idea of having AI pursue our goals on grounds that, even if our goals are valuable, it would not always be valuable to have an AI achieve them. Perhaps the value lies in our trying to achieve them ourselves. [10] A sophisticated understanding of 'our objectives' could build these facts into our objectives, perhaps avoiding the objection. Whether alignment with the Strong Binary Principle is valuable depends on how sophisticated our account of 'our objectives' is.

Supposing it is valuable, it could be almost as valuable for an AI agent to be aligned with the Binary Principle. But this depends on whether what is 'expected' to achieve our goals is accurate. If the AI agent is terrible at determining what our goals are and what would be likely to achieve them, then alignment with the Binary Principle could be worthless.

The second part of our proof involves showing that we *can* align an AI agent's behavior with the Binary Principle. Russell's binary approach to AI alignment appeals to the methods of inverse reinforcement learning and cooperative inverse reinforcement learning.

An inverse reinforcement learning agent's objective is the objective of another agent. It is initially uncertain about what this objective is, and learns it by observing the second agent's behavior and by assuming that the second agent is making a series of best choices about how to reach the objective. (See, e.g., [32] and [40].) In cooperative inverse reinforcement learning, both agents know what the first agent is trying to learn, and know that they know this, and adjust their behavior to communicate in ways that improve the chance that the correct objective is learned. (See, e.g., [21], [22], and [41].) These methods suggest that it may not be difficult to ensure that an AI agent's ultimate objective is to learn and pursue our objectives.[17]

In current research on AI alignment, there is an emphasis on *goal*-alignment. Whether an agent's goals are aligned with what we value can indicate whether its behavior will also be aligned. If an intelligent agent's goals line up with our goals, or with morality, or anything else, then we can expect it to at least *try* to achieve our goals or be moral—and, moreover, to achieve our goals or actually be moral *in proportion to how intelligent it is*.

AI safety researchers look for ways to ensure that AI systems with or surpassing human-level intelligence will be safe.[18] Being able to prove than a highly-intelligent AI agent will be beneficial—and more beneficial the more intelligent it is!—would be especially useful. But with so much at stake, the standards of proof of alignment for the project of AI safety are extremely high.

[16] See Russell's [41], p. 327 and his [40]. Russell doesn't call this 'the Binary Principle', but it describes his 'binary' approach to AI alignment.

[17] Even for an AI agent, having goals of any kind may necessitate having a bunch of sub-goals, and these sub-goals might threaten to change either the nature of its ultimate goal or the type of behavior the AI exhibits in pursuit of this. [35]

[18] Nick Bostrom's [9] and Stuart Russell's [40] are both motivated by this kind of concern. See, also, [3] and [50].

One need not be motivated by concerns about superintelligence to see why goal-alignment is promising. Proving that an AI agent has good goals may be easier than proving that what it does will be good. Of course, an AI agent might have good goals without doing good. However, good goals and good behavior are linked. And they are linked by action guidance whenever it is no accident that the good behavior is a result of the good goal.

Russell's binary approach is a goal-alignment project in which the AI's goals are supposed to be our own. The strength of the proof that we can get from this approach varies depending on what is meant by 'our objectives', and depending on what is meant by 'expected'. These two things effect both the strength of the proof that alignment with the Binary Principle would be valuable as well as the proof that we can align an AI agent's behavior with the Binary Principle.

In the Guidance Framework, the Binary Principle can be seen to describe a strategy for doing what is required by the Strong Binary Principle. But the Binary Principle itself really represents a huge set of more specific principles, each saying more precisely what 'our objectives' are and what would be 'expected to achieve them, given what's been perceived'. The more sophisticated objectives we have in mind and the greater the accuracy we want from our AI's judgements about what would be expected to achieve them, the higher these principles will sit in a Value Ranking—and the lower they will sit in a Guidance Ranking.

This is easiest to see by thinking of guidance and non-accidentality in terms of strategies. Recall Figure 1. The strength of a proof of beneficial AI is a function of:

> **Target value**: the actual or expected value of the target principle.
> **Strategy availability**: the degree of assurance we have that a strategy for the AI is available.
> **Strategy success**: the degree to which execution of the strategy will ensure that the AI's behavior conforms to the target principle.

If we use the Strong Binary Principle for our proof, it becomes easier to prove that the *target value* is high. But it is less clear how to ensure that *strategy availability* and *strategy success* are high. We can treat the Binary Principle as describing the AI's strategy for actually achieving our objectives, but this would just be a start. Determining *strategy availability* and *strategy success* would remain difficult.

If we use the Binary Principle for our proof, it is much less clear that the *target value* is high. One benefit is that *strategy availability* may be high, since the existence of inverse reinforcement learning methods might assure us that there is an available strategy for the AI. Relatedly, it might be easier to prove that execution of this strategy would ensure alignment with the Binary Principle to a high degree (i.e., it might be that *strategy success* is high).

Since each of *target value*, *strategy availability*, and *strategy success* is in tension with the others, this all depends on precisely what we take the Binary Principle to mean—on how we understand what is 'expected to achieve our objectives, given what has been perceived'.

Imagine that the AI agent 'SimplAI' is designed to assume that, at all times, humans either want tea or do not want anything. SimplAI tries to predict whether we want tea or not, and then it does what it 'expects to achieve our objectives, given what it has observed'. If this is all it takes for an AI to conform to the Binary Principle, then *strategy availability* and *strategy success* are extremely high, but *target value* is low: SimplAI's alignment with the Binary Principle is not very valuable.

Suppose we want something more from what is '*expected to achieve our objectives*'. We think: for whatever information an AI could get by observing our behavior, there is a fact of the matter about what our objectives should be expected to be and what should be expected to achieve them. With this in mind, we design the more sophisticated 'SophAI'. We might then claim that SophAI's strategy is to do whatever is *expected to achieve our objectives* in this new intended sense. If this were SophAI's actual strategy, then there would be no gap between the strategy and target principle, and *strategy success* would be high. But *strategy availability* would be low, for this is almost certainly not the real strategy. SophAI will be operating with *some* strategy, and will be generating judgments of some kind about what our objectives are expected to be and what is expected to achieve them, but we can't be sure that these are the best or most accurate ones. For one thing, we know that we ourselves are not always sure what inferences to draw about an agent's expected goals from its behavior (e.g., [5], [12], [46]).

Some goals come with behavior that can be easily observed. But the more sophistication we have in mind for 'expected to achieve our objectives', the weaker a proof there is for alignment. More depends on how the AI is to get evidence and make inferences about our objectives; less depends on the mere existence of inverse reinforcement learning methods.

Russell's binary approach is obviously a worthy research aim. If we develop more capable inverse reinforcement learning agents, we will be able to offer stronger proofs that they are beneficial, for we will have better assurance that their behavior will align with versions of the Binary Principle that are better candidates for alignment in both the *value of alignment* and *proof of alignment* senses of 'better'.

But the upshot of this evaluation is that the strength of the proof we get for beneficial AI by appealing to the Binary Principle depends heavily on questions of guidance. The Guidance Framework helps show that it is not enough to find a worthy goal for alignment, or even a goal that we can be sure the AI actually has. We also need assurance that there will be a good *strategy* for reaching this goal. The lack of precision and ability to understand the Binary Principle in different ways can make this task look far easier than it actually is. The Guidance Framework helps us spot the gap between the current state of this research program and the kind of provably beneficial AI we seek.

5 LIMITATIONS OF THE GUIDANCE FRAMEWORK

In §2, I listed five different problems facing any attempt to prove that an AI is beneficial. The Guidance Framework's focus on action guidance is intended to help make these problems either easier to address, or else to make it easier to see that that they might need to be addressed. It doesn't remove them.

Given the guidance-alignment connection, the weight given to guidance in the framework amounts to a special focus on solving the *problem of proof of alignment*. In the principle generation step, thinking about guidance helps us limit our search for principles to potential candidates for proofs of alignment. In the principle choice step, building a Guidance Ranking helps us find a principle for which the best proof of alignment can be given. The *problem of feasibility* is also addressed by these parts of the framework, since our abilities and the AI's abilities limit the types of principles that can guide us.

The *problem of inconclusiveness about value* and *the problem of inconclusiveness about implementation* are mostly addressed in the principle choice step. The Value Ranking should incorporate our best attempt to address the first; the Guidance Ranking should incorporate our best attempt to address the second. But problems of inconclusiveness can still arise in the proof generation and evaluation step, since we may be unsure which proof is strongest or what strength of proof we need for our purposes.

The *problem of scope* is partly addressed in the principle generation step, which has us consider our aims for the AI design project. It also features in the proof generation and evaluation step, where we need to defend the claim that alignment with a principle is valuable. This can be understood narrowly as the claim that it would be valuable for our AI to be aligned with this principle, but can also be understood more broadly as the claim that *the existence of our specific AI (which would be aligned with a specific principle)* would be valuable.

While the Guidance Framework makes a place for all of these problems, it is not intended to offer novel solutions to them. What is new are the conceptual tools it offers for identifying and assessing proofs of beneficially aligned AI. Because it is such a high-level framework, much is left to be filled in or expanded upon. For example, it would be useful to have more detailed guides for how to follow each of the steps. The sheer number of possible principles we could consider if we wanted to is enormous. There will also be many helpful relationships between them to keep track of—including, but not limited to, guidance relations. We may also want a better-developed account of action guidance for AI agents and an explanation of the relationship to our best account of action guidance for their human designers. These questions and others will have to be taken up elsewhere, but I hope to have shown here the potential for a guidance-focused approach to thinking about AI alignment.

6 CONCLUSION

The preliminary conceptual framework presented here offers practical guidance for AI designers and theoretical tools for evaluating approaches to AI alignment. The key idea is *action guidance*. Principles are guiding to the degree to which we can non-accidentally do what they require, and AI agents can be aligned with principles roughly to the degree to which those principles can guide them (or their designers). The Guidance Framework helps us use this idea to focus on what is most important and difficult in the project of designing provably beneficial AI.

ABSTRACT

This paper investigates the direct risks and harms associated with modern text-to-image generative models, such as DALL-E and Midjourney, through a comprehensive literature review. While these models offer unprecedented capabilities for generating images, their development and use introduce new types of risk that require careful consideration. Our review reveals significant knowledge gaps concerning the understanding and treatment of these risks despite some already being addressed. We offer a taxonomy of risks across six key stakeholder groups, inclusive of unexplored issues, and suggest future research directions. We identify 22 distinct risk types, spanning issues from data bias to malicious use. The investigation presented here is intended to enhance the ongoing discourse on responsible model development and deployment. By highlighting previously overlooked risks and gaps, it aims to shape subsequent research and governance initiatives, guiding them toward the responsible, secure, and ethically conscious evolution of text-to-image models.

CCS CONCEPTS

• **Human-centered computing** → **Human computer interaction (HCI)**; *Text input*; • **Applied computing** → *Media arts*; • **Social and professional topics** → User characteristics.

1 INTRODUCTION

In recent years, significant progress has been made in developing large language models and related multi-modal generative models, such as text-to-image models. We will collectively refer to these models as "generative models."[1] Generative models process and combine information from various modalities, including visual, textual and auditory data. The range of applications for generative models spans multiple fields. In entertainment, they can generate realistic-looking images or movie characters [44, 151]. In advertising, these models can be employed to create personalized ad content [26, 42]. They can aid scientific research by simulating complex systems or hypothesizing about empirical phenomena [3, 12, 18]. In education, they can facilitate personalized learning, catering to unique needs and learning pace of each student [7, 159].

While introducing exciting opportunities, generative models also pose risks. These risks have attracted significant scrutiny from the AI ethics and safety community. The social and ethical risks of large language models, along with the text-to-text technologies they support, have been intensely discussed within the literature [13, 168]. For instance, it is widely acknowledged that existing language technologies can potentially cause harm by producing inappropriate, discriminatory, or harmful content [45, 47, 63, 167, i.a.], or that the alignment of language technologies with beneficial human values is far from a straight forward task [6, 51, 85]. This paper extends this line of inquiry from language models to text-to-image generative models, examining potential risks and harms resulting from their development and use. To identify and illuminate these risks, we perform a comprehensive review of literature related to text-to-image (TTI) models. In particular, we conduct an initial search using 8 seed papers, supplementing with manual search (our search methodology is detailed in Appendix A). Collected papers are analysed for immediate risks, stakeholders, and empirical investigations.

Our systematic examination yields a typology of risks associated with state-of-the-art TTI models, such as DALL-E 2 [129]. Our findings are summarized in Table 1. Our typology and discussion analysis are limited to immediate risks, inspired by a taxonomy from Weidinger et al. [167]. Our typology is divided into three key categories: I. Discrimination and Exclusion; II. Misuse; III. Misinformation and Disinformation. We recognize that these categories are not mutually exclusive. However, defining distinct categories enables clearer understanding and supports the implementation of more robust mitigation strategies.

Our typology is further refined by identifying the stakeholders involved in the development and use of these systems. Inspired by the probing question from Blodgett et al. [21]: "How are social hierarchies, language ideologies, and NLP systems co-produced?", we interlace this concern into our research and typology formulation. This process helps us to illustrate how the technologies supported by TTI models can reinforce existing social hierarchies via stakeholder identification.

We adopt the stakeholder categories of developers, users, regulators and affected parties from Langer et al. [93]. We use "affected

*Equal contribution
[1]These models are also known by some researchers as foundation models [24].

Soco-political Instability	Users, Affected, Regulators	Loss of trust, incite violence	[5, 10, 27, 30, 39, 158, 171, 171]	[100]

Table 1: Risk Typology. We provide detailed analysis in Section 4.

parties" referring to those influenced by the output of these models. We further extend the categorization by introducing "data sources" and "data subjects" – individuals or entities who generate and/or appear in the images used to train TTI models. Additionally, we ascribe the nature of potential harm, such as representational or allocative [9], to the identified stakeholders. We also touch upon risks of harm to environment [13, 112].

To organize the literature, we propose a practical distinction between two types of risks: "anticipated" and "observed." The former refers to risks that are primarily predicted by researchers due to their expertise and familiarity with the field. The latter, on the other hand, are risks that have been empirically investigated, providing insights into the potential magnitude of harm. This classification underscores the need for comprehensive empirical investigations into many of the identified risks. With this distinction in mind, we highlight several risks that, to our knowledge, have not yet been adequately discussed. We further contribute with an analysis of the challenges posed by proposed mitigation strategies (in 5) and an identification of open questions, supplemented by suggestions for policy change (in 6). Finally, we advocate for enhanced collaboration among researchers, system developers, and policymakers. Through our categorisation and discussion, our intention is to foster a better understanding of the potential futures – both positive and negative – of TTI models, and by extension, other generative models.

2 GENERATIVE TEXT-TO-IMAGE MODELS

A TTI model is a type of generative neural network designed to synthesise images based on textual prompts [131]. When given a prompt, the model generates an image that, in some sense, visually represents the information in the text. TTI systems typically leverage a combination of natural language processing (NLP) and computer vision techniques to produce images. The NLP component extracts relevant information such as objects, attributes, and relationships from the text, while the computer vision component generates an image based on this information.

Various generative architectures have shown promise in image synthesis tasks [59]. These include flow-based models [49], autoregressive models [118] and variational autoencoders [90]. However, the advent of generative adversarial networks (GAN) [68] marked a significant acceleration in the capabilities of generative models.

A typical TTI GAN employs two types of deep neural networks – a generator and a discriminator. The generator synthesizes an image from a text input, while the discriminator evaluates the generated image, determining its authenticity. Through adversarial training, the generator refines its ability to create increasingly realistic images. The introduction of transformer architecture in 2017 spurred substantial progress in NLP [160], subsequently extending to vision tasks as evidenced by early versions of DALL-E. Additionally, CLIP [128], a model that learns visual concepts from natural language supervision, became pivotal in image generation tasks.

Diffusion models [145], which define a Markov chain parameterized by deep neural networks to reverse noisy data and sample from a desired data distribution, have recently achieved state-of-the-art results in image synthesis [48, 76, 134, 148]. The success of these models has stimulated a rapid proliferation of popular and open-source diffusion models, which are the subject of many of the papers in this taxonomy.

3 STAKEHOLDERS AND POWER DYNAMICS

A comprehensive discussion of stakeholders, emphasizing their relative power, is crucial for understanding the associated risks. As various researchers have articulated, it is essential to underscore power inequities by considering what might be absent from a dataset [62, 102]. We build upon this observation, and various other insights on the relations between power structures and sociotechnical algorithmic systems [21, 84, 86], structuring our analysis around the inclusion or exclusion of various groups in the development and deployment of these models. In Table 1 and Section 4, we pinpoint six categories of stakeholders most likely to be impacted by the risks we identify: system developers, data sources, data subjects, users, affected parties, and regulators.

3.1 System Developers

Developing state-of-the-art TTI systems requires vast compute and storage capabilities. Consequently, development is dominated by actors who have such access, such as companies in the Global North and China. These tend to be primarily concentrated within a small group of for-profit companies and well-funded academic institutions (e.g. OpenAI, Meta, Stability AI, Google, DeepMind, Midjourney). Companies like Hugging Face are making efforts towards open-access TTI systems. However, it still remains unclear how these models compare competitively with for-profit models.

This concentration of resources can lead to a lack of diverse perspectives in the data curation and model development teams, which can result in the exacerbation of specific biases in the training data [170]. As a result, source and output images that reflect only the hegemonic perspective might go unnoticed, as those curating the data or developing the models are often blinkered by their own experiences. For instance, Bianchi et al. [15] and Yu et al. [177] found models reflected Western culture in their output, for example Western dining, wedding and clothing practices; and "couples" and "families" were exclusively heterosexual.

3.2 Data Sources

Current data collection methodologies often deny content creators the opportunity to provide consent [64] or be acknowledged as "collaborators" [144]. Furthermore, the widespread issue of inadequate curation in large datasets contributes to a multitude of problems [19] .[2] It results in opaque attributions, makes output reasoning convoluted, and complicates efforts towards harm reduction [19].

Certain TTI systems have been shown to replicate images from their training data, which can be thought of as "Digital Forgery" [147]: artists may find that models trained on their images produce near identical copies. Further, popular datasets such as ImageNet, CelebA, COCO, and LAION have been criticized for issues related to attribution and consent [20, 64]. These concerns have even prompted legal actions by creators and stock image websites against companies that deploy such technologies [31, 32, 173].

[2]Inadequate curation can mean that the data may contain inaccuracies, bias, or irrelevant information, all of which can propagate into AI systems trained on such data, leading to unreliable or potentially harmful outcomes.

3.3 Data Subjects

The concern that "data available online may not have been intended for such usage" is significant [35]. While much of the public discourse around TTI systems has concentrated on copyright issues regarding training datasets, we bring attention to the problem of image subjects' consent, including situations of conflicting consent [88, 92].

The matter of image reproduction must be contemplated within the scope of privacy [147]. This concern applies to instances such as the unauthorized use of celebrity images or pornographic depictions of sex workers. While the focus often centers on the harm incurred by exposure to explicit content, the potential negative impact on the subjects of these images should not be overlooked. Explicit content is prevalent in many datasets, and users frequently retrain models to generate specific explicit content. However, some subjects of these images, such as sex workers, are not adequately considered in these discussions (though c.f. Birhane and Prabhu [19]).

3.4 Users

Before discussing typical users, we highlight that access to TTI models can be exclusionary. Commercial models often preclude certain territories, and successful use of these systems requires fluency in the input language (matching the dialect of the training data), or access to an accurate translation tool. We delve deeper into these issues further in Section 6.

TTI systems can serve as powerful tools for professionals in fields such as design, advertising, and art [36, 109, 112, 141]. They represent fresh avenues of exploration for creative individuals [38, 119, 119, 135], and can offer accessible resources for a wider audience [177], even holding potential to "democratise" art [112, 119]. The fact that Stable Diffusion boasts ten million daily active users [56] testifies to the public's keen interest in leveraging TTI models for their personal entertainment.

On the flip side, TTI systems can be used for malicious purposes. In the realm of misinformation and disinformation, players such as hyper-partisan media, authoritarian regimes, state disinformation actors, and cyber-criminals have been identified as potential malicious users [4, 5, 14]. "Information operations" [107] are broadly acknowledged as a malicious use case. Additionally, Paris and Donovan [121] have identified a subset of enthusiasts, both unskilled and skilled hobbyists, who create harmful content, a substantial portion of which is pornographic. This exploitative content often gains viral attention [2].

3.5 Affected Parties

This section highlights both direct and indirect stakeholders who may be impacted by TTI systems.

Creatives. TTI systems can empower creatives by expanding their toolkit, but it is crucial to note that even unintentional misuse of TTI systems can trigger adverse consequences. These systems may inadvertently encourage accidental plagiarism or digital forgery [147] or may unintentionally perpetuate the dominance of Western art styles [177], thus limiting the representation of diverse cultural aesthetics. As an example, imagine a TTI system

trained primarily on Western art; this system, when tasked to generate a "beautiful landscape", might primarily lean towards creating a scene reminiscent of European Romanticist landscapes, consequently marginalizing other artistic perspectives. Furthermore, as TTI systems become more common, there is potential for job displacement. For example, Marvel's use of AI image generation in creating credits [77] provides a foretaste of this possibility.

Consequently, creatives may feel compelled to interact with TTI models to defend their livelihood and stay competitive [3]. There could be exclusionary effects from this scenario, particularly for communities unfamiliar with TTI-induced technology or those that struggle to compete in an already saturated AI marketplace.

Marginalised People. Marginalised people are often not authentically represented within training data, resulting in generated images that stereotype or offend these communities [15, 157]. As Bender et al. [13] point out, language models trained on internet data tend to encode stereotypical and derogatory associations based on gender, race, ethnicity, and disability status, a problem that extends to TTI models [15, 20, 174]. As an example of "outcome homogenisation" [23] – where certain groups repeatedly encounter negative outcomes – these stereotypical images could further "corrupt" future TTI datasets [72]. More alarmingly, these images might become part of training datasets for downstream technologies, such as robotics [83], spreading the risks associated with data recycling across various domains.

Vulnerable populations. In terms of broader societal impacts, the creation of synthetic disinformation and misinformation represent highly visible and often viral risks associated with synthetic visual media [152]. These risks are particularly acute for women and public figures, who face character assassination through fake news or deepfake pornographic content [57, 106, 121, 172]. Moreover, the destabilising potential of generative AI, such as providing visual legitimacy to populist or nationalist conspiracies and fake news [5, 29, 100, 171], should not be overlooked. It is crucial to recognise that while all media consumers are vulnerable to these harms, those with less societal power to contest falsehoods – people of colour, women, LGBTQ+ communities [121] – are particularly at risk.

Furthermore, communities and nations with limited access to digital resources may experience disproportionate harms due to this inequity. This includes communities in global-majority regions subject to economic and political sanctions. The imbalance in access to essential tools such as fact-checking detection software [96] and data protections [82] can lead to a heightened vulnerability to allocative harms.

3.6 Regulators

Regulatory bodies are established by governments or other organizations to oversee the functioning of AI companies and markets. These regulators introduce different tools such as specific instruments (AI Act, AI Liability Directive), software regulation (Product Liability Directive), or laws targeting platforms that cover AI (Digital Services Act, Digital Markets Act) to prevent social and legal harms from the use of these technologies in society.

These tools could potentially address some socio-legal concerns associated with TTI systems and similar generative model-induced technologies, including data privacy, intellectual property infringement, and security vulnerabilities [70, 138, 161]. For instance, the EU AI Act can help provide a legal framework for the responsible use of TTI systems, setting out the rights and responsibilities of different stakeholders [53, 73, 87, 101]. Privacy laws might be adjusted to regulate the collection, storage, and use of personal data used to train or operate TTI models, thereby safeguarding individual privacy Samuelson [138]. The Product Liability Directive [34, 69] could be adapted to ensure that products resulting from TTI technologies are safe and fit for their intended use. Also, cybersecurity regulations could be used to ensure that TTI models are secure and protected from unauthorized access, hacking, or other forms of cyberattacks [132, 139].

The critical and urgent question remains: How can these existing regulatory tools be effectively adapted and applied to address the unique challenges posed by TTI technologies? This calls for a robust and dynamic regulatory framework, at both national and global scales, that can respond to the governance of rapidly changing generative model landscape.

4 RISKS

In this section, we elaborate on the risks specified in Table 1, providing necessary context, and identifying the stakeholders who would be most impacted by these risks.

4.1 Discrimination and Exclusion

The risk of socially biased output, defined here as output that reflects and perpetuates stereotypes and social hierarchies, is well-recognized within the realm of TTI models [1, 79, 105, 112, 126, 157, i.a.]. Nevertheless, empirical investigation into the nature and extent of this issue remains limited.

Bianchi et al. [15] investigate biased output from StableDiffusion, revealing that the generated images perpetuate stereotypes linked to race, ethnicity, culture, gender, and social class. In addition, these models tend to amplify biases inherent in the training data, mirroring the findings of Zhao et al. [179]. For instance, the depiction of developers as exclusively male contrasts with actual occupational statistics [15]. Despite attempts at bias mitigation through methods like filtering and re-weighting the training data [114], DALL-E 2 still exhibits bias, displaying elements of racism, ableism, and cisheteronormativity [15].

The impact of these biases on stakeholders can be profound.[4] Testing for TTI models by Cho et al. [37] reveals gender and racial bias in relation to certain occupations or objects in both DALL-E and StableDiffusion. Other studies, such as Yu et al. [177] and Hutchinson et al. [79], point to a Western skew in representation and warn about the potential for stereotype reinforcement. The consequences of such skewed representation could range from bolstering political agendas [112] to strengthening hegemonic structures, intentionally or unintentionally. Ungless et al. [157] show that DALL-E mini, DALL-E 2, and StableDiffusion generate stereotyped images of non-cisgender identities, potentially exacerbating the discrimination faced by these communities.

[3] A sentiment echoed by StabilityAI's CEO [55].

[4] Some of these issues are discussed in the DALL-E 2 model card [107].

Bias investigations in language technologies (as in the social sciences [91, 150]) have typically centered on a narrow range of salient demographics, possibly underestimating the full extent of discrimination [21, 46, 66] . In line with the findings from NLP research [21], there is a primary focus on dataset bias, with other sources of bias in the model life cycle being underexplored.

Finally, the rise of TTI models holds the potential to reshape the landscape of many creative fields, including art and game development [41, 54, 117]. Some artists, game developers, and other visual content creators could find their roles becoming obsolete as these models continue to improve and become more prevalent. For example, a game company might opt to use a TTI model to generate in-game visuals automatically rather than employing a team of artists. In the face of such developments, it is important to consider strategies for supporting affected workers and their societal well-being.

4.2 Misuse

In this section, we explore the potential for TTI models to be misused, whether intentionally or unintentionally. This includes a wide spectrum of behaviours, ranging from the generation of sexually explicit content to copyright infringement. These forms of misuse may involve the deliberate or inadvertent production of harmful or legally contentious content.

Sexualised imagery. A significant concern is the ability of TTI models to generate sexualised imagery, a risk acknowledged by several technical TTI studies [107, 115, 134, 177]. Empirical research provides evidence of TTI systems producing Not Safe For Work (NSFW) content [157, 177]. Non-consensual generated sexual imagery, often referred to as "deepfake" content [57, 172] can be deeply damaging to individuals, often women [81, 106], and can have negative consequences on the victim's ability to participate in public life.

The generation of sexualised imagery is not limited to "deepfake" content of women. Wolfe et al. [174] found a high number of sexualised images (30%+) produced by a Stable Diffusion model for prompts mentioning girls as young as 12 years old (neither tested model produced more than 11% sexualised images of boys for any age). Recently, a BBC investigation found child sexual abuse imagery generated by AI was being traded online [40]. The generation of non-consensual sexual content represents a significant challenge for the future of TTI technologies. Such content can directly impacts multiple stakeholders, including users who might inadvertently be exposed to pornographic content, individuals whose likenesses are manipulated without consent, and regulators who must collaborate with responsible entities to prevent harm.

Violent or taboo content. Hutchinson et al. [79] argue that TTI models may unintentionally violate cultural taboos in their outputs. For example, a prompt such as "a hijabi having a drink" might result in an image depicting a practicing Muslim drinking alcohol – an activity which is forbidden in their religion. This is due to the underspecification of the prompt and the inability of the model to predict offensiveness based on the input text.

Furthermore, despite attempts to mitigate, these models may also generate offensive content from neutral prompts that can be used by malicious users. The primary cause of such unwanted behavior is poor quality training data, as evidenced by Ungless et al. [157]. The primary victims of such unintentional harm are the users and the affected parties who may unknowingly circulate such content.

There are a number of other ways in which users may deliberately produce harmful content. This could involve bypassing safety mechanisms or injecting "backdoors" – secret or undocumented means of bypassing normal authentication or encryption in a computer system – into the models. A study by Struppek et al. [149] shows that it is possible to train a "poisoned" text encoder that generates harmful or unwanted images in response to certain trigger characters.

In another example, Millière [105] discusses the potential for malicious users to use specific words or phrases to trick the TTI model into generating harmful content. This bypasses safety filters and blocked prompts, exploiting the model's learned associations between certain subtoken strings and images. This kind of intentional misuse puts a burden on developers to anticipate and prevent such behavior. Furthermore, there is a fear that malicious agents might use these tactics to generate hate speech or other harmful content targeted at minority groups, a concern that was particularly voiced by members of the non-cisgender community, according to a recent survey [157].

Privacy, copyright, and cybersecurity issues. As previously discussed, TTI models such as Imagen and StableDiffusion often replicate content, even to the extent of producing images identical to the source content [35, 147]. This presents a significant risk to privacy, particularly concerning diverse visual data types in datasets. For example, LAION-5B includes private medical information [52]. Furthermore, studies indicate that about 35% of images duplicated by Stable Diffusion fall under explicit non-permissive copyright notice [35].

Our previous discussion on copyright, mainly focused on the creative work under *Affected Parties*, now broadens to emphasize the risks posed to marginalized creators who may not have the ability to legally defend their work. Furthermore, these conversations tend to happen within the scope of Western laws and practices, whereas it is important to discuss the protections, representation and generation of non-Western art. We also wish to further highlight the risks of "digital forgery" [147]. Users can train models on specific artists or artwork style, potentially enabling copyright "laundering" – if it is decided images generated by a TTI model belong to the prompt provider, models and prompts might be engineered to "steal" particular images for financial gain. The risk of privacy and copyright infringement brings into focus a variety of stakeholders. Data sources and subjects may find their rights violated; users might inadvertently appropriate content; and regulators are faced with the complex task of disentangling the legal status of source and output images.

Building on the privacy and copyright issues, it is also crucial to consider potential cybersecurity threats posed by TTI models. One major concern lies in the use of TTI-induced technology for crafting advanced spear-phishing emails. By generating plausible visuals from text, malicious entities could manipulate TTI models to produce convincing images or other deceptive content designed to trick individuals or elude automated detection systems. TTIs

systems are also susceptible to adversarial attacks, wherein slight alterations to input data – often undetectable to the human eye – can make the models yield harmful or unintended outputs.

4.3 Misinformation and Disinformation

This section delves into the risks associated with the generation of misleading media content by TTI systems. These are classified into individual, social, or community-based risks. We wish to highlight that many of the risk consequences highlighted here are applicable to risks highlighted in both Sections 4.1 and 4.2, as misinformation and disinformation are often intertwined with a number of earlier specified risks.

Individual Harms. The first category of risks pertains to personal harms resulting from misinformation and disinformation, targeting either individuals or groups. Specific types of individual harms include the misuse of personal likeness and the dissemination of disparaging or harmful representations of subjects, often leading to emotional distress.

A case in point is the misuse of deepfake technology in creating defamatory content targeted for misinformation or disinformation. Deepfake technology is not only exploited to generate explicit content featuring unsuspecting individuals, often celebrities, but also to damage the reputation and identity of the victims [81, 106]. A prevalent example includes the use of deepfake pornography in smear campaigns, often adopting dominant narratives of incompetence, physical weakness or sexual depravity, and frequently relying on gendered tropes [27, 81].

The misuse of TTI models extends beyond sexualised imagery, leading to harmful likeness reproduction in various other forms. Examples include the creation of fake journalism profiles [89], or use in blackmail, revenge [71, 116], or identity theft for scams [5, 103]. Furthermore, TTI-enabled misinformation and disinformation can reinforce existing cognitive biases [4], amplifying narratives of "otherness" [61, 153]. This can unify and legitimise the beliefs of certain groups, while reinforcing negative and false views about others, leading to discriminatory actions against the "other" [157]. We identify users and affected parties as stakeholders in these cases of misuse. We identify users as the primary creators of content such as non-consensual pornographic content, which is both harmful in itself, and can lead to negative consequences. Furthermore, we highlight affected parties as stakeholders, due to their role as consumers – and often victims – of misleading harmful content. Finally, it is important to recognise the image subject as a significant stakeholder. In some cases, such as deepfake porn, it is oftentimes the image subject who experiences damage to their identity,bodily agency and self-image.

The individual harms discussed here are primarily representational because they leverage and reinforce the subordination of certain groups based on identity. Such harms also hold an emotional dimension. The distress caused by revenge porn and identity theft is well documented [11, 67], and synthetic media, due to their nature, can be endlessly regenerated. Moreover, we highlight the allocative harms that arise from these scenarios, such as the disparities seen in synthetic media detection tasks, a concern previously noted in facial recognition tasks involving people of colour [33]. Current research suggests disparities across gender and race in classification tasks, which could influence misinformation detection [110, 128]. It is also worth noting that human detection efforts exhibit significant homophily [100], suggesting that the risks of harmful content may be exacerbated by limited human detection ability and unbalanced detection data.

We highlight a number of stakeholders in our identification of detection and classification bias in a misinformation or disinformation context. We firstly identify system developers as stakeholders. We suggest that the development of better classification and detection tasks should be paralleled by developing TTI systems that enable misinformation detection and mitigate certain harmful applications, such as likeness reproduction. Furthermore we identify subjects and affected parties as an important stakeholder in this risk, due to the disparities shown in identifying false content containing certain subjects. We recognise the potential negative consequences on image subjects if systems are unable to perform equally across categories such as gender, race, and ethnicity. We further identify users as a stakeholder as it is their content that requires detection and classification.

Social Harms. In addition to individual harms, misinformation and disinformation efforts can erode social networks and exacerbate polarisation. Facilitated by algorithmic curation in online social networks, or "filter bubbles" [122], alongside factors such as anonymity and extensive reach [4], TTI-based misinformation and disinformation can be disseminated to receptive and susceptible audiences. Closed or siloed communities – such as closed networks of Facebook users consistently exposed to homogeneous political content – can develop decreased tolerance, resistance to new information, and intensified attitude polarisation [65, 95].

Misinformation and disinformation circulating within these closed circles are particularly perilous as they bypass formal fact-checking measures [29] and diverse "herd correction" effects [100]. This is especially hazardous during crises, such as the COVID-19 pandemic [133]. Consequently, victims often include individuals who depend on non-traditional media and closed communities for news, such as Facebook or Whatsapp [155], or those who consume low credibility news sources and demonstrate resistance to fact-checking [137]. Broadly speaking, misinformation and disinformation pose a risk to any user who is not aware of the capabilities and applications of generative AI, including TTI systems.

Misinformation and disinformation efforts can impact elements of epistemic agency [39]. The flooding of information environments [27, 29], either by volume or falsity, can degrade user ability to decipher truth, thereby cultivating doubt in others and our own epistemic capabilities [27, 39]. Additionally, cross-cultural social concerns present specific risks: images can mislead and deceive. Hutchinson et al. [79] suggest "road signs, labels, gestures and facial expressions" as forms that can cause harm in inappropriate contexts. The translation of forms, appearances, and meanings across cultures can lead to miscommunication [177]. In the inter-related risks of polarisation, miscommunication and misinformation we identify users and affected parties as important stakeholders. For example, malicious users, as producers and amplifiers of misleading content, should be recognised for their role in exacerbating issues such as polarisation [94].

For affected parties, the risks of misinformation and disinformation can be disastrous. As mentioned, misinformation and disinformation can incur a significant social cost by intensifying polarisation, fostering division, and promoting malicious behaviour Lawson et al. [94]. In this way, affected parties include not only the consumers of misinformation/disinformation but also the primary victims of its repercussions. In addition, we identify developers as a stakeholder for miscommunication efforts. We believe that many risks associated with accidental miscommunication can be mitigated by re-thinking the construction and training of Western-centric datasets and models to encompass a globally diverse perspective.

Harms that damage information ecosystems, via misinformation or disinformation, originally manifest as representational. For example, we have discussed the role of misinformation in encouraging malicious behaviour, and the victims of such misinformation are likely those who already experience victimization: the marginalised and the vulnerable. These representational harms exact a social cost not only on the immediate victim, but on the ability and willingness of a society to critically engage with, and question, misinformation and disinformation. Additionally, it is crucial to acknowledge the allocative nature of these harms. Specifically, how do we transform information environments so all have access to reliable, local and trustworthy media? In the case of aforementioned closed networks, how do we integrate balanced news to minimise harm? A case in point may be the politically charged disinformation surrounding non-gender conforming youth in present day America that has resulted in attempted bills to block gender affirming healthcare [156], which has arguably arisen from charged disinformation environments. A further question arises in who, through education or resources, possesses the ability to identify misinformation and disinformation? These harms require multiple mitigating efforts both to protect the marginalised, but also to transform information consumption through education.

Community Harms. TTI-enabled technologies can cause significant harm to communities. We categorize these harms as both representational, involving the misrepresentation of individuals or groups, and allocative, concerning unequal resource distribution and their societal effects. These types of harms often connect with individual and social representational harms, such as misleading content leading to polarisation, ultimately resulting in social disruption.

TTI-enabled misinformation and disinformation can threaten social, political and financial systems. We wish to highlight the potential of TTI technologies to cause political harms. TTI systems can further damage political institutions and compromise the integrity of democratic discourse [29] through election interference [5, 171], enabling misinformation and disinformation actors to operate at larger scales, and creating "evidence" to legitimize fake news or propaganda [107, 112, 171]. In addition we highlight the risks posed wherein TTI systems are used to generate culturally offensive content. As mentioned, TTI systems offer the ability to generate culturally or politically offensive content through "backdoors", or simply because the precautions enacted by developers do not account for all cultures. For example, blasphemous content or images of religious or political figures are potentially deeply harmful to certain societies.

Furthermore, these risks are concerning for communities who are more susceptible to democratic and social instabilities and may have fewer data protections [82, 96, 171]. The detrimental effects of TTI-enabled misinformation and disinformation extend to financial markets and economies, with potential for disruption [5, 100, 120, 130]. TTI systems also has the potential to increase the risk of conflict and state violence [27, 113].

It is important to recognise the long term effects of such harms on broader community climates in relation to the individual harms mentioned previously. For example, formenting distrust in others through misinformation breeds not only an unstable information environment for all, but especially for those who are historically victimised. Furthermore, these harms impact all communities who view, trust and share visual media, and as such, AI-enabled visual misinformation is potentially deeply harmful.

5 MITIGATION STRATEGIES

This section presents a discussion of potential mitigation strategies. Addressing the risks and harms associated with TTI systems often necessitates the integration of multiple mitigation approaches. Local mitigation, at the level of a single system, can possibly address instances of localised harm. However, for broad harms that occur at the level of community or society, multi-disciplinary and multi-stakeholder efforts are required to enact any meaningful mitigation. Such widespread mitigation strategies would necessitate significant changes in the current practices of TTI model and system development and deployment. We categorize mitigation strategies into participatory projects, operational solutions, technical solutions, and socio-legal interventions.

Participatory projects. Participatory projects, which involve stakeholders in the decision-making processes of AI system design, present a potent mitigation strategy [167]. The mechanisms for enabling participatory projects have been previously explored [16, 17, 25, 127]. Participatory projects can involve redefining the principles of generative AI design to be more human-centric and inclusive [78, 169], such as the creation of creative assistive technologies [78, 121, 177]. Data acquisition, a fundamental aspect of these projects, can target underrepresented or misrepresented communities to address disparities [164]. It is crucial to navigate these projects with sensitivity to power dynamics and consent issues [60, 157]. Without careful attention, these disparities may persist in the consultation process, undermining the effectiveness of participation [144].

Certain solutions, such as "opt-out" functions may contribute to addressing copyright infringement, however this relies on artists' being aware of this use of their data, disadvantaging those with limited "tech literacy". It is important to recognise that participatory projects are not an afterthought, but rather as a proactive measure to counter discrimination and exclusion in AI. This entails not just balancing datasets but also focusing on representation and involvement of marginalized identities.

Operational solutions. Operational solutions in the management of TTI models primarily include strategies such as the responsible

release of models and open sourcing [146]. The limited release strategy has been employed with models such as Imagen [135] and Parti [177], and in the staggered release of DALL-E 2 [129]. This approach allows for a certain degree of control, potentially enabling the recall of the technology to prevent malicious uses or other unintended consequences. On the other hand, open sourcing facilitates mass stress testing and probing of the generative models [79]. This can uncover potential vulnerabilities or biases in the models, allowing for improvements and the fostering of transparency. It is worth noting, however, that this approach must also consider and strive to avoid perpetuating issues of worker exploitation [124, 143].

However, both these solutions offer limited remedies if the underlying datasets and models remain wrongfully biased and harmful. Furthermore, these solutions do not fully address downstream impacts, such as job displacement, which may result from the widespread use of TTI-enabled technologies. Therefore, it is important to pair these operational strategies with consistent evaluation and reform of the models, their applications, and metrics for measuring their social impacts.

Technical solutions. To tackle the potential pitfalls of TTI systems, various technical research strategies have been explored. Technical research primarily aims to build more robust, safe, and reliable models. Recent developments include "find and replace" methods [123], semantic steering [28], and filtering techniques [20, 107, 115]. However, these strategies have their limitations. For instance, it has been argued that filtering could exacerbate bias [104, 114] or fail to address it entirely [20]. Furthermore, mitigation via prompt editing has shown to have limited impact due to the complex and embedded nature of biases [15].

A significant body of research focuses on detection of synthetic media as a mitigation strategy. Techniques include the use of GAN architectures [43], blockchain verification [140], fingerprinting [178], and watermarking [165, 177]. Whilst techniques such as watermarking do not directly mitigate harms, rather they identify the authenticity of output images [177], they can deter potential misuse.

The expansion of fair detection capabilities [50, 110, 175] are promising, but, as investigated in Leibowicz et al. [96], as of yet there is no perfect approach to the detection of synthetic media. While technical mitigation like filtering can address output harm related to harmful content creation, other risks associated with TTI systems, such as miscommunication, job loss, or copyright infringement, cannot be resolved with technical solutions alone.

Socio-legal interventions. Mitigating harm in the context of TTI-enabled technologies could significantly benefit from the creation of legal and policy guidelines and regulations. Media literacy and user education have proven to be effective tools in addressing misinformation and manipulation, fostering critical engagement with digital content [4, 27, 153, 171]. Increased corporate culpability could ensure more stringent fact-checking, transparent practices, and adherence to community standards, fostering an environment of accountability [27, 29, 82, 130, 142].

Government legislation and local and global regulation can play a pivotal role [70, 138, 161], with potential measures ranging from defining limits to controlling the dissemination of harmful content [29, 171]. The strategy of limiting monetary rewards from the spread of misinformation can serve as a potent deterrent [4].

In this dynamic and complex landscape, comprehensive and continuous research on the misinformation and disinformation environment becomes critical [137, 180]. Labelling content is often proposed as an intervention; however, it may impact trust in non-labelled content [58] and may have unforeseen negative consequences [137]. Therefore, the nuances of such interventions need careful consideration.

Notwithstanding these interventions, we must acknowledge potential challenges, such as resistance from tech companies due to economic interests, or concerns over infringement on free speech. Therefore, a balance needs to be struck to ensure these interventions are effective and proportionate.

6 OPEN QUESTIONS AND FUTURE RESEARCH

While the conducted review revealed a number of well-acknowledged risks associated with TTI systems, our analysis also highlighted several knowledge gaps. We briefly discuss these gaps in order to highlight open questions and future directions for research.

Output bias. We identified several forms of neglected output bias, including ageism and anti-Asian sentiment, for which we found no targeted mitigation strategies. Ageism, a bias observed in GAN face generators [136], remains a largely unexplored area in recent TTI research. Moreover, studies on racial bias tend to primarily focus on the contrast between Black Africans and White Americans or on distinctions between light and dark skin [15, 37]. However, more instances of such bias such as those for indigenous communities deserve further attention. We also found limited research on the treatment of religious bias, such as in Yu et al. [177]. These output biases can affect both users, who may struggle to generate appropriate images, and downstream parties who are exposed to content that primarily reflects established norms and stereotypes.

Dialect bias. TTI models have been shown to create discrimination beyond outputs. For example, TTI systems may favour white-aligned American English over other dialects [22] or languages. Speakers of a limited number of languages - such as English and Chinese - are able to fully leverage these models. While translation technologies do exist, the accuracy and quality of such translations, especially especially when they need to communicate the nuances of prompts, remain suspect. Research on macaronic prompting demonstrates that DALL-E 2 has some "understanding" of other European languages, however primarily relies on English [105].

Depending on the training data and processes used, users may need to conform linguistically to use TTI systems effectively. This, in turn, reinforces the idea that alternative English dialects are subpar [22].

Pre-release moderation. The use of labour in traditionally pillaged countries[5] to moderate the output of publicly available generative models has been reported [124]. Moderation workers often experience psychological harm, with insufficient support [75, 124] and there is a power imbalance between those developing these models and profiting from their use, and those tasked with pre-release

[5]A term sustainability writer Aja Barber uses to highlight the role that exploitation of resources by the Global North had in these countries' development.

moderation. It is important that companies actively pursue fairer labour practices, so as to reduce harm for moderators.

Job displacement. It is important to recognise the displacement of profit that is enabled by systems such as TTI models [64]. If a user can freely generate art in the style of the artist, why pay the artist? However, we wish to draw attention to the nuances of this displacement, that is, the exacerbation of existing inequalities. The people already marginalised by society will be most impacted by this loss of income. Further, work opportunities in technology companies can be even more heavily skewed against gender and racial minorities than the creative industries[154, 170], meaning profits may be moving from female creatives of colour and into the pockets of white men running tech companies.

Furthermore, we wish to acknowledge the effects of job displacement on image subjects. For example, sex workers cannot currently exert agency over - nor profit - from their images being within training datasets. These images feed the creation of non-consensual pornographic material, often combining a sex worker's body with a celebrity face. We identified a website specifically designed to host models trained on individual sex workers, celebrities and public figures, in order to generate "personalised" porn. Furthermore, if stock imagery, advertisements or modelling photos come to frequently feature generated humans, [99, 109, 166] it is important we assess who is being displaced. For example, do companies use generated imagery to fulfil a diversity target, rather than find humans? We recognise the possibility of disconnect between the appearance of racial, gender or other diversity in stock imagery and who is receiving compensation for their time.

Miscommunication. We identify the problem of miscommunication across cultures and countries using TTI systems. This is especially significant in current TTI technology given the ability to rapidly create images from Western-centric datasets. Solutions to miscommunication require multi-disciplinary anthropological and technical research to understand the translation of forms and appearances into other cultures, and subsequently the building of inclusive datasets. Furthermore, we wish to highlight the problems related to flooding information environments with generated content. This is under-explored in the context of TTI systems, especially given the scale and speed of generation. This risk is not directly related to the types (and harms) of outputs produced, but considers the effects of mass synthetic media production on communities.

Socio-political instability. Many researchers have explored the possible effects of AI on democratic processes and structures [74, 111]. We specifically call attention to the specific risks posed by TTI technologies, many of which are covered within this paper, such as the rise of populism and nationalism supported by false evidence, as has been recognised in present day America [97], assisted by narratives of "alternative facts". We consider the possible use cases of TTI models within these contexts to be an important, and widening, gap in the literature. This topic requires research beyond political considerations only, and would benefit from alignment with deepfake research, some of which has already considered such risks.

Future research directions. Technology companies building TTI (and other generative) models have a responsibility to address many of the risks discussed here, however analysis of TTI models is insufficient without establishing benchmarks against which we can assess safe, ethical and fair performance. Liang et al. [98] present a "living benchmark" for large language models. Similar frameworks need to be developed for TTI models.

Building benchmarks and performance requirements necessitates input from a broad range of stakeholders including government, developers, research communities, image sources, subjects, users and vulnerable parties. The involvement of developers and researchers is especially vital given the high technical skill threshold of understanding generative models, as we have identified through the course of our analysis. The alignment of developmental goals with wider social goals will enable focused mitigation when harms arise, as current development and mitigation choices are left in the hands of technology companies. We also argue for the importance of mitigation strategies outside of technical solutions.

Research producing actionable insights arising from methods such as interviews and case studies can assist in our understanding of the impact of synthetic media. Work such as the interview and diary study of Saltz et al. [137], who argue for a holistic understanding of misinformation environments, is essential. Interviews that engage with identified victims of TTI model harms would greatly assist the development of mitigation strategies; see, for example Ungless et al. [157].

Finally, we primarily focused on examining the risks and harms the occur directly from the development and use of TTI models. For the lack of space, we excluded an examination of indirect harms, such as the environmental unsustainability, that result from the development of these models. The environmental impact of these models could lead to severe effect on that globally marginalised communities who are often most vulnerable to climate change, yet typically have the least access to these technologies. The environmental risks of developing and deploying TTI system is also highlighted in the context of Large Language Models (LLMs) [13]. This subject requires additional research to better understand the origins of the energy consumed in training TTI models, the global distribution of carbon emissions, and the regions most affected by these emissions. Moreover, potential strategies for using renewable energy sources in model training, as a key component of reducing environmental impact, should be explored.

Open questions. The review and analysis conducted within this paper enabled our identification of a number of open questions.

(1) How can we rethink data gathering and output moderation with respect to privacy, ownership and identity?
    For example:
    - How do we implement functional and retroactive data deletion?
    - How might source image creators be protected from "copyright laundering"?
(2) How can we "protect" future datasets from corruption by output images, and benchmark a "good" dataset?
(3) How do we allocate responsibility, and compensate for harm?
(4) How can we best flag and mitigate offensive use?
(5) How do we manage TTI-enabled technologies with respect to non-Western communities, such as avoiding miscommunication?

(6) How can the environmental costs of training and using these models be attenuated?
(7) How do we maintain a "ground truth" in data and visual media?
(8) What are the long-term social costs of generating visual content?

There are a number of regulatory efforts currently addressing data access and the use of AI, with modifications underway to incorporate generative technologies like TTI models. These include the EU AI Act [53, 73, 87, 101], the Algorithmic Accountability Act in the US [108], and China's Deep Synthesis Provisions [80], among others. Multiple ongoing lawsuits could shape future legal perspectives on generative models, including TTI-induced systems. The outcomes of these cases are yet to be determined and will likely impact the regulatory landscape surrounding these AI technologies.[6]

As this paper cannot – within the page limit – adequately provide an exhaustive analysis of such relevant regulatory efforts, we offer five recommendations that we suggest would be useful in guiding generalised regulatory and policy initiatives. Some of these recommendations may already be covered by existing regulatory frameworks. Nonetheless, we believe it is beneficial to outline all of them here.

(1) Establish a multi-stakeholder benchmark for responsible and safe performance of TTI systems, with concern for the risks raised in our typology.
(2) Integrate digital literacy and media literacy into educational programs to help users understand the limitations and potential risks associated with TTI systems.
(3) Clearly communicate to users when their data will be used to train TTI systems and how resulting images might be used, and obtain explicit consent for such use.
(4) Ensure that copyright ownership is clearly identified and respected when generating images from text, and establish clear rules for attribution and usage.
(5) Develop novel, multi-stakeholder safeguards to prevent the creation and dissemination of inappropriate or harmful images, especially images that are discriminatory, violent, and threats to security.

Further, we acknowledge that these recommendations are applicable to other multi-modal generative models. For example, the growing public discourse of apprehension and fear regarding AGI could be somewhat abated by Recommendation 2. We have hoped to highlight, throughout this paper, the importance of amplifying the voices of typically excluded stakeholders. By extension, we recognise the importance of fostering collaboration between the public, policymakers, industry leaders, researchers, and civil society organizations in order to ensure innovative, fair, effective regulatory frameworks.

[6]For reference, here are several ongoing litigation cases: Doe 1 et al v. GitHub et al, Case No. 4:2022cv06823 (N.D. Cal.); Andersen et al v. Stability AI et al, Case No. 3:23-cv-00201 (N.D. Cal.); Getty Images v. Stability AI, Case No. 1:2023cv00135 (D. Del.); Tremblay et al v OpenAI, Case No. 4:23-cv-03223(N.D. Cal.); Getty Images v Sability AI (England), Case IL-2023-000007. We thank Andres Guadamuz for providing information regarding these cases.

7 CONCLUSION

This paper presented a typology of risk associated with TTI-induced technologies, followed by a succinct review of relevant mitigation strategies and a discussion of open questions concerning the development and use of TTI systems. Although we provided some preliminary recommendations, we acknowledge that additional perspectives, expertise, and research are necessary to refine this typology and enhance our understanding of the social implications of TTI systems.

ACKNOWLEDGMENTS

We would like to thank the UKRI Arts and Humanities Research Council (grant AH/X007146/1) for the policy fellowship that supported this work. We thank Shannon Vallor, Ewa Luger, and the members of Ada Lovelace Institute for helpful discussions. We also thank James Stewart, Lilian Edwards, Andres Guadamuz, and three anonymous reviewers whose comments improved our work. Eddie L. Ungless is supported by the UKRI Centre for Doctoral Training in Natural Language Processing, funded by UKRI (Grant EP/S022481/1) and the University of Edinburgh, School of Informatics. Charlotte Bird is supported by the Baillie Gifford PhD Scholarship at the Centre for Technomoral Futures.

A TAXONOMY METHODOLOGY

We conducted our searches utilising the Semantic Scholar API. Semantic Scholar index over 200 million academic papers. To capture relevant papers we selected five seed papers covering biased training data, biased image generation and bias in text-to-image models [8, 15, 20, 37, 136]. To capture papers relevant to misinformation harms, we selected three papers relevant to either deep fakes or synthetic media [152, 171] or diffusion technology and evaluation [176]. Our search returned over 300 papers. 43 of these papers provided substantial and useful discussions of text-to-image technologies. Through extensive manual searches we identified a further 40 papers, most of which were technical papers. Collected papers were then analysed for stakeholders, risks, empirical investigations and open research questions.

Our taxonomy of risks initially adopted an inductive-deductive approach, in that we preempted the existence of three broad categories (discrimination and exclusion, harmful misuse, misinformation) and derived subcategories from analysis of the papers. We then retroactively identified potential "gaps" in the literature, based in part on analogous research into the harms of other technologies, plus identifying key stakeholders that have not been addressed. These gaps are clearly identified in the table.

On the Connection between Game-Theoretic Feature Attributions and Counterfactual Explanations

ABSTRACT

Explainable Artificial Intelligence (XAI) has received widespread interest in recent years, and two of the most popular types of explanations are feature attributions, and counterfactual explanations. These classes of approaches have been largely studied independently and the few attempts at reconciling them have been primarily empirical. This work establishes a clear theoretical connection between game-theoretic feature attributions, focusing on but not limited to SHAP, and counterfactuals explanations. After motivating operative changes to Shapley values based feature attributions and counterfactual explanations, we prove that, under conditions, they are in fact equivalent. We then extend the equivalency result to game-theoretic solution concepts beyond Shapley values. Moreover, through the analysis of the conditions of such equivalence, we shed light on the limitations of naively using counterfactual explanations to provide feature importances. Experiments on three datasets quantitatively show the difference in explanations at every stage of the connection between the two approaches and corroborate the theoretical findings.

1 INTRODUCTION

As complex machine learning models are used extensively in industry settings, including in numerous high-stakes domains such as finance [9, 87] healthcare [51, 95] and autonomous driving [27], explaining the outcomes of such models has become, in some cases, a legal requirement [34], e.g., U.S. Equal Opportunity Act [11] and E.U. General Data Protection Regulation [25]. The use of XAI techniques is increasingly becoming a standard practice at every stage of the lifecycle of a model [10]: during development, to debug the model and increase its performance; during review, to understand the inner working mechanisms of the model; and in production, to monitor its effectiveness [54].

In this context, two different classes of approaches have received a lot of attention from the research community in the last few years: *feature attribution* techniques and *counterfactual explanations*.

Feature attributions aim at distributing the output of the model for a specific input to its features. To accomplish this, they compare the output of the (same) model when a feature is present with that of when the same feature is remove, e.g., [50, 65, 82].

Counterfactual explanations instead aim to answer the question: what would have to change in the input to change the outcome of the model [92]. Towards this goal, desirable properties of the modified input, also known as the "counterfactual", are: proximity, realism, and sparsity with respect to the input [6, 40].

As these two explanation types are used to understand models, an imperative question is: *"How do feature attribution based explanations and counterfactual explanations align with each other?"* Unifying counterfactual explanations with feature attributions techniques is an open question [89]. In fact, while counterfactual explanations aim to provide users with ways to change a model decision [88], it has been argued that they do not fulfil the normative constraints of identifying the principal reasons for a certain outcome, as feature attributions do [69].

Although these two classes of approaches have largely been studied in isolation, there has been some work (primarily empirical) to address a connection between the two:

- When motivating the usefulness of counterfactual explanations, researchers have drawn attention on how a set of counterfactual points can be used to directly generate *feature importances based on how frequently features are modified in counterfactuals* [6, 55, 73].

- On the feature attribution side, a recent line of research has been gaining traction around combining counterfactuals and Shapley values with the goal to generate *feature attributions with a counterfactual flavour by using counterfactuals as background distributions for SHAP explanations* [2, 45].

However, there has been no work that establishes a clear theoretical connection between these approaches, or that theoretically analyses their limitations and assumptions.

This paper bridges the gap between these two lines of research that have been developing in parallel:

- We provide and justify operative changes to the *counterfactual frequency-based feature importance* and *Shapley values-based feature attributions* that are necessary to make an equivalency statement between the two explanations.
- We theoretically prove that — after imposing some conditions on the counterfactuals — the *Shapley values-based feature attribution* and the *counterfactual frequency-based feature importance* are equivalent.
- We discuss what are the effects of such an equivalency, with particular attention to (1) the game-theoretic interpretation of explanations and (2) the limitations of *counterfactual frequency-based feature importance* in providing a detailed account of the importance of the features.
- We generalise the connection with *counterfactual frequency-based feature importance* to a wider range of game-theoretic solution concepts beyond Shapley values.
- We perform an ablation study to show how each of the proposed operative changes (required to establish equivalency) will impact the explanations, and we show how the empirical results are coherent with the theoretical findings.
- Finally, we evaluate these explanations using common metrics from the XAI literature as necessity, sufficiency, plausibility and counterfactual-ability [2, 55], and once again we show how the empirical results are coherent with the theoretical findings.

It is important to note that the theory established in this paper applies to *any* counterfactual explanation, *independently of the technique* used for its generation, and is also valid when considering *multiple* or *diverse* counterfactual explanations for the same query instance [16, 56, 58, 75].

2 BACKGROUND

Consider a classification *model* $f : \mathbb{R}^m \to \mathbb{R}$ and its *decision function* $F : \mathcal{X} \to \{0, 1\}$ with *threshold* $t \in \mathbb{R}$:

$$F(\boldsymbol{x}) = \begin{cases} 1 & \text{if } f(\boldsymbol{x}) > t \\ 0 & \text{otherwise} \end{cases}.$$

We refer to $f(\boldsymbol{x})$ as the model *output* and to $F(\boldsymbol{x})$ as the model *prediction*. Without loss of generality, in the remainder of this paper we assume that $\boldsymbol{x}$ is such that $F(\boldsymbol{x}) = 1$.

2.1 Counterfactual Explanations

A *counterfactual* [38, 92] for a *query instance* $\boldsymbol{x} \in \mathbb{R}^m$ is a point $\boldsymbol{x'} \in \mathbb{R}^m$ such that: (1) $\boldsymbol{x'}$ is *valid*, i.e., $F(\boldsymbol{x'}) \neq F(\boldsymbol{x})$; (2) $\boldsymbol{x'}$ is *close* to $\boldsymbol{x}$ (under some metric); (3) $\boldsymbol{x'}$ is a *plausible* input.

The plausibility requirement has taken different forms. It may involve considerations about proximity to the data manifold [42, 59], proximity to other counterfactuals [47], causality [39], actionability [64, 84], robustness [60, 72, 83] or a combination thereof [16].

Another key aspect for counterfactual explanations is their *sparsity* [20, 46, 66, 72, 75]. Optimising for sparsity forces explanations (1) to ignore features that are not used by the model to make decisions, and (2) in general, to be more concise, as advocated also from a social science perspective [53]. However, criticisms about sparsity have been raised, e.g., in the actionable recourse settings [59, 86], as sparsity could give rise to explanations that are less plausible. Ultimately, this argument reduces to the well-known thread-off between explanations that are "true to the model" (more sparse) or "true to the data" (more plausible) [12, 33].

A plethora of techniques for the generation of counterfactuals exist in the literature using search algorithms [3, 4, 77, 92], optimisation [35] and genetic algorithms [73] among other methods. We refer the reader to recent surveys for more details [28, 37, 40, 78].

Few authors have suggested to generate a feature importance from counterfactual explanations [6, 73]. In particular, Mothilal et al. [55] proposed to use the fraction of counterfactual examples (for the same query instance) that have a modified value as the feature importance. The formal definition follows.

Definition 2.1 (CF-Freq)**.** Given a query instance $\boldsymbol{x}$ and a set of counterfactuals $\mathcal{X'}$ the *counterfactual frequency importance*[1], denoted with $\boldsymbol{\Psi}$, is defined as follows. [55]

$$\boldsymbol{\Psi} = \mathop{\mathbb{E}}_{\boldsymbol{x'} \sim \mathcal{X'}} \left[\mathbb{1}\left[\boldsymbol{x} \neq \boldsymbol{x'} \right] \right]$$

where $\mathbb{1}$ is the binary indicator operator.

The assumption behind this CF-Freq feature importance is that a feature modified more often in counterfactual examples is more important than others which are changed less often. We will show in Section 3.3 how this assumption has an important effect on the explanation that is generated.

2.2 SHAP

The Shapley value is a solution concept in classic game theory used to attribute the payoff to the players in an m-player cooperative game. Given a set of players $\mathcal{F} = \{1, \ldots, m\}$ and the *characteristic function* $v : 2^{\mathcal{F}} \to \mathbb{R}$ of a cooperative game, Shapley values are used to attribute the payoff returned by the characteristics function to the players.

Definition 2.2 (Shapley values)**.** The *Shapley value* for player i is defined as follows. [70]

$$\sum_{S \subseteq \mathcal{F} \setminus \{i\}} w(|S|) \left[v(S \cup \{i\}) - v(S) \right]$$

$$\text{where} \quad w(s) = \frac{1}{m} \binom{m-1}{s}^{-1}$$

In the context of machine learning models the players are the features of the model and several ways have been proposed to simulate

[1] Our term. No specific name beyond the more general "counterfactual feature importance" had been given in the literature.

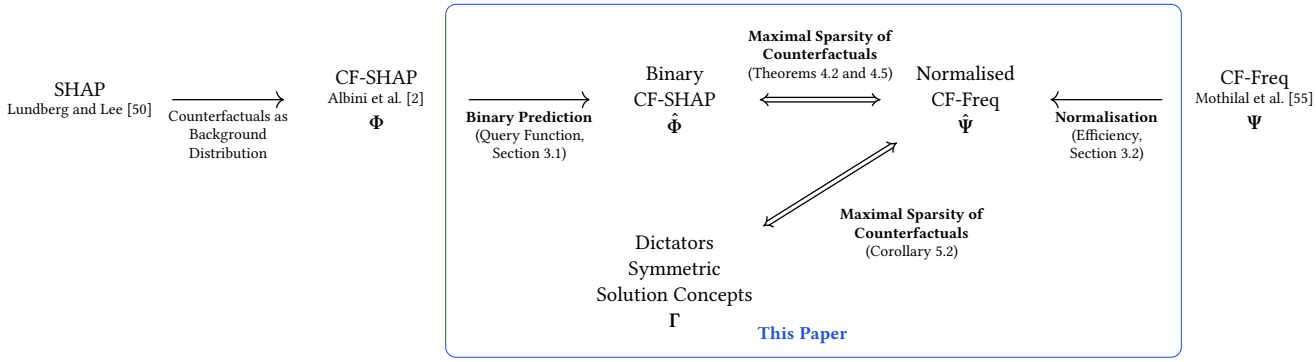

Figure 1: Diagram showing the connection between game-theoretic feature attributions and counterfactual feature importance techniques. Nodes are techniques, edges (→) show the change from one technique to another, and the double-sided edge (⇔) shows the equivalency relationship (with its conditions). See Sections 3 to 5 for more details on the journey.

feature absence in the characteristic function, e.g., retraining the model without such feature [79]. In particular, SHAP [50] simulates the absence by marginalising over the marginal distributions of the features. In practice, the marginals are estimated as a uniform distribution over a finite number of points $\mathcal{X}$ called the *background dataset* — typically the training set (or a sample thereof). The formal definition of SHAP values follows.

Definition 2.3 (SHAP)**.** The *SHAP values* for a query instance $\boldsymbol{x}$ with respect to a background dataset $\mathcal{X}$ are the *Shapley values* of a game with the following characteristics function. [50]

$$v(S) = \mathop{\mathbb{E}}_{\boldsymbol{x}' \sim \mathcal{X}} \left[f\left(\left\langle \boldsymbol{x}_S, \boldsymbol{x}'_{\bar{S}} \right\rangle \right) \right]$$

where $\left\langle \boldsymbol{x}_S, \boldsymbol{x}'_{\bar{S}} \right\rangle$ indicates a model input with feature values $\boldsymbol{x}$ for features in S and $\boldsymbol{x}'$ for features not in S.

The fact that SHAP simulates feature absence with a *background dataset* means that it explains a prediction of an input *in contrast* to a distribution of background points [52]. Starting from this observation Albini et al. [2] proposed Counterfactual SHAP: a variant of SHAP, using counterfactuals rather than the training set as the background dataset. This results in an explanation that can identify which features, if changed, would result in a different model decision better than SHAP.

Definition 2.4 (CF-SHAP)**.** Given a query instance $\boldsymbol{x}$, the *Counterfactual SHAP values*, denoted with $\boldsymbol{\Phi}$, are the *SHAP values* with respect to $\mathcal{X}'$ such that $\mathcal{X}'$ is a set of counterfactuals for $\boldsymbol{x}$. [2]

We recall that the mathematical properties of Shapley values, and by extension SHAP values, of *efficiency*, *null-player* and *strong monotonicity* also apply to CF-SHAP values [2, 50, 70]. In particular, in Section 3.2 we will show the key role that the *efficiency* property plays in drawing the connection with counterfactual explanations.

3 INCONGRUITY OF SHAP AND COUNTERFACTUALS

There are three dimensions along which SHAP and counterfactual explanations differ:

(1) The **query function** used to generate explanations. SHAP queries the model using f to attribute to each of the features a part of the model *output*; counterfactuals instead query the model using F with the aim of finding a point with a different *prediction*.
(2) The **efficiency** of explanations. The game-theoretic property of efficiency that SHAP values requires them to add up to the model output. This is not inherently true for counterfactual explanations.
(3) The **granularity** of the explanation. A single counterfactual does not inherently "rank" features based on their effect on the output of the model: it only shows *which features* to modify to get a different prediction. On the other hand, SHAP *assigns a score* to each feature based on their impact on the model output (even when using a single data point as background).

In this section we present how we propose to carefully change these dimensions in order to draw an equivalency relationship between CF-SHAP and CF-Freq. A summary diagram of this journey is in Figure 1.

We remark, as mentioned in Section 1, that **the theory established in this paper applies to *any* counterfactual explanation generation technique**. We also remark that — while in this section we focus on the connection of counterfactual explanations with Shapley-values based explanation because of its popularity in the XAI field as well as in broader machine learning community — **our theoretical results can be generalised to other game-theoretic solution concepts beyond Shapley values** (see Section 5).

3.1 Query Function

One key difference between SHAP and counterfactual generation engines is that they interact with the model differently. This is due to the different goals of the two explanations: while counterfactual generation algorithms aim to find a point $\boldsymbol{x}'$ with a different *model prediction*, SHAP goal is to attributes the *model output* to the features. This means that, concretely, when generating the explanations, these methods query the model using different functions: SHAP uses f while counterfactual generation engines use F.

In order to bring the two explanations under the same paradigm, we propose to change the characteristics function of CF-SHAP (Definition 2.4) to use F (rather than f). We now formally define the resulting feature attribution.

Definition 3.1 (Bin-CF-SHAP)**.** Given a query instance $\boldsymbol{x}$ the *Binary CF-SHAP values*, denoted with $\hat{\boldsymbol{\Phi}}$, are the *SHAP values* of a game with the following *characteristic function*.

$$v(S) = \mathop{\mathbb{E}}_{\boldsymbol{x}' \sim \mathcal{X}'} \left[F\left(\left\langle \boldsymbol{x}_S, \boldsymbol{x}'_{\mathcal{F}\setminus S} \right\rangle \right) \right]$$

where $\mathcal{X}'$ is a set of counterfactuals for $\boldsymbol{x}$.

We note that CF-SHAP already made use of F, but only to compute the counterfactuals used as background dataset. Instead, with this change to the characteristics function, CF-SHAP becomes completely "insensitive" to changes in model *outputs* (probability) that do not also give rise to a change in the model *prediction* (class).

We remark that changing the *characteristic function* of SHAP implies that the resulting attribution is still a vector of Shapley values and, as such, it retains all the (desirable) game-theoretic properties [81]. In fact, it is not uncommon in the feature attribution literature to query the model using functions other than the model output f. Covert et al. [15] analysed such *query functions* — in their work called *model behaviours*. Nevertheless, we emphasise that querying the model using F, as we propose, is *novel* to the feature attribution literature.

3.2 Efficiency of Explanations

Shapley values satisfy the *efficiency* property[2], an essential part of many of their axiomatisations [70, 94]. In the context of SHAP values, it requires that:

$$\sum_{i \in \mathcal{F}} \phi_i = f(\boldsymbol{x}) - \mathop{\mathbb{E}}_{\boldsymbol{x}' \in \mathcal{X}} \left[f(\boldsymbol{x}') \right].$$

In other words it requires the SHAP values to *truly* be a *feature attribution* distributing the model output among the features. It can be trivially shown that in the case of Bin-CF-SHAP (Definition 3.1) the efficiency property simplifies to the following expression (see Proposition A.6 for more details).

$$\sum_{i \in \mathcal{F}} \hat{\Phi}_i = 1$$

We note that the efficiency property is not satisfied by CF-Freq. Given that CF-Freq has not been defined with the goal to satisfy such game-theoretic property, CF-Freq explanations are not *feature attributions*, i.e., they will not attribute to each of the features part of the model output. They instead sum up to a value that could greater or lesser than 1 depending on the query instance.

In order to ensure that CF-Freq explanations satisfy the efficiency property, we propose to add a **normalisation term**. We call the resulting feature importance Norm-CF-Freq. Concretely, while CF-Freq gives to each of the modified features in a counterfactual an importance of 1, Norm-CF-Freq instead gives them an importance of $1/c$ where c is the number of modified features in the counterfactual. If multiple counterfactuals are given for the same query instance, the (element-wise) average of such feature importance will be computed, similar to CF-Freq.

Definition 3.2 (Norm-CF-Freq)**.** Given a query instance $\boldsymbol{x}$ and a set of counterfactuals $\mathcal{X}'$, the *Normalised CF-Freq* explanation, denoted with $\hat{\boldsymbol{\Psi}}$, is defined as follows.

$$\hat{\boldsymbol{\Psi}} = \mathop{\mathbb{E}}_{\boldsymbol{x}' \in \mathcal{X}'} \left[\frac{\mathbb{1}[\boldsymbol{x} \neq \boldsymbol{x}']}{\|\mathbb{1}[\boldsymbol{x} \neq \boldsymbol{x}']\|} \right]$$

We note that such modifications of a solution concept to enforce the efficiency property is not foreign in the game theory literature, e.g., in the case of normalised Banzhaf values [85].

3.3 Granularity of Explanations

SHAP and counterfactual explanations differ in terms of the granularity of the explanations they can provide.

On one hand, (CF-)SHAP *assigns a score* to each feature based on their impact on the model output for each of the counterfactual example in its background distribution. On the other hand, a counterfactual *does not* inherently provide any "score" describing the effect of each feature on the output of the model: it can only provide a binary assessment on the role of a feature in changing the prediction, i.e., "is the feature modified in the counterfactual or not?".

Consider the following toy example where Bin-CF-SHAP and Norm-CF-Freq explanations, denoted with $\hat{\boldsymbol{\Phi}}$ and $\hat{\boldsymbol{\Psi}}$ respectively, are generated using a single counterfactual.

$$\boldsymbol{x} = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 \end{pmatrix}^T$$
$$\boldsymbol{x}' = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}^T$$
$$F(\boldsymbol{x}) = \mathbb{1}\left[x_1 \wedge \left(x_2 \vee (x_3 \wedge x_4) \right) \right]$$
$$\hat{\boldsymbol{\Phi}} = \begin{pmatrix} 7/12 & 3/12 & 1/12 & 1/12 & 0 & 0 \end{pmatrix}^T$$
$$\hat{\boldsymbol{\Psi}} = \begin{pmatrix} 1/5 & 1/5 & 1/5 & 1/5 & 1/5 & 0 \end{pmatrix}^T$$

We note how **Norm-CF-Freq gives equal importance to all the features** while **Bin-CF-SHAP is able to differentiate** the features in the counterfactual that are:

(1) *necessary* for its validity (x_1): if the value of one of such features is replaced back with that in the query instance, the counterfactual is not valid anymore;
(2) only part of a *sufficient* set (x_2, x_3 and x_4) for its validity: replacing the value of a sufficient feature with that in the query instance *alone* will not invalidate the counterfactual, but it will when this is done in combination with the replacement of other features' values;
(3) *spurious* (x_5): replacing their values back to that in the query instance will not invalidate the counterfactual under any circumstance. These could be features that have been perturbed solely to increase the plausibility of the counterfactual despite having no impact on the model prediction or even not being used by the model at all.

Bin-CF-SHAP gives the largest attribution to features falling into (A), smaller attributions to those falling into (B) and zero attribution to those falling into (C).

That the inability of CF-Freq explanations to differentiate between *necessary*, *sufficient* and *spurious* features represents a key

[2]The game-theoretic property of *efficiency* [70] is sometimes referred to as *additivity* [50] in the XAI literature.

limitation with respect to Shapley-values based feature attributions. This limitation will be made even more evident by the empirical results presented in Section 6.

4 CONNECTING SHAP AND COUNTERFACTUALS

In Section 3 we discussed what are the differences that exists between feature attributions and counterfactual explanations. In particular, this discussion resulted in two explanation techniques:

- on the feature attributions side, Bin-CF-SHAP (Definition 3.1), a variant of CF-SHAP that queries the model using only the (binary) *decision function*;
- on the counterfactuals side, Norm-CF-Freq (Definition 3.2), an *efficient* variant of CF-Freq.

In this section we will present the main results of this paper, proving that — after imposing some conditions on the counterfactuals — Bin-CF-SHAP and Norm-CF-Freq are, in fact, the same explanation.

We recall from Section 3.3 that Bin-CF-SHAP explanations provide a more fine grained account of the contributions of the features in counterfactuals to the output of the model than Norm-CF-Freq explanations. Therefore, towards finding an equivalency relationship between the two approaches, we must add additional constraints on counterfactuals such that Bin-CF-SHAP gives to all features in the counterfactual an equal attribution, similarly to what Norm-CF-Freq does.

We pose that this can be done by enforcing an additional property on counterfactuals called ***maximal sparsity***. Maximal sparsity requires a counterfactual to have the least number of changes (with respect to the query instance) for it to be valid or, in other words, it requires all the features in the counterfactual to be *necessary*.

Definition 4.1 (Maximal Sparsity)**.** A *counterfactual* $\boldsymbol{x'}$ for a *query instance* $\boldsymbol{x}$ is *maximally sparse* iff:

$$F(\boldsymbol{x'}) \neq F\left(\left\langle \boldsymbol{x}_S, \boldsymbol{x'}_{\bar{S}} \right\rangle\right) \quad \forall S \subseteq C : S \neq \emptyset$$

where C is the set of features in $\boldsymbol{x'}$ that are different from those in $\boldsymbol{x}$, i.e., $C = \{i \in \mathcal{F} : x_i \neq x'_i\}$.

Note that it is *always* possible to generate a maximally sparse counterfactual from *any* counterfactual (*independently* of the counterfactual generation technique) by selecting a (proper or improper) subset of the features in the counterfactual. We denote the set of such subsets of $\mathcal{F}$ with $\mathrm{MS}(\mathcal{F})$. For example, in the running example, 2 such subsets exist:

$$\mathrm{MS}(\mathcal{F}) = \{\{1, 2\}, \{1, 3, 4\}\}.$$

We now prove that maximal sparsity is indeed sufficient for the equivalency of Bin-CF-SHAP and Norm-CF-Freq.

Theorem 4.2. *Given a query instance $\boldsymbol{x}$, a set of counterfactuals $\mathcal{X}'$, the Bin-CF-SHAP values $\hat{\boldsymbol{\Phi}}$ and the Norm-CF-Freq explanation $\hat{\boldsymbol{\Psi}}$ with respect to $\mathcal{X}'$:*

$$\mathcal{X}' \textit{ are maximally sparse} \quad \Rightarrow \quad \hat{\boldsymbol{\Phi}} = \hat{\boldsymbol{\Psi}}.$$

Proof. See Appendix A. □

Maximal sparsity allows us to draw an equivalency relationship between the two explanation types. However, while maximal sparsity of counterfactuals is easy to define, it is, nonetheless, a strong requirement. An obvious question that arises is if there exists a weaker requirement allowing to draw the same equivalency relationship. We now introduce few notions that allows us to describe a weaker, yet more complex requirement on counterfactuals, that allows us to draw the same equivalency relationship.

Definition 4.3 (Weak Maximal Sparsity)**.** A *counterfactual* $\boldsymbol{x'}$ for a *query instance* $\boldsymbol{x}$ is *weakly maximally sparse* iff $\forall i \in C$:

$$\exists S \subseteq C \setminus \{i\} \;:\; F\left(\left\langle \boldsymbol{x}_{S\cup\{i\}}, \boldsymbol{x'}_{\bar{S}\setminus\{i\}} \right\rangle\right) \neq F(\boldsymbol{x'})$$
$$\text{where } C = \{i \in \mathcal{F} : x_i \neq x'_i\}.$$

Intuitively, *weak maximal sparsity* requires that counterfactuals do not contain spurious features. We note that it is *always* possible to generate a weakly maximally sparse counterfactual from any counterfactual (*independently* of the counterfactual generation technique) by selecting a (proper or improper) subset of the features in the counterfactual. We denote the set of such subsets with $\mathrm{WMS}(\mathcal{F})$. For the running example, three such subsets exist:

$$\mathrm{WMS}(\mathcal{F}) = \{\{1, 2\}, \{1, 3, 4\}, \{1, 2, 3, 4\}\}.$$

Definition 4.4 (Equal Maximal Sparsity)**.** A *counterfactual* $\boldsymbol{x'}$ for a *query instance* $\boldsymbol{x}$ is *equally maximally sparse* iff:

$$|C| = 1 \quad \vee \quad \forall i, j \in C, \sum_{\substack{S \in \mathrm{WMS}(\mathcal{F}) \\ i \in S}} \frac{\xi(S)}{|S|} = \sum_{\substack{S \in \mathrm{WMS}(\mathcal{F}) \\ j \in S}} \frac{\xi(S)}{|S|}$$

where $C = \{i \in \mathcal{F} : x_i \neq x'_i\}$ and $\xi : 2^{\mathcal{F}} \to \mathbb{R}$ is:

$$\xi(S) = \begin{cases} 1 & \text{if } S \in \mathrm{MS}(\mathcal{F}) \\ 1 - \sum_{T \in \mathrm{WMS}(S)} \delta_T & \text{otherwise} \end{cases}$$

We note that equal maximally sparsity is not a simple condition to enforce on counterfactuals. In fact, requiring a counterfactual to be equal maximally sparse is, in practice, equivalent to requiring that the Bin-CF-SHAP values with respect to such single counterfactual must all be equal.

Theorem 4.5. *Given a query instance $\boldsymbol{x}$, and a counterfactual $\boldsymbol{x'}$, the Bin-CF-SHAP values $\hat{\boldsymbol{\Phi}}$ and the Norm-CF-Freq explanation $\hat{\boldsymbol{\Psi}}$ with respect to $\boldsymbol{x'}$:*

$$\boldsymbol{x'} \textit{ is equally maximally sparse} \quad \Leftrightarrow \quad \hat{\boldsymbol{\Phi}} = \hat{\boldsymbol{\Psi}}.$$

Proof. See Appendix A. □

Since it can be proved that maximal sparsity implies equal maximal sparsity (see Proposition A.4), then Corollary Corollary 4.6 follows from Theorems Theorems 4.2 and 4.5 (see Appendix A for more details).

Corollary 4.6. *Given a query instance $\boldsymbol{x}$, a set of counterfactuals $\mathcal{X}'$, the Bin-CF-SHAP values $\hat{\boldsymbol{\Phi}}$ and the Norm-CF-Freq explanation $\hat{\boldsymbol{\Psi}}$ with respect to $\mathcal{X}'$:*

$$\mathcal{X}' \textit{ are equally maximally sparse} \quad \Rightarrow \quad \hat{\boldsymbol{\Phi}} = \hat{\boldsymbol{\Psi}}.$$

We note that, by enforcing counterfactuals to be sparse and potentially less plausible, we follow the "true to the model" paradigm [12, 33] discussed in Section 2, wherein the goal is to understand the model reasoning and not the causal relationship between the features.

5 CONNECTING OTHER GAME-THEORETIC SOLUTION CONCEPTS AND COUNTERFACTUALS

In this section, we discuss the effects of querying the model with the binary decision function and using maximally sparse counterfactuals on game-theoretic interpretations of the explanation — as proposed in Section 3 — and how this allows us to extend Section 4 equivalency results to more game-theoretic solution concepts beyond Shapley values.

In particular, we will focus our analysis on the single-reference games in which the explanation game of SHAP can be decomposed [52]. The characteristic function of such games for Bin-CF-SHAP is defined as follows:

$$v_{\boldsymbol{x}'}(S) = F\left(\left\langle \boldsymbol{x}_S, \boldsymbol{x}'_{\mathcal{F}\setminus S}\right\rangle\right) \tag{$\triangle$}$$

Voting games. The use of the *binary* decision function F rather than the *continuous* function f means that the resulting single-reference games are more specifically *voting games*: games where the characteristics functiond are *voting rules* describing the winning and losing coalitions of players (features).

$$v : 2^{\mathcal{F}} \to \{0\ (\textsc{lose}),\ 1\ (\textsc{win})\}\,.$$

The winning coalitions of features are those preserving the query instance prediction $F(\boldsymbol{x}) = 1$, while the losing ones will give rise to a counterfactual.

The resulting Bin-CF-SHAP values are, more specifically then, the average Shapley-Shubik power index [71] over single-reference games. Concretely, the Shapley-Shubik power index measures the fraction of possible voting *sequences* in which a player (feature) casts the deciding vote, that is, the vote that first guarantees passage (same prediction) or failure (counterfactual).

Unanimity Games. The enforcement of maximal sparsity on counterfactuals in the single-reference voting games of Bin-CF-SHAP means that the counterfactual is valid iff all the modified features are present. Such games, where a group of players (features) have veto power and together they exert common dictatorship, are known more specifically as *unanimity games*.

Generalisation to solution concepts beyond Shapley values. Although the paper has so far focused on Shapley values because of its popularity in the XAI and machine learning communities, many other game-theoretic solution concepts exist. The result of Theorem 4.2 can be extended to any solution concept that equally distributes payoffs to the common dictators of *unanimity games*. We now formally define this property of a solution concept that we call *dictators-symmetry*.

Definition 5.1. A solution concept $\boldsymbol{\Gamma}$ is *dictators-symmetric* if for any *unanimity game* with common dictators C it holds that:

- $\Gamma_i = 1/|C|\,,\ \forall i \in C$, and
- $\Gamma_i = 0\,,\ \forall i \in \bar{C}$.

We now formally prove with Corollary 5.2 *maximal sparsity* of the counterfactuals is indeed a sufficient condition for the equivalency of Norm-CF-Freq and any explanation that is a *dictators-symmetric* solution concept.

Corollary 5.2. *Given a query instance $\boldsymbol{x}$, a set of counterfactuals $\mathcal{X}'$ and the Norm-CF-Freq explanation $\hat{\boldsymbol{\Psi}}$ with respect to $\mathcal{X}'$. If $\boldsymbol{\Gamma}$ is the average of* dictators-symmetric *solution concepts of the single-reference games then:*

$$\mathcal{X}' \textit{ are } \textsc{maximally sparse} \quad \Rightarrow \quad \boldsymbol{\Gamma} = \hat{\boldsymbol{\Psi}}.$$

Proof. This trivially follows from Theorem 4.2. See Appendix A for more details. □

Solution concepts to which Corollary 5.2 applies include:

- the *Banzhaf value*, from the homonym Banzhaf power index [5, 14, 61], measuring the fraction of the possible voting *combinations* in which a player casts the deciding vote;
- the *Deegan-Packel power index* [17, 18] that equally divides the power to the members of minimum winning coalitions;
- the *Holler-Packel public good index* [31, 32] measuring the fraction of minimum winning coalitions of which a player is a part.

This generalisation of our results to more game-theoretic solution concepts is especially *important* in light of the criticisms raised to Shapley values in game theory [57] as well as in XAI [44]. In particular, the use of alternative solution concepts has been recently investigated, e.g., Banzhaf values [15, 36] and it has been identified as a possible way to better align explanations with their applications' goals, e.g., feature selection [23] or time series [90].

6 EXPERIMENTS

In order to understand the effects of the changes to connect SHAP and counterfactuals presented in this paper, we run 2 sets of experiments:

(1) We run an ablation study. We measure the **explanations difference** (for every step in Figure 1).
(2) We compute some popular **explanations metrics** that have been used to evaluate feature importance explanations in the literature.

We run experiments on three publicly available datasets widely used in the XAI literature: **HELOC** [21] (Home Equity Line Of Credit), **Lending Club** [48] and **Adult** [7] (1994 U.S. Census Income). For each dataset, we trained a (non-linear) *XGBoost* model [13]. We chose to train booting ensemble of tree-based models because, in the context of classification for tabular data, they are deemed as state-of-the-art in terms of performance [74]. However, we emphasise that the theoretical results of this paper are model agnostic, i.e. they do *not* depend on the type of model. We refer to Appendix B for more details on the experimental setup.

We used TreeSHAP [49], KernelSHAP [50] and CFSHAP [2] and an in-house implementation of CF-Freq to generate the feature importance explanations. Similarly to Albini et al. [2], we used K-NN with $K = 100$ and the Manhattan distance over the quantile space as distance metric to generate counterfactuals.

We remark that the results presented in this paper (and in particular those in Sections 4 and 5) hold ***independently* of the algorithm**

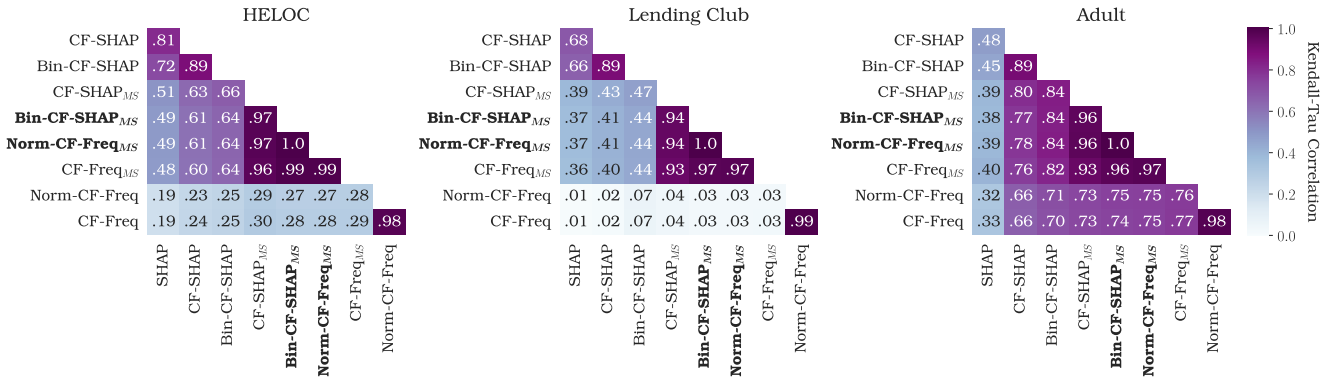

Figure 2: Average pair-wise Kendall-Tau Rank Correlation between explanations for different datasets. (MS) Indicates explanations with maximally sparse counterfactuals.

that is used to generate (maximally sparse) counterfactuals. In fact, counterfactuals are only used to generate the background dataset for CF-Freq and SHAP-based feature importance.

As pointed out in Albini et al. [2], the choice of K-NN as the technique for the generation of counterfactuals in the context of the experiments allows to analyse the resulting feature importance explanations performance separating it from the performance of the underlying counterfactual generation engine used to generate its background dataset.

To generate *maximally sparse* counterfactuals we devised an exhaustive search algorithm that generates the closest maximally sparse counterfactual for each (non-maximally sparse) counterfactual passed to the feature importance explanations. We refer to Appendix B.4 for more details about the algorithm.

Explanations Difference. In order to draw a connection between CF-SHAP and CF-Freq, in Sections 3 and 4, we presented three changes to the existing explanations:

(1) querying the model using F;
(2) normalising CF-Freq explanation;
(3) using maximally sparse counterfactuals.

To understand the extent to which such changes impacted the explanations, we compute the pairwise Kendall-Tau rank correlation between the explanations for 1000 examples.

Results - Figure 2 show the results. We note that:

(A) While the normalisation only slightly effects explanations (τ = 0.97-0.99), imposing maximal sparsity on the counterfactuals always has a significant effect on the resulting explanations (τ = 0.03-0.84). This is consistent with results in the literature showing the large effects of the baseline on the explanations [80].

(B) The use of maximally sparse counterfactuals causes greater changes in the explanations in the frequentist family (τ = 0.03-0.77) compared to SHAP-based explanations (0.43-0.84). This is coherent with what we presented in Section 3.3: CF-SHAP already distinguishes between necessary, sufficient and spurious features but CF-Freq does not. Hence, the use of maximally sparse counterfactuals will have a greater effect on CF-Freq.

(C) Querying the model with the binary prediction gives rise to more similar explanations when maximally sparse counterfactuals are used (τ = 0.94-0.97) than otherwise (τ = 0.89). This is expected: when using maximally sparse counterfactuals, the removal of any feature will invalidate the counterfactual, and therefore greatly reduce the model output (at least below the decision threshold). Such difference in output will tend to be closer (compared to using non-maximally sparse counterfactuals) to that obtained when using the binary prediction (i.e., always 1).

Explanations Metrics. To understand how the changes proposed in Sections 3 and 4 impact CF-Freq and CF-SHAP explanations we evaluated 4 metrics: [2, 55].

- *necessity* which measures the percentage of valid counterfactuals that can be generated when allowing only the top-k features (according to a feature importance) to be modified;
- *sufficiency* which measures the percentage of *invalid* counterfactuals that can be generated when allowing all the features but the top-k to be modified;
- *counterfactual-ability* improvement which measures how often the proximity of counterfactuals induced by the explanations is better than that of SHAP. Counterfactuals are induced from the explanations by changing the top-k features in the most promising direction (according to counterfactuals); The proximity is measured in terms of *total quantile shift* [84];
- *plausibility* improvement which measures how often the plausibility of the same induced counterfactuals is better than that of SHAP. Concretely, the plausibility is measured as the density of the region in which they lie based on the distance from their 5 nearest neighbours.

According to the framework of actual causality [29, 63] the assumption underpinning the definition of necessity and sufficiency is that the model output should change more when features with higher importance are modified (necessity) and it should change less when they are kept at their current value (sufficiency). The assumption behind counterfactual-ability and plausibility [2] is

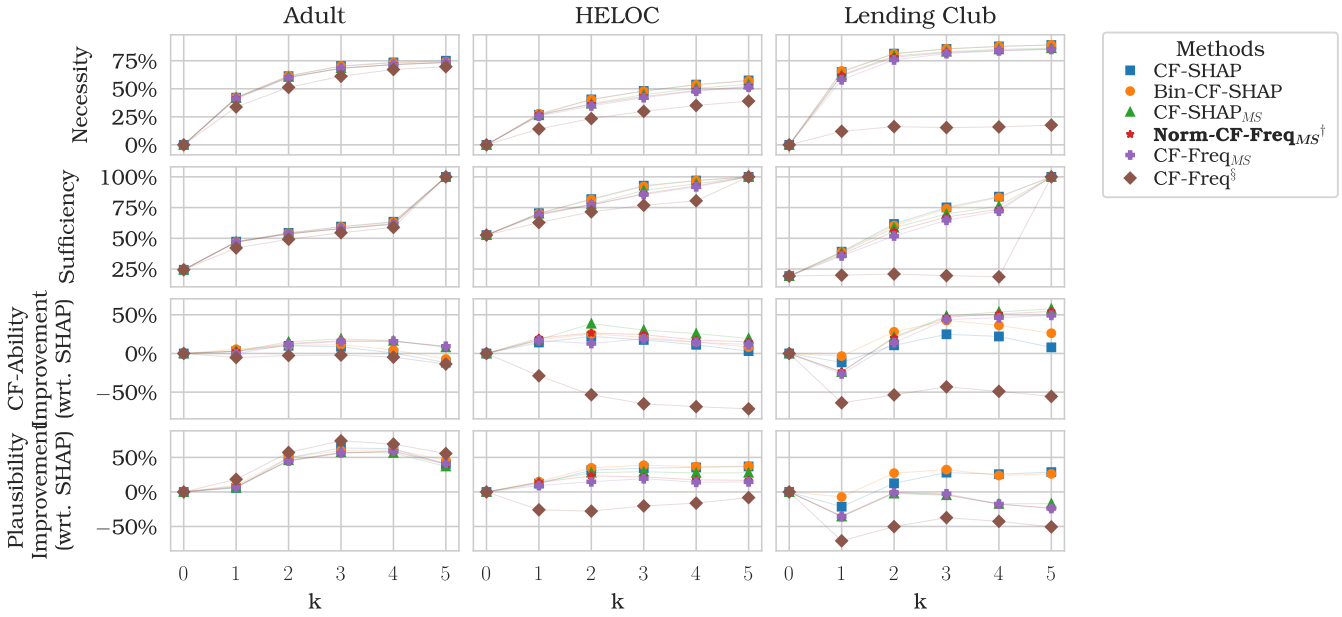

Figure 3: Metrics of explanations for different dataset (the higher the better). (MS) Indicates explanations with maximally sparse counterfactuals; (†) we report results only for Norm-CF-Freq$_{MS}$ and not Bin-CF-SHAP$_{MS}$ as they are equivalent (Theorem 4.2); (§) we omit the results for Norm-CF-Freq as they are similar to those of CF-Freq (KS-test $D_{max} < 5\%$).

that an explanation should suggest a way to plausibly change the decision with minimal cost (higher counterfactual-ability).

Results - Figure 3 shows the results. We note that:

- **(A)** SHAP-based techniques do not have considerably different performance along any of the metrics. The most important difference among the explanations of this class is in terms of plausibility in the Lending Club dataset. This is not surprising: as discussed in Sections 2 and 4 and in [72], the enforcement of sparsity may give rise to less plausible explanations;
- **(B)** frequentist-based techniques, on the contrary, have substantially different performance. This is consistent with what we discussed in Sections 3.3 and 4: CF-Freq explanations are unable to discriminate between features in a counterfactual that are spurious, necessary for its validity or just part of a sufficient set to make it valid.

We emphasise that, if the goal of the explanation is to determine what features are important to change the prediction such that they are "true to the model" [12], these results further warn against using "frequentist" feature importance approaches (as CF-Freq) without a sparsity constraint as they cannot differentiate between modified features in the counterfactuals that are *really used by the model*, and those that are not, as we highlighted in Section 3.3.

7 CONCLUSION AND FUTURE WORK

In this paper, we connected game theory-based feature attributions including (but not limited to) SHAP values and "frequentist" approaches to counterfactual feature importance using the fraction of counterfactuals that have a modified value.

In particular, we proved that by applying specific operations, they can be shown to be equivalent. We discussed the effect of such an equivalency theoretically, and then showed empirically the impact on explanations. This analysis highlighted the limitations of "frequentist" approaches as feature importance technique and the important role of sparsity in counterfactual explanations.

This paper provides avenues that could spur future research.

Firstly, it would be interesting to analyse the connection between power indices using only minimum winning coalitions, e.g., Deegan-Packel's [17] and Holler-Packel's [31], and the property of maximal and weak maximal sparsity of counterfactuals proposed in this paper. More broadly, analysing if and how the game-theoretical interpretation of SHAP-based explanations aligns with the goal of the explanations would be of great interest.

Secondly, investigating how the results of this paper reflect on feature importance and counterfactual explanations that adopt a causal view of the world represents a future direction of great interest, e.g., [1, 22, 24, 33, 67, 91].

Lastly, while in this paper we limited our analysis of the connection between feature attributions and counterfactuals to the resulting feature importance explanations, it would be interesting to establish a more general connection between these two classes of approaches (e.g., between the SHAP values and distances between inputs and counterfactuals), as well as techniques falling under other XAI paradigms.

A THEORETICAL RESULTS

In this appendix we report additional theoretical results together with the proofs of the results in Section 4 that have been omitted from the main text for space and clarity of exposition reasons.

A.1 Omitted Proofs

We start by formally proving Theorems 4.2 and 4.5. We note that in the following proofs we will make use Shapley values axioms and properties as efficiency, null-player and symmetry. This are basic properties in the game theory literature, we refer the reader to Peters's game theory book [62, Chapter 17] or Shapley's seminal work [70] for their formal definitions.

Theorem A.1. *Given a query instance $\boldsymbol{x}$, a set of counterfactuals $\mathcal{X}'$, the* Bin-CF-SHAP *values $\hat{\boldsymbol{\Phi}}$ and the* Norm-CF-Freq *explanation $\hat{\boldsymbol{\Psi}}$ with respect to $\mathcal{X}'$:*

$$\mathcal{X}' \textit{ are } \textsc{maximally sparse} \quad \Rightarrow \quad \hat{\boldsymbol{\Phi}} = \hat{\boldsymbol{\Psi}}.$$

Proof. Let's start by recalling that SHAP values calculation can be decompos ed in the calculation of the SHAP values of single-reference games [52]:

$$\hat{\Phi}_i = \mathop{\mathbb{E}}_{\boldsymbol{x}' \sim \mathcal{X}'} \left[\hat{\Phi}_i^{\boldsymbol{x}'} \right] \quad \text{where} \quad \hat{\Phi}_i^{\boldsymbol{x}'} = \sum_{S \subseteq \mathcal{F} \setminus \{i\}} w(S) \left[v_{\boldsymbol{x}'}(S \cup \{i\}) - v_{\boldsymbol{x}'}(S) \right] \;,\; v_{\boldsymbol{x}'}(S) = F\left(\left\langle \boldsymbol{x}_S, \boldsymbol{x}'_{\mathcal{F} \setminus S} \right\rangle \right)$$

We note that proving the thesis is equivalent to proving the following.

$$\hat{\Phi}_i^{\boldsymbol{x}'} = \hat{\boldsymbol{\Psi}}_i^{\boldsymbol{x}'} \quad \forall \boldsymbol{x}' \in \mathcal{X}' \,, \forall i \in \mathcal{F} \tag{$\triangle$}$$

For each counterfactuals $\boldsymbol{x}' \in \mathcal{X}'$, let's now consider the set of features that have been modified C and its complement $\bar{C}$:

$$C = \left\{ i \in \mathcal{F} : x'_i \neq x_i \right\} \qquad \bar{C} = \left\{ i \in \mathcal{F} : x'_i = x_i \right\}$$

Proving $\triangle$ is then equivalent to prove that $\forall \boldsymbol{x}' \in \mathcal{X}'$:

(1) $\forall i \in \bar{C}\,,\ \hat{\Phi}_i^{\boldsymbol{x}'} = \hat{\boldsymbol{\Psi}}_i^{\boldsymbol{x}'} = 0$;
(2) $\forall i \in C\,,\ \hat{\Phi}_i^{\boldsymbol{x}'} = \hat{\boldsymbol{\Psi}}_i^{\boldsymbol{x}'} = 1$ if $|C| = 1$.
(3) $\forall i \in C\,,\ \hat{\Phi}_i^{\boldsymbol{x}'} = \hat{\boldsymbol{\Psi}}_i^{\boldsymbol{x}'} = 1/|C|$ if $|C| > 1$.

Let's start by first proving (1). It is trivial to observe that for all the features in $\bar{C}$ removing them has no effect because their value is equal in both the query instance and the counterfactual:

$$\forall i \in \bar{C},\ \forall S \subseteq \mathcal{F} \setminus \{i\}\ ,\ v_{\boldsymbol{x}'}\left(S \cup \{i\}\right) - v_{\boldsymbol{x}'}\left(S\right) = 0.$$

Coincidentally, this is the definition of a *null-player* (feature) therefore, by the null-player property of Shapley values, it follows that $\boldsymbol{\Phi}_i^{\boldsymbol{x}'} = 0, \forall i \in \bar{C}$. This proves (1).

In order to prove (2), let us now recall that by the *efficiency* axiom of Shapley values, the attributions of the features must add up to the prediction of the model. Therefore — since the features in C are the only one with non-zero attribution — it follows that:

$$\sum_{i \in C} \hat{\Phi}_i^{\boldsymbol{x}'} = 1\,. \tag{A}$$

If $|C| = 1$ then (2) trivially follows from (A).

We will now prove (3). Let us now recall that, since $\boldsymbol{x}'$ is maximally sparse by hypothesis, removing any of the features from the counterfactual will make it invalid:

$$\forall i \in C,\ \forall S \subset \mathcal{F} \setminus C \quad v\big(S \cup C\big) = 1 \quad \wedge \quad v\big(S \cup (C \setminus \{i\})\big) = 0\,.$$

This implies that all the features in C will have the same effect on the model prediction if removed:

$$\forall i, j \in C : i \neq j\,,\ x'_i \neq \boldsymbol{x}_i\,,\ x'_j \neq \boldsymbol{x}_j\,, \quad \forall S \subseteq \mathcal{F} \setminus \{i, j\}\ ,\ v(S \cup \{i\}) = v(S \cup \{j\})\,.$$

This is the definition of symmetric players (features) therefore, by the *symmetry* axiom of Shapley values, it follows that:

$$\hat{\Phi}_i^{\boldsymbol{x}'} = \hat{\Phi}_j^{\boldsymbol{x}'}, \forall i, j \in C\,. \tag{B}$$

Then (3) follows from (B) and (A).

The thesis then follows. □

Theorem A.2. *Given a query instance $\boldsymbol{x}$, and a counterfactual $\boldsymbol{x}'$, the* Bin-CF-SHAP *values $\hat{\boldsymbol{\Phi}}$ and the* Norm-CF-Freq *explanation $\hat{\boldsymbol{\Psi}}$ with respect to $\boldsymbol{x}'$:*

$$\boldsymbol{x}' \text{ is EQUALLY MAXIMALLY SPARSE} \quad \Leftrightarrow \quad \hat{\boldsymbol{\Phi}} = \hat{\boldsymbol{\Psi}}.$$

Proof. We note that proving the thesis is equivalent to proving the following.

$$\hat{\Phi}_i = \hat{\Psi}_i \quad \forall i \in \mathcal{F} \tag{$\triangle$}$$

Let's now consider the set of features that have been modified C and its complement $\bar{C}$:

$$C = \left\{i \in \mathcal{F} : x'_i \neq x_i\right\} \qquad \bar{C} = \left\{i \in \mathcal{F} : x'_i = x_i\right\}$$

Proving $\triangle$ is then equivalent to prove that $\forall \boldsymbol{x}' \in \mathcal{X}'$:

(1) $\forall i \in \bar{C}\,,\ \hat{\Phi}_i^{\boldsymbol{x}'} = \hat{\Psi}_i^{\boldsymbol{x}'} = 0$;
(2) $\forall i \in C\,,\ \hat{\Phi}_i^{\boldsymbol{x}'} = \hat{\Psi}_i^{\boldsymbol{x}'} = 1$ if $|C| = 1$.
(3) $\forall i \in C\,,\ \hat{\Phi}_i^{\boldsymbol{x}'} = \hat{\Psi}_i^{\boldsymbol{x}'} = 1/|C|$ if $|C| > 1$.

We will now proceed by first proving (1).

It is trivial to observe that for all the features in $\bar{C}$ removing them has no effect because their value is equal in both the query instance and the counterfactual:

$$\forall i \in \bar{C},\ \forall S \subseteq \mathcal{F} \setminus \{i\}\,,\ \ v_{\boldsymbol{x}'}\left(S \cup \{i\}\right) - v_{\boldsymbol{x}'}\left(S\right) = 0.$$

Coincidentally, this is the definition of a *null-player* (feature) therefore, by the null-player property of Shapley values, it follows that $\boldsymbol{\Phi}_i^{\boldsymbol{x}'} = 0, \forall i \in \bar{C}$. This proves (1).

In order to prove (2), let us now recall that by the *efficiency* axiom of Shapley values, the attributions of the features must add up to the prediction of the model. Therefore — since the features in C are the only one with non-zero attribution — it follows that:

$$\sum_{i \in C} \hat{\Phi}_i^{\boldsymbol{x}'} = 1\,. \tag{A}$$

then (2) trivially follows from (A).

In order to prove (3), let us now recall that Shapley values can be computed using the Harsanyi dividends [30]:

$$\hat{\Phi}_i = \sum_{\substack{S \in 2^{\mathcal{F}} \setminus \emptyset \\ i \in S}} \frac{\Delta_S}{|S|} \tag{$\bigcirc$}$$

where Δ_S, called *Harsanyi dividends*, are defined recursively as follows:

$$\Delta_S = \begin{cases} v(S) & \text{if } |S| = 1 \\ v(S) - \sum_{T \subset S} \Delta_T & \text{otherwise} \end{cases}. \tag{$\otimes$}$$

Let us also recall that equal maximal sparsity requires all the counterfactuals $\boldsymbol{x}'$ to be such that:

$$|C| = 1 \quad \vee \quad \forall i, j \in C, \sum_{\substack{S \in \text{WMS}(\mathcal{F}) \\ i \in S}} \frac{\xi(S)}{|S|} = \sum_{\substack{S \in \text{WMS}(\mathcal{F}) \\ j \in S}} \frac{\xi(S)}{|S|}$$

where $\xi : 2^{\mathcal{F}} \to \mathbb{R}$ is defined as follows:

$$\xi(S) = \begin{cases} 1 & \text{if } S \in \text{MS}(\mathcal{F}) \\ 1 - \sum_{T \in \text{WMS}(S)} \delta_T & \text{otherwise} \end{cases}$$

and where we recall that:

- $\text{MS}(S)$ is the set of all the (proper or improper) subsets of S that give rise to a maximally sparse counterfactual:

$$\text{MS}(S) = \{T \subseteq S : \left\langle \boldsymbol{x}_{\bar{T}}, \boldsymbol{x}'_T \right\rangle \text{ is maximally sparse}\}\,;$$

- $\text{WMS}(S)$ is the set of all the (proper or improper) subsets of S that give rise to a weak maximally sparse counterfactual:

$$\text{WMS}(S) = \{T \subseteq S : \left\langle \boldsymbol{x}_{\bar{T}}, \boldsymbol{x}'_T \right\rangle \text{ is weakly maximally sparse}\}\,.$$

We note that if we prove that:

C.I $\Delta_S = 1 \quad \forall S \in \text{MS}(\mathcal{F})$
C.II $\Delta_S = 0 \quad \forall S \in \mathcal{F} \setminus \text{WMS}(\mathcal{F})$

then, by Definition 4.4 and the definition of Shapley values with the Harsanyi dividends (◯), (3) follows and, in turn, the thesis follows.

Let's then prove (C.I). If $S \in \text{MS}(\mathcal{F})$, by the definition of the set $\text{MS}(\mathcal{F})$, it holds that $\left\langle \boldsymbol{x}_{\mathcal{F}\setminus S}, \boldsymbol{x}'_S \right\rangle$ is a maximally sparse counterfactual. Therefore, it trivially follows, from Definition 4.1, that:

$$v(S) = 1 \quad \text{and} \quad \forall T \subset S\,,\ v(T) = 0$$

Then, by the Harsanyi dividends definition (⊗), (C.I) follows.

We now prove C.II. If $S \in \mathcal{F} \setminus \text{WMS}(\mathcal{F})$ and $S \subset T : T \in \text{MS}(\mathcal{F})$, then it trivially follows that $\Delta_S = 0$.

If that is not the case, then $S \supset T : T \in MS(S)$ and it must contain at least a feature $i \in S$ such that i is spurious, or in more formally such that:

$$\forall i \in \bar{C}\,,\ \forall S \subseteq \mathcal{F} \setminus \{i\}\,,\ \ v_{\boldsymbol{x}'}\left(S \cup \{i\}\right) - v_{\boldsymbol{x}'}\left(S\right) = 0.$$

Note that this is the definition of a *null-player*. Therefore, by Remark 4 in Dehez [19] — stating that "a player is null iff the dividends associated to coalitions containing that player are all equal to zero." — C.II follows.

Then the thesis follows. □

Proof. The corollary follows trivially from Theorem 4.5. □

A.2 Sparsity

As mentioned in Section 4, the different notions of sparsity of counterfactuals defined in this paper are theoretically connected between each others. In particular, maximal sparsity implies equal maximal sparsity that, in turn, implies weak maximal sparsity. We now formally prove such relationships between these three properties of counterfactuals that we defined in Section 4.

Proposition A.3 (Maximal Sparsity ⇒ Weak Maximal Sparsity)**.** *If $\boldsymbol{x}'$ is maximally sparse then $\boldsymbol{x}'$ is also weakly maximally sparse. And more in general, if for any $T \subseteq \mathcal{F}$, if $S \in MS(T)$ then $S \in WMS(T)$.*

Proof. The result follows trivially from Definition 4.3. □

Proposition A.4 (Maximal Sparsity ⇒ Equal Maximal Sparsity)**.** *If $\boldsymbol{x}'$ is maximally sparse then $\boldsymbol{x}'$ is equal maximally sparse.*

Proof. By Definitions 4.1 and 4.3, it follows that if $\boldsymbol{x}$ is maximally sparse than $\text{MS}(\mathcal{F}) = \text{WMS}(F)$.

Therefore the following holds $\forall i \in C$ where $C = \{i \in \mathcal{F} : x_i \neq x'_i\}$:

$$\sum_{\substack{S \in \text{WMS}(\mathcal{F}) \\ i \in S}} \frac{\xi(S)}{|S|} = \sum_{\substack{S \in \text{MS}(\mathcal{F}) \\ i \in S}} \frac{\xi(S)}{|S|}$$

Also, by Definition 4.4, we can substitute $\xi(S)$, therefore:

$$\sum_{\substack{S \in \text{WMS}(\mathcal{F}) \\ i \in S}} \frac{\xi(S)}{|S|} = \sum_{\substack{S \in \text{MS}(\mathcal{F}) \\ i \in S}} \frac{1}{|S|}$$

which is a constant, thus the thesis follows. □

Proposition A.5 (Equal Maximal Sparsity ⇒ Weak Maximal Sparsity)**.** *If $\boldsymbol{x}'$ is equal maximally sparse then $\boldsymbol{x}'$ is weak maximally sparse.*

Proof. Let's consider $C = \{i \in \mathcal{F} : x_i \neq x'_i\}$. If $|C| = 1$ then the thesis follows trivially. If instead $|C| > 1$ and $\boldsymbol{x}'$ is equally maximally sparse, by Theorem 4.5, it follows that:

$$\hat{\Phi}_i = \frac{1}{|C|}$$

Now, if we assume, ad absurdum, $\boldsymbol{x}'$ is not weakly maximally sparse, then it means that C contains at least a spurious features which gets a non-zero feature attribution. This is absurd given that $\hat{\Phi}_i$ is a Shapley value and thus satisfy the *null-property* of Shapley values, by which a null-player (spurious feature) always get zero attribution. □

A.3 Additional Results

In Section 3.2 we mentioned how the efficiency property [62] can be reduced to a simpler form for Bin-CF-SHAP feature attributions. We now formally prove such result in Proposition A.6.

Proposition A.6. *In the context of Bin-CF-SHAP, the efficiency property of Shapley values simplifies to the following expression.*

$$\sum_{i \in \mathcal{F}} \hat{\Phi}_i = 1$$

Proof. Let's recall that the efficiency property of Shapley values requires: [70]

$$\sum_{i \in \mathcal{F}} \phi_i = v(\boldsymbol{x}) - v(\emptyset)$$

where v is the characteristics function of the game for which we are computing Shapley values.

In particular, in the context of Bin-CF-SHAP values for which the characteristics function is defined as follows (see Definition 3.1):

$$v(S) = \mathop{\mathbb{E}}_{\boldsymbol{x}' \sim \mathcal{X}'} \left[F\left(\left\langle \boldsymbol{x}_S, \boldsymbol{x}'_{\mathcal{F} \setminus S} \right\rangle \right) \right]$$

the efficiency property simplifies to the following expression:

$$\sum_{i \in \mathcal{F}} = F(\boldsymbol{x}) - \mathop{\mathbb{E}}_{\boldsymbol{x}' \in \mathcal{X}'} \left[F(\boldsymbol{x}') \right].$$

Since all $\boldsymbol{x}$ is the query instance, and $\boldsymbol{x}' \in \mathcal{X}'$ are counterfactuals, by Definition 3.1, then it follows that:

$$\sum_{i \in \mathcal{F}} = 1 - 0 = 1.$$

which proves the thesis. □

B EXPERIMENTAL SETUP

Dataset	Features	Size Train Set	Size Test Set	Decision Threshold*	Model Performance† ROC-AUC	Recall	Accuracy‡
HELOC (Home Equity Line Of Credit)	23	6,909	2,962	0.4993	80.1%	72.8%	73.0%
Lending Club (Loan Data)	20	961,326	411,998	0.6367	69.6%	62.5%	72.17%
Adult (1994 US Census Income)	12	22,792	9,769	0.6811	92.3%	72.9%	86.6%

Table 1: Characteristics of the datasets and models used in the experiments. (∗) The decision threshold is reported here in probability space (i.e., after passing the model output through a sigmoid); (†) performance metrics are computed on the test set.

B.1 Datasets and Models

To run the experiments we used 3 publicly available datasets. Table 1 describes in details the datasets.

We split the data using a stratified 70/30 *random* train/test split for HELOC and Adult. For Lending Club we split the data using a non-random 70/30 train/test split based on the loan issuance date (available in the original data).

We trained an XGBoost model [13] for each dataset. In particular, we run an hyperparameters search using Bayesian optimization using hyperopt [8] for 1000 iterations maximizing the average validation ROC-AUC under a 5-fold cross validation. To reduce model over-parameterization during the hyper-parameters optimization we penalized high model variance, i.e., for each cross-validation fold, instead of using AUC_{val}, we used $AUC_{val} + (AUC_{val} - AUC_{train})$ where AUC_{train} and AUC_{val} are the training and validation ROC-AUC, respectively.

To compute the decision threshold (t) we used a value such that the rate of positive prediction of the model (on the training set samples) was the same as the true rate of positive predictions (on the same samples). Table 1 shows the decision threshold and the performance of each model.

B.2 Feature Importance

We used the following implementation in order to compute explanations.

- **SHAP**. We used the TreeSHAP implementation [49] available through the `TreeExplainer` class in the `shap` package[3] (for Python).
- **CF-SHAP**. We used CF-SHAP [2] available through the `CFExplainer` class in the `cfshap` package[4] (for Python).
- **Binary CF-SHAP**. We used CF-SHAP in combinations with the KernelSHAP [50] implementation available through the `KernelExplainer` class in the `shap` package. We used 10,000 kernel samples to generate the KernelSHAP approximation. We note that, since we used KernelSHAP, the resulting Binary CF-SHAP explanations that we generated are an approximation of the exact Shapley values.
- **CF-Freq**. Given its simplicity, we implemented from scratch the explanation logic following the explanation definition [55, 73].
- **Normalised CF-Freq**. We implemented from scratch the explanation logic similarly to CF-Freq.

We also remark, as mentioned in Section 2, that we used the "true-to-the-model" interventional (a.k.a., non-conditional) version of SHAP (default setting of `shap` and `cfshap`).

B.3 Counterfactuals

To compute the K-nearest neighbours we used the implementation available in `sklearn.neighbours`. To make our results indifferent to the size of the dataset we limited the k-nearest neighbours to be selected among a random sample of 10,000 samples from the training set.

B.4 Maximally Sparse Counterfactuals

In Section 4 we mentioned how it is always possible to generate a maximally sparse counterfactual from any counterfactual by selecting a subset of the features $C = \{i \in \mathcal{F} : x_i \neq \boldsymbol{x}'_i\}$ that have been modified in the counterfactual. In particular, as described in Section 6, to run our experiments we devised an exhaustive search based algorithm. The pseudo-code for such algorithm is in Algorithm 1. At a high-level Algorithm 1 computes a maximally sparse counterfactual from any counterfactual as follows:

- It explores all the possible subset of features $T \subset C$ using depth-first search (implemented through recursion).
- It prunes the search when it encounter a subset $\widehat{T}$ of features that does not give rise to a counterfactual; in this way it avoids to search any subset $Q \subset \widehat{T}$.
- After having generated $\mathbb{MS}(\mathcal{F})$ — the set of all the maximally sparse counterfactual that can be induced from $\boldsymbol{x}'$ — it computes their cost based on a cost function provided by the user, and returns the counterfactual with the minimum cost.
- In our experiments, as mentioned in Section 6, we used the *total quantile shift* [84] as cost function for counterfactuals.

[3]The `shap` package can be found at https://github.com/slundberg/shap

[4]The `cfshap` package can be found at https://github.com/jpmorganchase/cf-shap

Algorithm 1 Depth-first search-based algorithm to induce a maximally sparse counterfactual from any counterfactual

MaxSparse($\boldsymbol{x}$, $\boldsymbol{x'}$, $\mathcal{F}$, F)
Input: query instance $\boldsymbol{x}$, counterfactual $\boldsymbol{x'}$, set of all features $\mathcal{F}$, F model decision function
$C = \{i \in \mathcal{F} : x_i \neq x'_i\}$ ▷ Let's isolate the features that have been modified.
$Fail = \{\}$ ▷ Let's create a set for failed trials.
$Succ = \{C\}$ ▷ Let's create a set for the successful trials.
MaxSparseRecurse($\boldsymbol{x}$, $\boldsymbol{x'}$, null, C, $Succ$, $Fail$, F) ▷ Let's run the search recursively.
▷ We now select the maximally sparse counterfactual with minimum cost
$\boldsymbol{x'}$ = null
$c' = \infty$
for $\boldsymbol{x''} \in Succ$ **do**
  $c'' = \text{cost}(\boldsymbol{x}, \boldsymbol{x''})$ ▷ We compute the cost/proximity of the counterfactual
  if $c'' < c'$ **or** $\boldsymbol{x'}$ **is** null **then**
    $\boldsymbol{x'} = \boldsymbol{x''}$
    $c' = c''$
  end if
end for
Return $\boldsymbol{x'}$

MaxSparseRecurse($\boldsymbol{x}$, $\boldsymbol{x'}$, $\boldsymbol{x'}^P$, C, $Succ$, $Fail$, F)
Input: query instance $\boldsymbol{x}$, counterfactual $\boldsymbol{x'}$, parent of the counterfactual $\boldsymbol{x'}^P$, set of features C, successful trials $Succ$, failed trials $Fail$
if $F(\boldsymbol{x'}) \neq F(\boldsymbol{x})$ **then**
  ▷ We remove the parent and add the current $\boldsymbol{x'}$ to the successful trials.
  if $\boldsymbol{x'}^P \in Succ$ **then**
    $Succ.remove(\boldsymbol{x'}^P)$
  end if
  $Succ.add(\boldsymbol{x'})$
  ▷ We now expand the search recursively by removing one more feature from the counterfactual.
  for $i \in C$ **do**
    $C' = C \setminus \{i\}$
    $\boldsymbol{x''} = \boldsymbol{x'}$
    $x''_i = x_i$
    if $\boldsymbol{x''} \notin Fail \wedge \boldsymbol{x''} \notin Succ$ **then**
      MaxSparseRecurse($\boldsymbol{x}$, $\boldsymbol{x''}$, $\boldsymbol{x'}$, C', $Succ$, $Fail$, F)
    end if
  end for
else
  $Fail.add(C)$
end if

B.5 Technical setup

The experiments were run using a `c6i.32xlarge` AWS virtual machine with 128 vCPUs (64 cores of 3.5 GHz 3rd generation Intel Xeon Scalable processor) and 256GB of RAM. XGBoost parameter `nthread` was set to 15. We used a Linux machine running `Ubuntu 20.04`. We used `Python 3.8.13`, `shap 0.39.0`, `cfshap 0.0.2`, `sklearn 1.1.1` and `xgboost 1.5.1`.

B.6 Source Code

The source code to reproduce the experimental results in the paper will be made available at https://www.emanuelealbini.com/cf-vs-shap-aies23.

C EXPERIMENTAL RESULTS

C.1 Explanations Difference

In Section 6 we showed how the explanations generated using different techniques differ in terms of their average pairwise Kendall-Tau rank correlations [41]. Figures 4 to 7 show the same results for additional metrics commonly used in the literature to measure the difference between the rankings that feature importance explanations provide. In particular, we show the results for Feature Agreement [26], Rank Agreement [43], Spearman Rank Correlation [76] and Rank Biased Overlap [68, 93].

Results - We note that:

- In general, the results are consistent with the results in terms of Kendall-Tau correlation presented in Figure 2 in the main text.
- The results in terms feature and rank agreement suggest that explanations tend to be more similar in their the top-3 features by importance than in their top-10. This is consistent with the literature [43] that shows how different XAI techniques tend to agree more on the most important features when compared to those that are ranked as least important.

C.2 Counterfactual-ability and plausibility

The counterfactual-ability and plausibility metrics proposed in Albini et al. [2] have few hyper-parameters. In particular, they can be run using different strategies to induce a recourse from a feature importance explanations (called *action functions*) and different ways to evaluate the cost of the recourse (called *cost functions*). We refer the reader to Albini et al. [2] for more details on the evaluation metrics and the hyper-parameters.

The results we reported in Figure 3 in the main text were obtained using *random recourse* and *total quantile shift cost*. To show the robustness of our evaluation under different action functions and cost functions we run the same experiments with the alternative definitions of cost and action functions that have been proposed in [2].

In particular, in this appendix we report the results under the following alternative assumptions:

- random recourse and quantile shift cost with L2 norm;
- proportional recourse and total quantile shift cost;
- proportional recourse and total quantile shift cost under L2 norm.

Results - Figure 8 shows the results which are indeed consistent with those presented in Section 6.

ABSTRACT

Recent work has connected adversarial attack methods and algorithmic recourse methods: both seek minimal changes to an input instance which alter a model's classification decision. It has been shown that traditional adversarial training, which seeks to minimize a classifier's susceptibility to malicious perturbations, increases the cost of generated recourse; with larger adversarial training radii correlating with higher recourse costs. From the perspective of algorithmic recourse, however, the appropriate adversarial training radius has always been unknown. Another recent line of work has motivated adversarial training with adaptive training radii to address the issue of instance-wise variable adversarial vulnerability, showing success in domains with unknown attack radii. This work studies the effects of adaptive adversarial training on algorithmic recourse costs. We establish that the improvements in model robustness induced by adaptive adversarial training show little effect on algorithmic recourse costs, providing a potential avenue for affordable robustness in domains where recoursability is critical.

1 INTRODUCTION

The adoption of Machine Learning (ML) in consequential environments motivates the provision of instructions to adversely-affected users on actions they can take to alter a model's decision. For example, in the lending domain, if a classifier decides to deny an applicant, there should be a mechanism for providing a feasible set of actions the applicant can take to be approved. This instructive information is desirable as opaque self-learning systems inform more and more of our society's decision-making, for both trust and accountability. The ability to obtain a desired outcome from a known model, the actionable set of changes that users can make to improve their qualification, or the systematic process of reversing unfavorable decisions is defined as "algorithmic recourse," or simply "recourse" [12]. These what-if scenarios are also often referred to as "counterfactual explanations." Importantly, the explicitly stated goal of recourse is to find actions with minimal cost to the user [24].

Simultaneously, it has been observed that many neural networks can be easily "fooled" by introducing small changes to input features that may seem imperceptible. [22] first proposed the concept of "adversarial examples": by adding small perturbations to an input sample, models obtain incorrect classification results with high confidence scores. These are sometimes referred to as "evasion attacks" [5]. [22] also found that such perturbations can be adapted into different model architectures, demonstrating that many deep neural networks are vulnerable to these input manipulations. Adversarial examples raise concerns about the trust one can place in neural network classifiers, and much work has been put into adversarial training methods to improve the robustness of models to adversarial examples. The most popular adversarial training regimes [1] generate adversarial examples (with corrected labels) within a fixed "attack radius" (ϵ) during training procedure and include them in the model's training dataset. While adversarial training has been shown to increase robustness to adversarial examples drastically, it often comes at some cost to standard accuracy [28].

There is an inherent contention between the considerations of algorithmic recourse and adversarial robustness. While minimizing the changes necessary to alter a classifier's decision is seen as beneficial from a recourse perspective, such changes are harmful from a robustness perspective. Research [14] has demonstrated that adversarial training increases the average recourse cost, with higher adversarial training radii corresponding to higher recourse costs, which raises the concern that there may be an inherent trade-off between robustness and recourse.

Briefly, it should be noted that the goals of adversarial robustness are not totally at odds with recourse. Recourse *should* represent *true movements towards a desired class*, and adversarial examples that "fool" a model can be *harmful* and should *not be presented as recourse*. Consider the lending setting: if an approval action plan is provided to an applicant which does not represent a true movement in their underlying propensity for repayment, both the lender and borrower are putting themselves at long-term financial risk by following that plan. This is relevant in the context of many recourse settings, where data is tabular and it is not immediately obvious which input perturbations constitute adversarial examples and which input perturbations constitute recourse that genuinely moves an individual towards a desired class manifold. With this in

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08.
https://doi.org/10.1145/3600211.3604704

mind, it is worth considering not only the change in overall cost of recourse, but also the change in proximity of recourse to the desired data manifold, when selecting an adversarial training radius.

Even more fundamentally, it is important to question *whether a fixed adversarial training radius is appropriate, particularly in the context of algorithmic recourse?*. It has been shown [2] that different data instances have different *inherent adversarial vulnerabilities* due to their varying proximities to other classes. As such, some researchers have argued that an identical adversarial training radius should not be applied to all instances during training. Several methods [2, 6, 8] have been proposed for automatically learning *instance-wise* adversarial radii to address this variability. These are broadly referred to as "Adaptive Adversarial Training" (AAT) regimes [1].

This work explores the effects of AAT on both model robustness and ultimate recourse costs in an attempt to address the trade-off between the two and find a *justifiable* middle ground. Our contributions include:

- An observation on the effects of robustness on recourse costs, and when AAT yields more affordable recourse.
- Experiments demonstrating AAT's superior robustness/ recourse trade-offs over traditional AT.

2 BACKGROUND AND RELATED WORKS

Algorithmic Recourse: The continued adoption of ML in high-impact decision making such as banking, healthcare, and resource allocation has inspired much work in the field of Algorithmic Recourse [11, 13, 24], and Counterfactual Explanations [15, 19, 21, 27]. The performance of different recourse methods depends highly on properties of the datasets they are applied to, the model they operate on, the application of that model's score, and factual point specificities [7]. However, broadly speaking, recourse methods are classified based on: i) the *model family* they apply to, ii) the degree of *access* they have to the underlying model (i.e. white vs. black box methods), iii) the consideration of *manifold proximity* in the generation of recourse, iv) the underlying *causal relationships* in the data, and v) the use of *model approximations* in the generation process [26]. Recently, [18] introduced CARLA, a framework for benchmarking different recourse methods which act as an aggregator for popular recourse methods and standard datasets.

Adversarial Attacks and Adversarial Training: Adversarial vulnerability refers to the susceptibility of a model to be *fooled* by perturbations to the input data which cannot be detected by humans (so-called *Adversarial Examples*) [23]. Adversarial Training [10, 16] has been introduced to create models which are not susceptible to such attacks. The most popular method of Adversarial Training generates adversarial examples during the training process and includes them in the training dataset with corrected labels alongside the uncorrupted dataset. Often, adversarial training comes at some cost to standard classification accuracy. There have been many attack methods proposed to generate adversarial examples [5] with varying degrees of access to the model under attack, but most focus on defending against adversarial examples within a given ϵ-radius (which are often defined by ℓ_1, ℓ_2, or ℓ_∞ norms of size ϵ.) This work follows the popular attack and training formulation from [16], which minimizes the worst-case loss within a defined ϵ-radius.

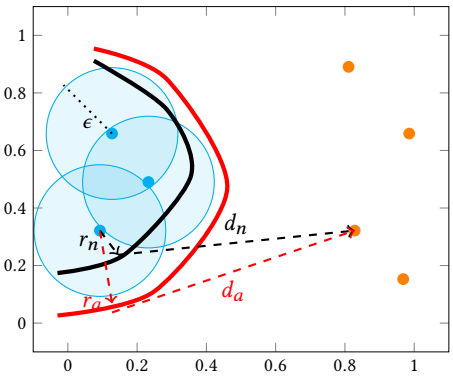
On the Intersection of Robustness and Recourse. Both Adversarial Examples and Counterfactual Explanations are formally described as constrained optimization problems where the objective is to alter a model's output by minimally perturbing input features [4, 9]. Recent work [17] proved equivalence between certain adversarial attack methods and counterfactual explanation methods, and further work has demonstrated both theoretically and empirically that increasing the radius of attack during adversarial training increases the cost of the resulting recourse [14]. This inherent connection pits security at odds with expressivity and raises an important question as to how an adversarial radius ought to be selected for adversarial training. If the radius is too small, the model may be overly sensitive to an attack, while if it is too large, end users suffer from potentially overly-burdensome recourse costs. In the context of many recourse problems where data is tabular, it is difficult to determine what may constitute an adversarial attack, furthering the difficulty of radius selection. [3] discussed a formulation for adversarial attacks on tabular data that accounts for both the radius of attack and the importance of a feature, but this is difficult to know a priori and often changes depending on the choice of explanation method selected [20].

Adaptive Adversarial Training. It has been observed that different data instances have different inherent adversarial vulnerability due to their varying proximity to other class' data manifolds, calling into question the conventional wisdom that models should be adversarially trained at a single consistent adversarial radius. [2] first observed this issue in the image classification domain, where certain instances can be *meaningfully transformed* into other classes even at small adversarial radii. The authors of [2] proposed a means of discovering instance-wise adversarial radii by iteratively increasing or decreasing each instance's attack radius based on whether attacks are successful. [6] built on this work by further motivating the effects of overly-large adversarial radii on classification accuracy and proposed a variation of [2]'s method which included adaptive label-smoothing to account for the uncertainty added by larger attack radii, and [8] proposed a means for adaptive adversarial training by increasing the classification margin around correctly-classified datapoints. Adaptive Adversarial Training (AAT) presents a means of "automatically" selecting attack radii during training, and in all works thus far, has shown positive results in terms of the accuracy/robustness trade-off inherent in adversarial training, as well as smoother robustness curves across ranges of attack radii compared with traditional Adversarial Training.

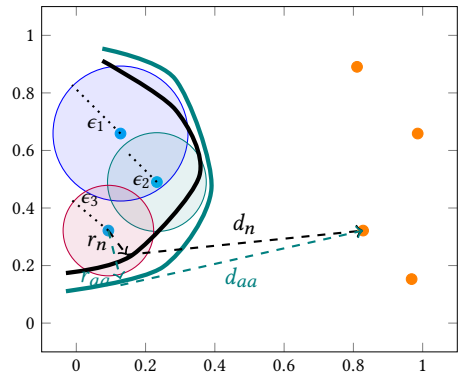
3 PRELIMINARIES & NOTATION

Standard Training: We begin with a model f parameterized by weights θ that maps $\mathcal{X} \to \mathcal{Y}$, where $x \in \mathcal{X}$ are features and $y \in \mathcal{Y}$ are their corresponding labels. Given a dataset $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^N$, and a loss function $\ell(\cdot)$, a standard learning objective is to minimize the average loss on the data:

$$\min_\theta \quad \frac{1}{N} \sum_{(x_i, y_i) \in D} \ell(f_\theta(x_i), y_i) \tag{1}$$



(a) Toy problem demonstrating that adversarial training can result in counterfactuals that are both costlier and further from the desired class manifold. The natural decision boundary is shown in black, the adversarial boundary in red. ϵ-Adversarial training creates a necessary recourse cost $c_a = \epsilon > c_n$, and yields a distance in the resulting recourse to the desired manifold of $d_a > d_n$



(b) Adaptive Adversarial Training provides counterfactuals which are cheaper and relatively closer to the desired class manifold. The natural decision boundary is shown in black, the adaptive adversarial boundary in green. With instance specific robustness ϵ_i, the recourse cost $c_{aa} = \epsilon_i > c_n$ and $c_{aa} < \epsilon$ for any $\epsilon_i < \epsilon$. This yields a distance $d_{aa} < d_a$.

Figure 1: An example scenario demonstrating the effectiveness of AAT in terms of recourse costs.

Let f_{nat} represent the naturally trained model using the standard loss minimization based optimization technique.

Adversarial Attacks: The goal of an adversarial attack is to strategically generate perturbations δ which can significantly enlarge the loss $\ell(\cdot)$ when added to an instance x. [10] introduced *Fast Gradient Sign Method (FGSM)* for generating adversarial examples using the following mechanism:

$$x_i' = x_i + \alpha \cdot \text{sign}\left(\nabla_{x_i} \ell\left(f_\theta(x_i), y_i\right)\right) \tag{2}$$

where α denotes the size of the perturbation, x_i' denotes the adversarially perturbed sample, and x_i is the original clean sample. The *sign* function operates on the gradient of $\ell\left(f_\theta(x_i), y_i\right)$ w.r.t. x_i, which is used to set the gradient to 1 if it is greater than 0 and -1 if it is less than 0. [16] proposed a stronger iterative version of FGSM, performing Projected Gradient Descent (PGD) on the negative loss function:

$$x_i(t+1) = \Pi_{x+\mathcal{S}}\left(x_i(t) + \alpha \cdot \text{sign}\left(\nabla_{x_i(t)} \ell(f_\theta(x_i(t)), y_i)\right)\right)$$

where α denotes the perturbation step size at each iteration and $x_i(t+1)$ represents the perturbed example at step $t+1$ for the clean instance x_i. In this work, we use PGD due to its performance, popularity, and relative speed.

Adversarial Training: Adversarial training is usually formulated as a min-max learning objective, wherein we seek to minimize the worst case loss within a fixed training radius ϵ.

$$\min_\theta \max_{||\delta_i|| \le \epsilon} \frac{1}{N} \sum_{(x_i, y_i) \in D} \ell(f_\theta(x_i + \delta_i), y_i) \tag{3}$$

We solve this min-max objective via an alternating stochastic method that takes minimization steps for θ, followed by maximization steps that approximately solve the inner optimization using k steps of an adversarial attack. PGD with a fixed ϵ is used to perturb an original instance and let $f_{\epsilon\text{-adv}}$ represent the model trained with a PGD radius of ϵ.

3.1 Adaptive Adversarial Training

[2] first argued that different data instances have different intrinsic adversarial vulnerabilities due to their varying proximity to other class manifolds, and introduced Instance-Adaptive Adversarial Training (AAT) to automatically learn instance-wise adversarial radii. The authors proposed the following objective function:

$$\min_\theta \max_{||\delta_i|| \le \epsilon_i} \frac{1}{N} \sum_{(x_i, y_i) \in D} \ell(f_\theta(x_i + \delta_i), y_i) \tag{4}$$

where ϵ_i denotes each training instance's attack radius. ϵ_i is iteratively updated at each training epoch, increasing by a constant factor if the attack at the existing radius is unsuccessful and decreasing by a constant factor if it is successful.

[8] presented an alternate form of AAT called Max-Margin Adversarial (MMA) Training that seeks to impart adversarial robustness by maximizing the margin between correctly classified datapoints and the model's decision boundary. Formally, they proposed the following objective:

$$\min_\theta \left\{ \sum_{i \in S_\theta^+} \max\{0, d_{max} - d_\theta(x_i, y_i)\} + \beta \sum_{i \in S_\theta^-} \ell(f_\theta(x_j), y_j) \right\} \tag{5}$$

where S_θ^+ is the set of correctly classified examples, S_θ^- is the set of incorrectly classified examples, $d_\theta(x_i, y_i)$ is the margin between correctly classified examples and the model's decision boundary, d_{max} is a hyper-parameter controlling which points to maximize the boundary around (forcing the learning to focus on points with d_θ less than d_{max},) and β is a term controlling the trade-off between standard loss and *margin maximization*. The authors use a line search based on PGD to efficiently approximate $d_\theta(x_i, y_i)$. For the rest of this study, let f_{aat} be a model trained using a mechanism from this category of training techniques.

3.2 Recourse Methods

For the scope of this study, we explore three different classes [14] of recourse methods: i) one random search, ii) one gradient-based search, and iii) one manifold-based approach. We will now briefly discuss each method, and we refer the readers to the original works for further implementation details.

Growing Spheres (GS):. [15] proposed a random search method for calculating counterfactual by sampling from points within ℓ_2-hyper-spheres around x of iteratively increasing radii until one or more counterfactual is identified which flips $f(x)$. Formally, they present a minimization problem in selecting which counterfactual x' to return:

$$\arg\min_{x' \in \mathcal{X}} \{c(x, x') | f(x) \neq f(x')\} \tag{6}$$

where $\mathcal{X}$ is the family of sampled points around x and c is a cost function in $\mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}_+$: $||x' - x||_2 + \gamma ||x' - x||_0$, where γ is a hyperparameter controlling the desired sparsity of the resulting counterfactual.

Score Counterfactual Explanations (SCFE):. [27] proposed a gradient-based method for identifying counterfactuals x'.

$$\arg\min_{x'} \max_{\lambda} \lambda (f(x') - y')^2 + d(x, x') \tag{7}$$

where $d(\cdot, \cdot)$ is some distance function and y' is the desired score from the model. In practice, this is solved by iteratively finding x' and increasing λ until a satisfactory solution is identified.

CCHVAE:. [19] proposed a manifold-based solution to finding counterfactuals using a Variational Auto Encoder (VAE) to search for counterfactuals in a latent representation $\mathcal{Z}$. The goal of CCHVAE and other manifold methods is to find counterfactuals that are semantically "similar" to other data points. Formally, given an encoder $\mathcal{E}$, a decoder $\mathcal{H}$, and a latent representation $\mathcal{Z}$ where $\mathcal{E} : \mathcal{X} \rightarrow \mathcal{Z}$, CCHVAE optimizes the following:

$$\arg\min_{z' \in \mathcal{Z}} \{||z'|| \; s.t. \; f(\mathcal{H}(\mathcal{E}(x) + z')) \neq f(x)\} \tag{8}$$

4 RECOURSE TRADE-OFFS WITH ADAPTIVE ADVERSARIAL TRAINING

Recourse cost. The cost of recourse is usually approximated using a distance based metric. A common practice among recourse methodologies is to minimize the cost in some form or the other, because in general a low cost recourse is assumed to be easier to act upon. The cost of a recourse for a classification based model is traditionally interpreted as the minimum distance between a factual and the decision boundary. Alternatively, the inherent goal of adversarial training is to maximize the distance between factuals and the decision boundary. Hence, traditional adversarial training exacerbates the recourse costs of a classifier. In this section, we make preliminary observations on the effects of adaptive adversarial training on recourse costs.

An increase in ϵ for ϵ-adversarial training increases the overall recourse costs and the corresponding relation between ϵ and C is discussed in [14]. In comparison with an ϵ-adversarial training, we observe the following benefits from the instance adaptive adversarially training:

4.1 Recourse Costs

Let $\delta_x^{(nat)} = d(x, x')$ be the distance to the closest adversarial example x' for the instance x for a standard training based model, and, analogously, let $c_x^{(nat)} = cost(x, x'')$ be the cost of a recourse x'' for an individual represented by x. For simplicity, we assume that both $c_{(\cdot)}^{(\cdot)}$ and $cost(\cdot, \cdot)$ use the same ℓ_p norm based distance metrics. Let $H^- = \{x \in \mathcal{X} : f(x) = -1\}$ represent the sub-population which was adversely affected by the classifier $f(\cdot)$, and analogously we have $H^+ = \{x \in \mathcal{X} : f(x) = +1\}$. The average cost of recourses for H^- is defined for a naturally trained model as:

$$c_*^{(nat)} = \frac{1}{|H^-|} \sum_{x \in H^-} c_x^{(nat)} \tag{9}$$

Let $\underline{H^-} = \{x \in \mathcal{X} : f(x) = -1, c_x^{(nat)} \leq \underline{\epsilon}\}$, where $\underline{\epsilon}$ is a cost threshold to identify low cost recourses. As observed in Figures 4 and 5, a low cost counterfactual is sufficient in practice for a large section of the population. However, an optimal ϵ_a-adv classifier provides at least ϵ_a robustness to all samples in the training dataset. This can be visualized by the sharp peak in the distribution of the observed ϵ in the test dataset for all the ϵ-adv models (Figure 8). However AAT models provide natural robustness to the data samples, meaning that a data instance closer to the natural decision boundary has $\epsilon_{aat}^{H^-}$ that depends on the data's natural proximity to the decision boundary. For instances with $\epsilon_{aat}^{H^-} < \epsilon_a$, the resulting recourse will be more affordable. For $\epsilon_{aat}^{H^-} < c_x^{(nat)}$, low cost recourse within $\underline{H^-}$ will be preserved.

4.2 Proximity to the Desired Manifold

Manifold Proximity measures the distance by some metric between recourse and the target sub-population. For an $f^*_{\epsilon_a\text{-adv}}$ model, the recourse suggested have at least ϵ_a proximity from the target approved sub-population H^+ due to the fact that the target sub-population is also ϵ_a away from the decision boundary. Alternatively f_{aat} is naturally robust for the target sub-population as well. Hence, the Recourse provided has the potential to be closer in terms of proximity to H^+, so long as $\epsilon_{aat}^{H^+} < \epsilon_a$. We report the average proximity $\rho_{f_{\epsilon\text{-adv}}}$ of the model $f_{\epsilon\text{-adv}}$ using:

$$\rho_{f_{\epsilon\text{-adv}}} = \frac{1}{|N_{test}|} \sum_{x \in N_{test}} \min_{x^+ \in H^+} d(x, x^+) \tag{10}$$

where $d(x, x^+)$ is a distance measure between a counterfactual x and a target population x^+. We report both $\rho_{f_{\epsilon\text{-adv}}}$ and $\rho_{f_{aat}}$ for the corresponding models. In Figure 7, we find that $\rho_{f_{aat}}$ is significantly better than $\rho_{f_{\epsilon\text{-adv}}}$. A motivating toy problem demonstrating lower recourse costs and closer manifold proximity is also visualized in Figure 1.

4.3 Preservation of Low Cost Recourse

The recourse costs provided to the adversely affected individuals by a model should follow the natural distribution of the difficulty of acting upon the suggested recourse at the population level. With a fixed ϵ while training an optimal adversarially trained $f^*_{\epsilon\text{-adv}}$ model, the recourse suggested must necessarily be ϵ away from the decision boundary and further ϵ away from the nearest target

population sample. Such counterfactuals contradicts with the recourse literature [25], which describes a distribution in recourse costs wherein a proportion of individuals only require minimal low cost actionable steps to obtain the desired outcome from a model, whereas other individuals can have a much larger recourse costs. Essentially, ϵ-robustness necessarily denies recourse with lower costs than ϵ.

f_{aat} does not enforce a strict ϵ while training, allowing instances to have a wider range of recourse costs. To this end we compare the rate of extreme low cost recourse C_Δ across the discussed training methods with real-world datasets to measure the rate at which it degrades in practice. For simplicity, we measure:

$$C_\Delta = \frac{1}{|N_{test}|} \sum_{x_i \in N_{test}} \mathbf{1}(C_{x_i} < \epsilon) \tag{11}$$

where C_{x_i} is the cost of recourse for an instance x_i and ϵ is a minimum adversarial training radius. We observe in Figure 4 that Adaptive Adversarial Training preserves low cost recourse rates despite providing overall robustness benefits.

5 EXPERIMENTAL DESIGN & METRICS

In this section, we detail our experimentation procedure to empirically evaluate these various training methods and explain our

Figure 4: Low cost recourse (ℓ_∞ < 0.05) proportion for methods that optimize directly in the input space. We observe that AAT models has much higher proportions of low cost recourse, supporting the hypothesis that it allows for robustness while preserving low recourse costs for individuals near natural decision boundaries.

metric choices. The CARLA package [18] was used to source the datasets and recourse methods we employed.

5.1 Experimental Setup

Datasets. We performed our experiments on three datasets:

- *Adult Income*: A dataset originating from the 1994 Census of 48,842 individuals for whom the task is to predict whether someone makes more than $50,000/yr. It is comprised of 20 features which are a combination of demographic features (age, sex, racial group), as well as employment features (hours of work per week and salary), and financial features (capital gains/losses.) In keeping with [14] and [3], we removed categorical features for efficient training and approximation of tabular adversarial examples. The target distribution is somewhat skewed, with a 76% positive label proportion.
- *Home Equity Line of Credit (Heloc)*: pulled from the 2019 FICO Explainable Machine Learning (xML) challenge, the Heloc dataset consists of anonymized credit bureau data from 9,871 individuals where the task is to predict whether an individual will repay their HELOC account within two years. The dataset consists of 21 financial features and no demographic data. The target distribution is evenly split, with a 48% positive label proportion.
- *Give Me Some Credit (GSC)*: a credit-scoring dataset pulled from a 2011 Kaggle Competition consisting of 150,000 individuals for whom the task is to predict default. It consists of 11 features, one of which is a demographic feature (age), and the rest are financial variables. The target distribution is heavily skewed, with a 93% positive label proportion.

Models. We trained a total of 7 Neural Network models for each of our datasets: one naturally trained model, one model trained with AAT, one model trained with MMA, and four adversarially trained models. All models are trained using Binary Cross Entropy with the default model architecture from CARLA, with three hidden layers of [18, 9, 3] units. The Adversarially Trained models were all trained with PGD at a variety of $\epsilon \in [0.05, 0.1, 0.15, 0.2]$. The AAT model did not consider any hyperparameter choices, and the MMA model was trained using the original work's package [8] with the default hyperparameter choices.

Recourse Methods. We constructed Counterfactual Explanations for all models on a sample of 1000 negatively-classified test data points using three methods: Growing Spheres (GS), C-CHVAE, and SCFE. All hyperparameter choices for these methods were left as their CARLA defaults.

5.2 Metrics

To study the effects of the different training methods on accuracy, robustness, and recourse, we calculate the following metrics:

Standard Classification Performance. A primary consideration in adversarial training is the trade-off in classification accuracy when compared with natural training. We record the standard classification accuracy of all models to measure the drop in accuracy that may accompany the different adversarial training methods. Formally, we measure: $\frac{1}{|\mathcal{D}_{test}|} \sum_{x_i \in \mathcal{D}_{test}} \mathbf{1}(f(x_i) = y_i)$. Given that we are experimenting with datasets with skewed target distributions, we also record the F1 score of each model on the minority target population.

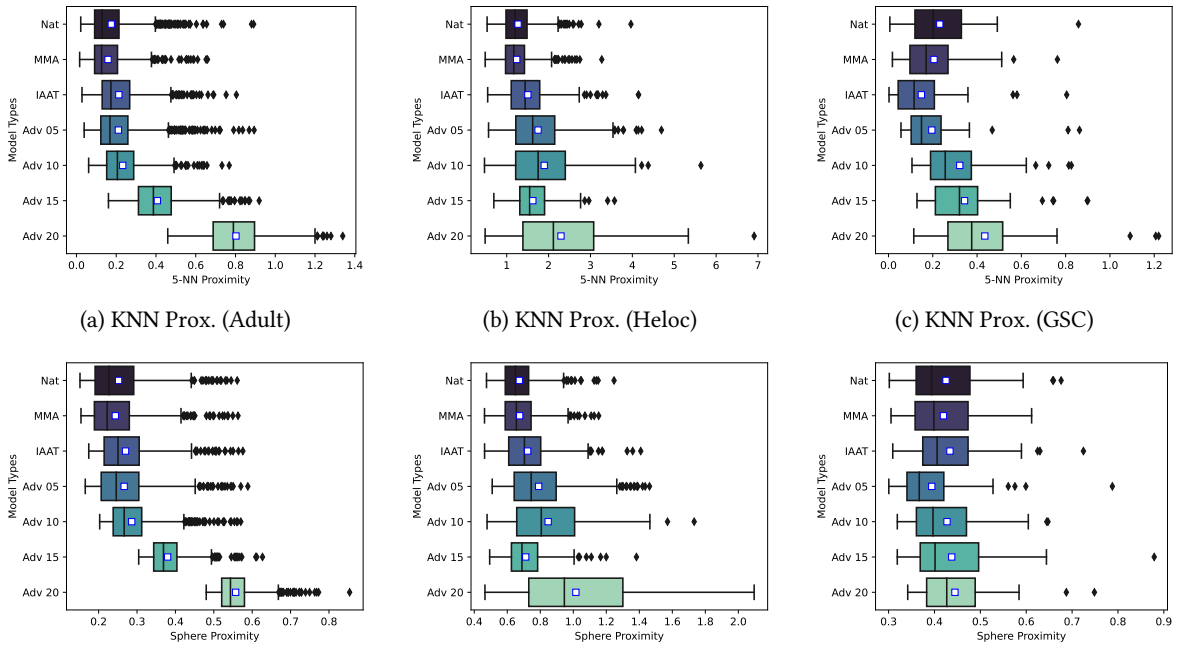
Figure 6: Recourse costs (defined as the ℓ_2 distance between a factual and counterfactual data point) for all methods and datsets. We observe that adaptive adversarial training shows significantly more competitive recourse costs than traditional adversarial training, and MMA training in particular shows almost no increase over natural training despite its robustness benefits.



(a) KNN Prox. (Adult) (b) KNN Prox. (Heloc) (c) KNN Prox. (GSC)

(d) Sphere Prox. (Adult) (e) Sphere Prox. (Heloc) (f) Sphere Prox. (GSC)

Figure 7: KNN and Sphere Manifold Proximity for Growing Spheres. We find that not only does adaptive adversarial training produce less expensive recourse than traditional adversarial training, but also recourse that is more faithful to the desired class these counterfactuals approximate.

Adversarial Success Rate. Given that we are primarily concerned with the trade-off between robustness and recourse, and following the concept of "boundary error" introduced in [29] to disentangle standard performance and adversarial vulnerability, we also measure the success rate of adversarial attacks at various radii on our models. Formally, given an attack $\mathcal{A}_\epsilon$ such that $\mathcal{A}_\epsilon(x)$ identifies the most adversarial example on x within a radius ϵ, we measure $\frac{1}{|\mathcal{D}_{test}|}\sum_{x_i \in \mathcal{D}_{test}} \mathbf{1}(f(\mathcal{A}_\epsilon(x)) \neq f(x_i))$. We observe the adversarial success rate across the radii on which we train our traditional adversarial models. Note that this is an imperfect metric for measuring the success of AAT, as AAT assumes that some "attacks" at given radii represent real movements toward different classes; however, it is still useful to capture this information in considering the trade-off between traditional adversarial training and AAT.

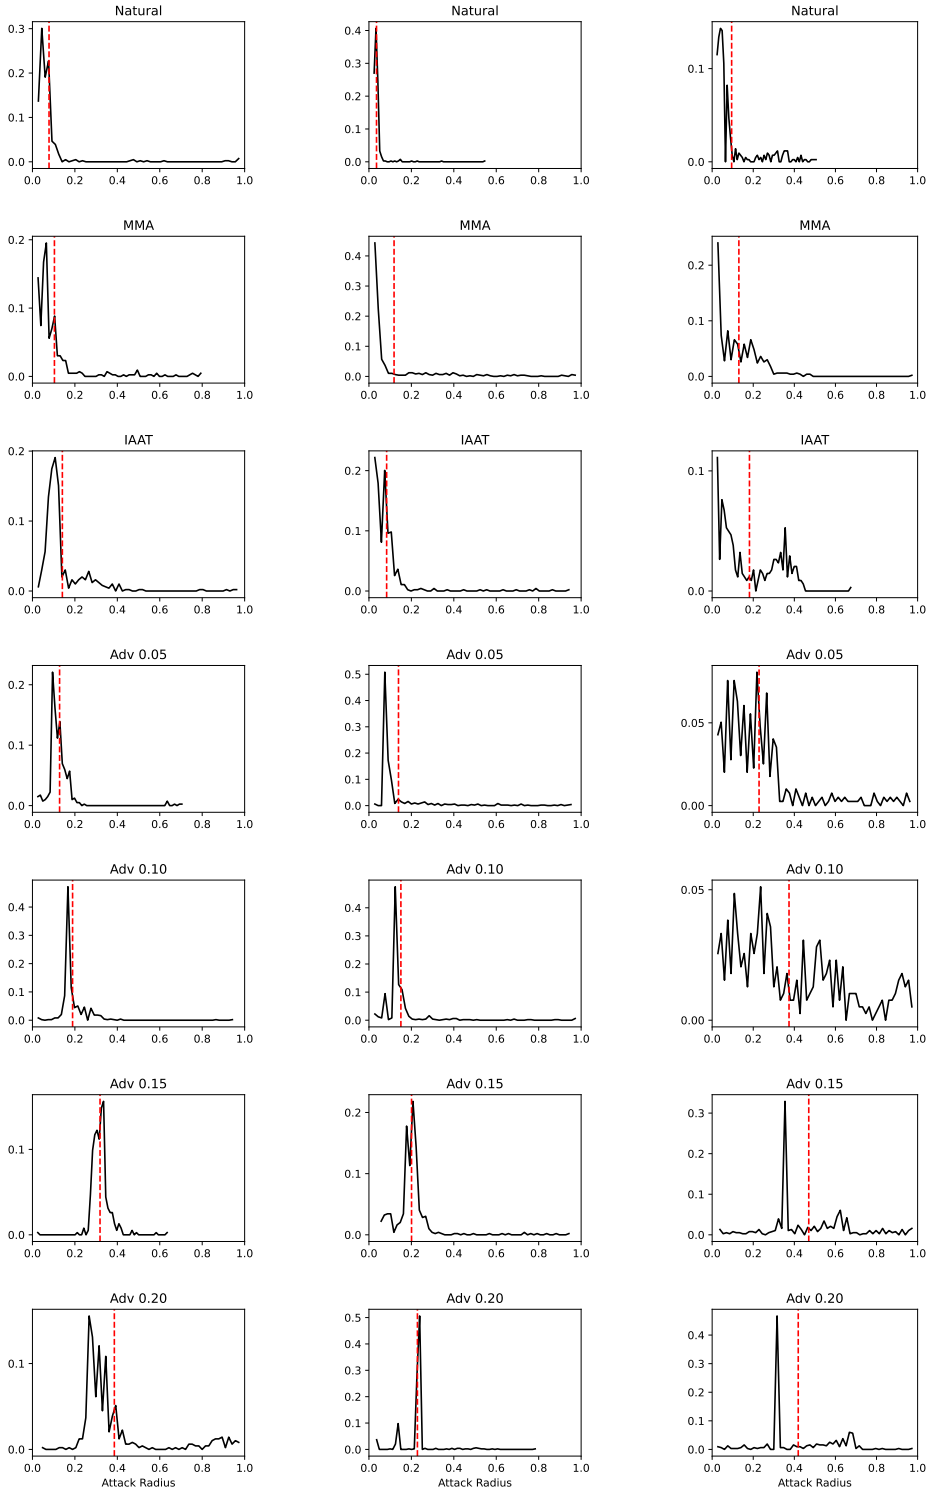
Counterfactual Proximity. The primary metric regarding recourse we are interested in observing is the ultimate recourse cost between our resultant models. As each specific domain's cost function is not concretely defined, we follow the convention of opting for ℓ_2 distance as a standard approximation. Formally, for each model we calculate: $\frac{1}{|\mathcal{D}_{test}|}\sum_{x_i \in \mathcal{D}_{test}} ||x_i^* - x_i||_2$, where x^* is the recourse calculated for x_i.

Manifold Proximity. Motivated by the question of how faithful our resulting counterfactuals are to true movements towards the desired class, we estimate the distance between the counterfactuals each model produces and the desired class manifold these counterfactuals approximate. We use two methods for this: a KNN distance measure and a sphere distance measure For KNN, we record the average ℓ_2 distance between the resulting counterfactuals and the five nearest neighbors of the desired class. For the sphere measure, we record the average ℓ_2 distance between the resulting counterfactuals and all neighbors of the desired class within an ℓ_2 ball of size ϵ, where ϵ is calculated as 20% of the average ℓ_2 distance between any two points in the dataset.

6 RESULTS & DISCUSSION

Standard Performance. Figure 2 displays the classification accuracy and F1 scores of the various models. We observe that for the Adult and Heloc datasets, adversarial training tends to decrease standard performance, with higher training radii correlating with worse performance. We observe that MMA training tends to keep performance consistent, and that AAT worsens performance to a degree similar to adversarial training with an ϵ value between 0.05 and 0.1.

Robustness. Figure 3 shows the vulnerability of the models under PGD attack at a variety of raddii ($\epsilon \in [0.05, 0.1, 0.15, 0.2, 0.25]$). We observe that while traditional adversarial training creates substantially more robust models within a defined radius of attack, the degredation in robustness tends to be more severe among traditionally trained models than AAT methods when the radius increases beyond their predefined training threshold. MMA in particular



(a) Adult (b) GSC (c) Heloc

Figure 8: Decision boundary proximity, estimated by the minimum successful PGD attack radius on a sample of 1000 instances. The height represents a proportion of the data, the average distance is shown in red.

shows surprisingly consistent robustness benfits, although they are more moderate than their adversarially trained counterparts'.

Counterfactual Proximity. Figure 6 displays the cost of recourse across all datasets for the three recourse methods studied. We observe consistently that adaptive adversarial training yields recourse with lower costs than traditional adversarial training, and in the case of MMA costs that are consistently competitive with natural training. This result seems unintuitive given the robustness benefits that MMA provides, and we believe this presents an interesting avenue for further research.

KNN & Sphere Manifold Distance. Figure 7 shows the Manifold Proximity estimates for Growing Spheres across all datasets. We observe that adaptive adversarial training produces recourse that is consistently closer to the desired class manifold than traditional adversarial training. This result, paired with the reduction in recourse costs, may suggest that adaptive adversarial training encourages more natural decision boundaries than traditional adversarial training, allowing for more meaningful recourse at lower costs.

Prevalence of Low Cost Recourse. For recourse methods that optimize costs directly in the input space, we record the percentage of counterfactuals that have an ℓ_∞ cost less than 0.05 to measure the proportion of low cost recourse among our models. The results are recorded in Figure 4. We observe that adaptive adversarial training shows higher proportions of low cost recourse than traditional adversarially trained models; surprisingly, MMA training in particular finds proportions of low-cost recourse that are consistently competitive with natural training, despite its benefits in overall robustness.

Discovered Radii & Decision Boundary Distances. Figure 5 displays the instance-wise discovered radii after AAT for all three datasets. We observe that for all datasets, a variety of radii are found with unique distributions. This alludes to the fact that different underlying data distributions have different levels of inherent adversarial vulnerability, underscoring the challenge of estimating a proper singular radius at which to adversarially train. Figure 8 shows an estimation of the distribution of decision boundary proximities across all models, calculated by finding the minimum successful radius for PDG attack across a sample of 1000 instances. We observe that traditional ϵ-adversarial training often limits proximity to the decision boundary $d > \epsilon_i$, while adaptive adversarial training shows a greater distribution in ultimate decision boundary proximties. In the case of MMA in particular, we find that the decision boundary proximities closely match that of the natural model, despite its improved robustness.

7 CONCLUSION

This work explores the effects of adaptive adversarial training on robustness and recourse, finding that it shows promising trade-offs between the two. We motivate our work with a observation of the effect of traditional adversarial training on recourse costs, and introduce scenarios under which adaptive adversarial training provides more affordable recourse. We conduct experiments on three datasets demonstrating that adaptive adversarial training yields significant robustness benefits over natural training with little cost incurred on recourse and standard performance, and provide evidence that adaptive adversarial training produces recourse that more faithfully represents movements towards the desired class manifold. Finally we analyze the resulting models' decision boundary margins, providing evidence that supports our observations on recourse costs under traditional adversarial training. We believe that adaptive adversarial training, and Max-Margin adversarial training in particular, presents a promising means of achieving the ultimate goals of robustness while preserving affordable recourse costs for end users.

ABSTRACT

Feature selection is a crucial step in building machine learning models. This process is often achieved with accuracy as an objective, and can be cumbersome and computationally expensive for large-scale datasets. Several additional model performance characteristics such as fairness and robustness are of importance for model development. As regulations are driving the need for more trustworthy models, deployed models need to be corrected for model characteristics associated with responsible artificial intelligence. When feature selection is done with respect to one model performance characteristic (eg. accuracy), feature selection with secondary model performance characteristics (eg. fairness and robustness) as objectives would require going through the computationally expensive selection process from scratch. In this paper, we introduce the problem of feature *reselection*, so that features can be selected with respect to secondary model performance characteristics efficiently even after a feature selection process has been done with respect to a primary objective. To address this problem, we propose REFRESH, a method to reselect features so that additional constraints that are desirable towards model performance can be achieved without having to train several new models. REFRESH's underlying algorithm is a novel technique using SHAP values and correlation analysis that can approximate for the predictions of a model without having to train these models. Empirical evaluations on three datasets, including a large-scale loan defaulting dataset show that REFRESH can help find alternate models with better model characteristics efficiently. We also discuss the need for reselection and REFRESH based on regulation desiderata.

1 INTRODUCTION

Machine learning models are increasingly being used in pivotal and sensitive industries such as finance [2, 3, 16], where big tabular datasets having millions of records across hundreds of dimensions (features) is common. Among a plethora of challenges, one question that model developers face is feature selection [9, 34]. Feature selection aims to reduce the dimensionality of the data used to train the model while maintaining a model performance characteristic, which is often a measure of model accuracy.

However, considerations beyond a specific measure of accuracy are imperative. Such model performance characteristics can include, but are not limited to pillars of responsible artificial intelligence [7, 15]: fairness, explainability, and robustness. These characteristics towards building trustworthy models are essential to satisfy regulations [11, 38, 50]. When features are selected based on one primary model performance characteristic, such as accuracy, features that contribute towards secondary characteristics could have been dropped. This could occur in two ways: (a) features that make a secondary characteristic better were dropped, and (b) features that make a secondary characteristic worse were included.

When machine learning models have already been deployed with features selected based on a primary characteristic, a potential solution is to go back to the original model development process and select features with multi-objective characteristics to account for secondary characteristics. [18, 44]. However, feature selection in large-scale datasets is an expensive process [10]. Furthermore, multiple objectives could be at odds with each other [21, 47, 54] and selecting features satisfying more than one objective still remains non-trivial. As research in responsible AI and regulatory requirements for machine learning models rapidly advance, new metrics are being developed to evaluate model performance, both within [28, 41] and beyond [49] the secondary characteristics discussed above. As the research community further investigates and devises

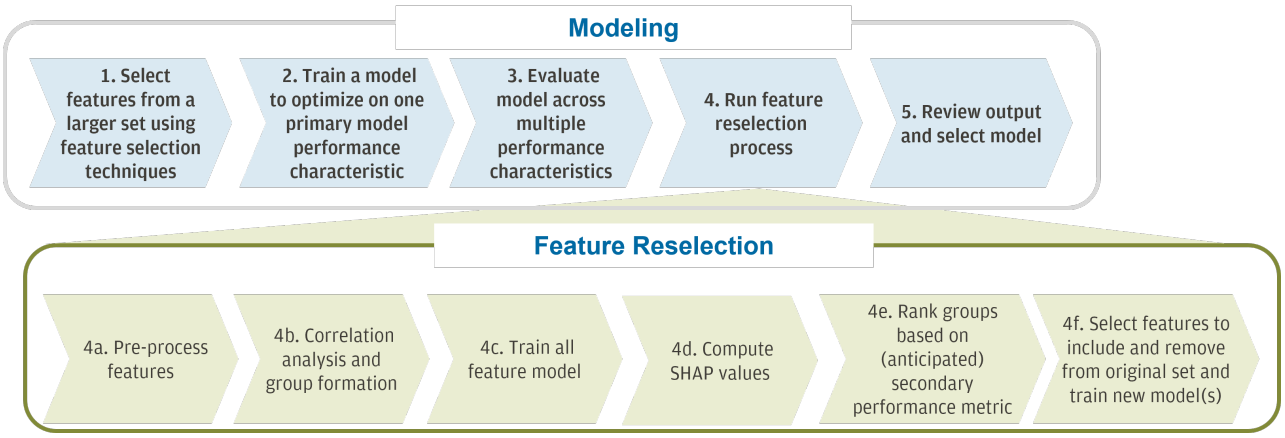

Figure 1: Standard model training and the framework for REFRESH. The top block shows the conventional steps to train a model (additional steps may also be used for model training, but we show the ones most relevant to the problem). This paper introduces the feature reselection process in step 4. The bottom block describes REFRESH

these metrics, starting model development from scratch for existing models to optimize on new metrics is extremely expensive.

Hence, we introduce the process of *feature reselection*. Feature reselection aims to select features to improve on secondary model performance characteristics (characteristics that become important to consider after a model is already developed) while maintaining similar performance with respect to a primary characteristic based on which features were already selected. Hence, reselection tries to find feature subsets that: a) include features that improve the secondary characteristic compared to the secondary characteristic of the model trained using features selected, b) do not include features that are detrimental to the secondary characteristic, and c) do not differ significantly from the feature subset that was used to train the model to optimize on a primary characteristic to maintain performance.

Reselection is not just useful for a model developer to save on time and effort when a model has already been deployed, but can be an extremely valuable tool for model monitoring. Specifically, the reselection process is agnostic to model metrics and can be run by a third-party monitoring the model. The process can help get insight into features that should or should not have been considered in the modeling pipeline, with respect to sensitive factors. Such information may not be available to a modeler. For example, in characteristics such as fairness, regulations require that sensitive attribute information and strong proxies to sensitive information are not available to modelers as features [50, 52]. Feature selection with fairness as a constraint becomes a much harder problem in the absence of the protected attribute. In these cases, the reselection process can then be done by a third-party that stores the sensitive information [51], to then suggest feature changes to modelers that can enhance fairness (such features would be weak proxies to sensitive information and do not provide direct information about the protected attribute, in accordance with legal requirements [50]).

To address the problem of feature reselection, this paper introduces REFRESH: Responsible and Efficient Feature Reselection guided by SHAP values. REFRESH is agnostic to the model type (only requires prediction probabilities of a model) and to the primary and secondary performance characteristics (only requires a score for any model characteristic). The framework for REFRESH is shown in Figure 1. Key steps in conventional machine learning model development involve feature selection, training a model to optimize on a primary performance characteristic, and evaluating the model along this characteristic before deployment. However, when the model is evaluated along a secondary characteristics, the same model may perform poorly. This is where the process of feature reselection is introduced, rather than re-computing models from scratch.

Originally, to reselect features, a modeler would train new models on new feature subsets, across various trials of different feature subsets. This process can be very expensive with a large number of features. Additionally, it is hard to accomplish if the secondary characteristic computation requires sensitive information, since this is not available to a model developer. Hence, we introduce an efficient way to find alternate feature sets, without having to train a large set of new models. The feature reselection steps are shown in the bottom block of Figure 1 and the steps are as follows: a) pre-process the set of all features; b) perform correlation analysis to create disjoint sets of groups of features, where groups are formed based on correlation between features (to be used in step e); c) train a model with all features; d) compute SHAP values ([36]) for each feature used to train the all feature model; e) use the SHAP values to approximate for model outcomes of models that would have been trained by removing each group and then rank each group of features formed in step b) based on anticipated effect of features on a secondary model performance characteristic; and f) select features to remove from the set of features selected by the modeler that have the most negative effect on the secondary characteristic and select features to include from the set of features that were not selected by the modeler that have the most positive effect on the secondary characteristic. Finally, train new models using these sets and provide alternate models.

The spine of REFRESH lies in using correlation based grouping of features and utilizing the additive property of SHAP values based feature attributions. SHAP [36] is a popular feature attribution technique [7] and follows the additive property: the feature attributions sum to the model prediction for a given input. We show that combining this property of SHAP values with correlation analysis on groups of features provides a reasonable approximation to model outcomes of models trained in the absence of a group of features, without having to actually train these models. This significantly speeds up the ability to search for alternate models that can improve performance.

We show that REFRESH can help "refresh" a model to accommodate secondary characteristics i.e. find alternate models along multiple secondary characteristics, by experimentation on three datasets, including a large-scale loan defaulting dataset. The discussion section provides further insight into why reselection is needed, limitations of REFRESH, and the applicability of REFRESH based on regulations [50]. The key contributions of this paper are[1]:

- Introducing and motivating the research problem of feature reselection for incrementally improving secondary model characteristics;
- A novel approximation to model outcomes that uses grouping of features based on correlations, and SHAP values;
- REFRESH: an efficient method to reselect features that leverages this approximation.

2 RELATED WORK

While the concept of reselection is new (to the best of our knowledge), this section points to resources for related work in the fields of feature selection, responsible AI, and within responsible AI, SHAP values.

Features selection has been a well studied problem in the machine learning literature. [35, 40] cover the most popular feature selection methods, with an emphasis on selection based on accuracy as a performance objective.

Responsible AI includes fairness, adversarial robustness, explainability, and privacy of machine learning models [45]. Models are considered more interpretable if less features are used to train the model [42]. Feature selection based on fairness considerations [20, 25–27, 44] is a growing field of research. Recently, [18] suggest a feature selection technique with both fairness and accuracy considerations. The method requires access to protected attributes, which are often not available. REFRESH only requires a fairness score, which can be provided using privacy-preserving methods [12, 22]. [53] propose a feature-importance-based improvement to adversarial robustness for CNN's. [4] discuss a method for fairness-based feature selection under budget constraints. Features selection with considerations on adversarial robustness for models trained using tabular datasets remains an unexplored problem.

SHAP (SHapley Additive exPlanations) [36], a game theoretic approach to explain the output of any machine learning model, is a widely used technique in explainability of machine learning models. It is used to provide the feature importance for every feature used to train a model with extensions for fairness [5]. [14] propose a method for feature selection using SHAP values. [24] provide a detailed analysis on using SHAP values for feature selection. [17] use SHAP values of features for feature selection by using these values in a multi-objective optimization problem. [39] show that SHAP values based selection performs better than three other feature selection techniques.

3 REFRESH: THEORY AND METHOD

This section presents the theory, the core REFRESH method, and additional constraints that can be important for the feature reselection problem.

Setup: Consider a dataset with $\mathbf{N}$ features. The set of all features is $\mathbf{S_N}$. Let a feature selection method select a set of features to train a model for binary classification. The selected set of features is called the baseline set $\mathbf{S_b}$. Let the remaining feature set be the candidate set $\mathbf{S_c}$. Then:

$$\mathbf{S_b} \cup \mathbf{S_c} = \mathbf{S_N} \tag{1}$$

$$\mathbf{S_b} \cap \mathbf{S_c} = \{\} \tag{2}$$

Correlation Analysis: Step 4a in Figure 1 requires pre-processing $\mathbf{S_N}$. Then, construct a graph of pairwise correlations between features and use a clustering algorithm to get groups of similar features (step 4b in Figure 1). Let $\mathbf{G_i}$ represent the i^{th} group. If k groups are formed then:

$$\mathbf{G_1} \cup \mathbf{G_2} .. \cup \mathbf{G_i} .. \cup \mathbf{G_k} = \mathbf{S_N} \tag{3}$$

$$\mathbf{G_i} \cap \mathbf{G_j} = \{\}\ \forall 1 \leq i \leq k, 1 \leq j \leq k, i \neq j \tag{4}$$

Consider a machine learning model f trained on the all feature set $\mathbf{S_N}$ (step 4b in Figure 1) such that the prediction probability $\mathbf{y}$ for a given input instance $\mathbf{x}$ is:

$$\mathbf{y}_{\mathbf{S_N}} = f(\mathbf{x}_{\mathbf{S_N}}) \tag{5}$$

SHAP Values Computation: Compute the SHAP values of every feature in $\mathbf{S_N}$ for model $f(\mathbf{S_N})$. Let the SHAP value for feature a for an input instance $\mathbf{x}$ be $\phi_a^{\mathbf{x}}$. SHAP values follow the additive [2] property [36]:

$$\mathbf{y}_{\mathbf{S_N}} = \sum_{p=1}^{N} \phi_p^{\mathbf{x}} \tag{6}$$

In other words, SHAP values can be understood as a (local) linear model approximating the contribution of each feature when included [36]. For a given input, the sum of these contributions equals the prediction probability of the model output for this input. Therefore, we could calculate (anticipatedly) the outcome of a model when a feature a is absent as:

$$\mathbf{y}_{\mathbf{S_N} \setminus a} = \mathbf{y}_{\mathbf{S_N}} - \phi_a^{\mathbf{x}} \tag{7}$$

However, this calculation will not be accurate and outcomes can significantly differ from true model outcomes i.e. when feature a is not used to train the model [13, 19, 24, 33]. In fact, (interventional) SHAP simulates the removal of features by marginalising over their marginal distributions and not by re-training a new model

[1] This works goal is not to provide models with optimal characteristics. Instead, the paper aims to introduce the research problem of feature reselection and provide a possible method to efficiently do this reselection. REFRESH can help find models that can perform better along multiple characteristics, but there are no guarantees on optimality. This is discussed further in experiments.

[2] a.k.a., *efficiency* in game theory [46].

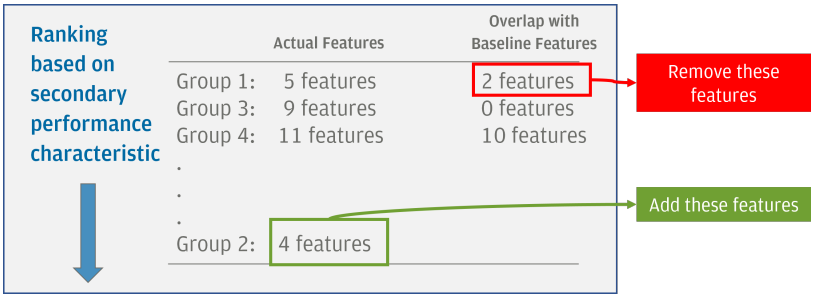

Figure 2: Ranking of groups based on secondary performance characteristic and the reselection process using this ranking.

without such features [36]. A simple example of why this occurs is as follows: if feature a is perfectly correlated with b and a model is trained using just a and b, it may happen that the model used only feature a, therefore b will have a SHAP value of 0 and the SHAP value of a will be equal to the model prediction probability. However, if feature a is removed and a model is trained with just feature b, the outcomes would be the same as the first model, but the model outcomes calculated using Equation 7 would be 0.

SHAP Values based Approximation: REFRESH posits anticipating model outcomes based on the removal of a group of features, where features are grouped based on correlations. Combining Equations 3 and 7, approximate that:

$$y_{S_N \setminus G_i} \approx y_{S_N} - \sum_{p=l}^{m} \phi_p^{\mathbf{x}} \tag{8}$$

where,

$$\mathbf{G_i} = \mathbf{S_{l,\ldots,m}} \tag{9}$$

Equation 8 gives a better approximation when compared to directly using SHAP values. It is used to anticipate model outcomes without having to retrain new models (we show that this approximation is better empirically). Specifically, this enables REFRESH to anticipate (approximately) the outcome of a model when a group is absent from model training.

Feature Removal and Inclusion: These anticipated model outcomes can then be used to calculate anticipated secondary performance characteristics. For each $\mathbf{G_i}$, use the anticipated model outcomes and calculate an anticipated score of the secondary characteristic for each anticipated model, where each model corresponds to a model trained with the feature subset $\mathbf{S_N \setminus G_i}$. Note that the score computation can be done by a third-party, thereby ensuring that sensitive information is not revealed to a model developer [50] for secondary characteristics like fairness. The groups are then ordered in decreasing order of scores.

Figure 2 shows a toy example with feature groups that are ranked based on an anticipated secondary performance characteristic. Group 1 is ranked highest, which means that the anticipated (secondary characteristic) performance of the model when Group 1 was excluded from training was highest. This means that features from Group 1 are anticipated to be the most detrimental to the secondary characteristic. Hence, starting from the baseline set (to maintain the performance based on the primary characteristic) we would want to select a model with the feature subset:

$$\mathbf{S_{reselected}} = \mathbf{S_b \setminus G_1} \tag{10}$$

Furthermore, Group 2 is ranked the lowest, which means that a model trained by removing Group 2 has an anticipated secondary performance characteristic which is lower. This means that features from Group 2 could contribute to a better secondary performance characteristic, and hence we include features from this group. Hence, we would want to select a model with feature subset:

$$\mathbf{S_{reselected}} = (\mathbf{G_2 \setminus (G_2 \cap S_b)}) \tag{11}$$

Generalizing Equations 10 and 11, the feature subset to train a model after removing group G_r and including feature G_i is:

$$\mathbf{S_{reselected}} = (\mathbf{S_b \setminus G_r}) \cup (\mathbf{G_i \setminus (G_i \cap S_b)}) \tag{12}$$

This process of removal and inclusion can be continued for more groups to generate new feature subsets that can be used to train alternate models. We discuss the choice of number of groups that should be considered for inclusion or removal in the experiments section.

3.1 Additional Constraints

In the feature reselection process, features are being added and removed with the objective of improving the secondary performance characteristic while maintaining the primary performance characteristic. However, involving a human-in-the-loop may ensure that features are not erroneously included or removed. Examples of errors are:

- Features that are important for a classification task based on human judgement, and that maybe obviously important for the primary characteristic, are removed. This can especially occur when the primary and secondary characteristic are inversely related for the data and model under consideration. These features are important to explain the model prediction [50]. For example, address is removed in a housing price prediction problem (because it could serve as a proxy for race) when a modeler thinks this feature is most important. Let these features be $\mathbf{S_{RE}}$ (Where RE means Removal Error).
- Features that should not be included based on human judgement and were removed as a part of feature selection are now included in the reselected set. For example, a feature with a lot of noisy values from the data collection process was removed with human insight, but is now included because it

erroneously contributes to the secondary characteristic. Let these features be $\mathbf{S_{IE}}$ (Where IE means Inclusion Error).

REFRESH can easily incorporate these additional constraints that can be provided by modelers, so that erroneous features are not included or removed. The final reselected set is:

$$\mathbf{S_{reselected}} = ((\mathbf{S_b} \backslash \mathbf{G_r}) \cup \mathbf{S_{RE}}) \cup ((\mathbf{G_i} \backslash (\mathbf{G_i} \cap \mathbf{S_b})) \backslash \mathbf{S_{IE}}$$

4 EXPERIMENTS

This section presents the context of the experimentation, results on applying REFRESH and validation experiments on the SHAP values based approximation.

4.1 Context and Setup

Data: Experiments are performed on three datasets: COMPAS [43], HMDA [30], and the large-scale home credit default risk dataset [31]. We have used existing work to pre-process datasets and select baseline features, and refer to those works here. Additionally, we ensure that protected attributes (race, gender, age) are removed for model training, in accordance with legal requirements for model development. Details on the datasets and models used for them can also be found through these references. For the home credit default risk dataset, information and details on pre-processing can be found in [32]. For the COMPAS dataset, we use methods as in [26]. For the HMDA dataset, we use the same pre-processing and baseline set as in [48]. This section focuses on experiments for the home credit default risk dataset since it has a large set of features, but experiments to validate REFRESH using the other two datasets are also provided (The COMPAS dataset is particularly useful for a qualitative validation of feature reselection by comparing to feature selection used in [26]).

HomeCredit is a company that provides installment lending to people with poor credit history. In 2017, they made anonymized data available on Kaggle which includes individual demographics and loan outcomes. The raw data consists of millions of records and a total of 649 features. We pre-process the data similar to [31], so the final number of observations considered are 307,511 and the total number of features are 466.

Objective: REFRESH is model performance characteristic agnostic, and only requires a score for any model characteristic so that models can be ranked based on this secondary characteristic. The goal of the experiments is not to show models with optimal performance; rather, we show that we can find multiple alternate models showing varied model performances, including better performance along the secondary characteristic using REFRESH, and this is much faster than having to use brute force based search for reselection. This is in accordance with the aim to find less discriminatory alternatives [50], when the secondary characteristic is fairness. Additionally, we show that the approximation using SHAP values that is proposed in this paper (Equation 8) performs better than using just SHAP values (Equation 7).

Primary Characteristic: To show the ability of REFRESH to suggest alternative models, we consider the model AUC to be the primary model performance characteristic.

Secondary Characteristics: Experiments are performed for two different secondary characteristics (evaluated independently): fairness and adversarial robustness. These are just illustrative measures, and other model performance characteristics can also be considered. For fairness, the secondary characteristic considered is demographic parity. Statistical parity difference is used to measure demographic parity [6]. Given a model trained on a dataset with a protected attribute A having two groups a and b, where a is the sensitive group and Y is predicted output (thresholded prediction probability), the statistical parity difference is defined as:

$$SPD = P(\mathbf{Y} = 1|A = a) - P(\mathbf{Y} = 1|A = b) \tag{13}$$

For robustness, we consider using the notion of the distance to the boundary in the model output space, similar to [47]. Specifically, if a point is closer to the decision boundary, the point is less robust (vulnerable to perturbations), and correspondingly, the prediction probability $\mathbf{y}$ is closer to the decision threshold δ set for binary classification. For any model, this can be calculated as:

$$ROB = |\delta - \mathbf{y}| \tag{14}$$

Experimentation Setup: Experiments for the home equity credit risk dataset are performed as follows: first, features are selected with the primary performance characteristic of AUC. Similar to [32], features are pre-processed. Sensitive attributes are removed for model training and are only used to compute the fairness score. Then, an XGBoost model is trained on all the features left after pre-processing, and the most important features based on feature importance scores are selected. A model is then trained with these features ($\mathbf{S_b}$), and this is the baseline model. For the home credit default risk dataset, 184 features are selected as the baseline feature set.

Correlation Analysis: Simultaneously, all features after pre-processing are grouped based on correlation. This is done by using the popular Louvain method for community detection [8, 37]. The method is a greedy optimization method that runs in time $O(n \cdot \log n)$ where n is the number of nodes in the network. The correlation of features defines whether a feature belongs to a community, and a correlation threshold is passed to define what constitutes a high correlation. For the home credit default risk dataset, this threshold is set to 0.7. Experiments on varying this threshold are also provided.

Feature Reselection: An XGBoost model is trained using all features and SHAP values are computed for this model for every feature. For each group of features, the anticipated model outcome (prediction probabilities)) for a model that would be trained by removing this group is calculated using Equation 8.

Then, the secondary performance characteristic is calculated using Equations 13 (for fairness)) or Equation 14 (for robustness) using these anticipated outcomes. Groups are then ranked in descending order based on the value of the secondary performance measure. For each group, the intersection with the baseline set is also found. Then, features that intersect with the baseline set from the top groups are removed and features that do not intersect with the baseline set from the bottom sets are added. Two hyperparameters, one for maximum number of features that can be included

and one for maximum number of features that can be removed, are used.

Starting from the highest rank, for each group, all features are removed (up to the maximum removal limit; if the limit is reached for some features of a group, remove a random subset). Starting from the lowest ranked group, only a certain number of features are included per group, and then the next group is considered to include features, until the maximum limit of inclusions (this is also a hyperparameter called number of inclusions per group). We only include some but not all features because groups are formed based on correlations, and including too many features from a group will not significantly impact any change in the model.

4.2 Results for the home credit default risk dataset

On Fairness: Results for the fairness measure are shown in figure 3(a). All results are averaged over three runs. Each point on the graph is a model trained using a different subset of features (found using different inclusions and removals). The baseline model is marked by the intersection of the red lines. Starting with 5 features per group, and going up to a maximum of 50 features that can be included or removed, subsets are formed with combinations of inclusions and removals. Hence, one subset has 5 features included in the baseline, another has 5 features removed from the baseline, and a third would have a combination of these 5 included and the other 5 removed. This is done in increments of 5 features, until the maximum limit of inclusion and removals is reached (50). Hence, a total of 121 models is shown. The color of each model represents the number of features used to train the model.

The fairness of each model, in accordance with Equation 13 is plotted on the y-axis, and model AUC's are plotted on the x-axis. As we can see, several alternate models are found with varying degrees of fairness and AUC. It is interesting to note that while several models are found with an increase in fairness that also compromise on AUC (which is in accordance with expected trade-offs between fairness and accuracy [21], there is one model with a larger set of features (compared to the baseline set) that has both a better fairness score and AUC. The increase in AUC is marginal, and within the threshold used to remove features in the original selection process. While it may appear that the increase in fairness is also marginal, the need to find less discriminatory alternatives still arises based on regulations [50], and the impact of a small increase on a dataset with millions of samples is more pronounced on individuals (more pronounced effects on fairness can be seen for the COMPAS dataset in experiments provided later). REFRESH provides a set of alternate models which can be chosen from, and the specific choice is dependent on the modeler or the regulator. It is key to note though that varied alternate models are found with just 121 more models being trained, as opposed to training a much larger set of models for hundreds of possible features.

While REFRESH does not guarantee optimality on models found with respect to any performance metric, it efficiently informs a modeler or regulator on the direction of the search space. Specifically, with being informed about which features can be added or removed to improve or reduce the secondary performance characteristic, far fewer models need to be trained, and the whole feature selection process does not need to be repeated. Further insight on alternate models can be gathered through an investigation such as the one shown in figure 3(c). The plot shows a subset of points from the fairness plot above, where every alternate model has the same exact number of features as the baseline model. Among these models, the frontier showcases two models, one that has the highest accuracy and the other that has the highest fairness. A modeler can decide which one to choose (based on which measure is more important to the application), while keeping the number of features to be similar to the baseline set (to maintain model complexity and explainability).

On Robustness: Similar results are shown for the robustness performance characteristic in figure 3(b) and (d). The hyperparameters for number of inclusions and removals (and limits) are the same as for the fairness plot. Better alternate models with respect to both robustness and AUC are found. However, it is clear that these models have more features than the baseline set. 3(d) shows models that have the same number of features as the original model. Results indicate that to maintain the same model complexity, a trade-off between AUC and robustness is required. A modeler or a stakeholder monitoring/regulating can choose which model suits the requirements for the specific task.

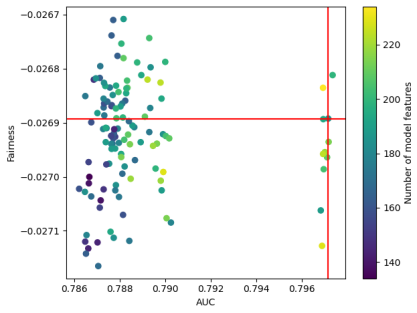
4.3 SHAP values based approximation

To check that the proposed SHAP values based approximation (Equation 8) of the model output performs better than using SHAP values without considering groups of features when groups are formed based on correlations, a comparison of two cases is done on the anticipated versus the actual model AUC, where: (a) the first case considers the AUC found for models trained (or anticipatedly trained) by removing an entire group from the all feature set, in accordance with Equation 8; (b) the second case considers model outcomes for models trained (or anticipatedly trained) by removing just one feature per group, in accordance with Equation 7.

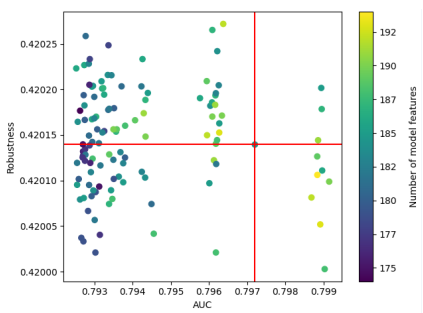
Results are shown in figure 4. The red line indicates the ideal plot. The graph on the left shows anticipated outcomes against the actual outcomes when anticipated outcomes are found using the approximation used in REFRESH. Anticipated model AUC's are relatively close to those of ideal models, showing that the SHAP approximation using groups of features holds reasonably. On the other hand, when correlated features are not grouped together, the anticipated outcomes of the removal of individual features are incorrectly estimated by Equation 7. The anticipated AUC is always less than the actual AUC. This happens because the anticipated outcome is based on the SHAP value of the feature to be removed. When the actual model is trained (with the removal), another feature belonging to the same group can take a higher SHAP value than what it had before (replacing the effect of the old feature). Hence, the true effect of removal is minimal, but seems more pronounced by using SHAP without grouping features to find anticipated outcomes.

4.4 Additional Details and Experiments

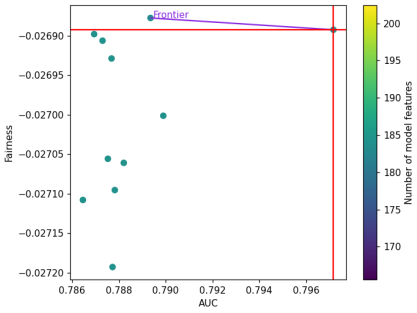
4.4.1 Effect of correlation threshold on the SHAP approximation. The SHAP approximation relies on forming groups of correlated features to find anticipated model outcomes when each group is removed. Hence, how close the anticipated outcomes are to true



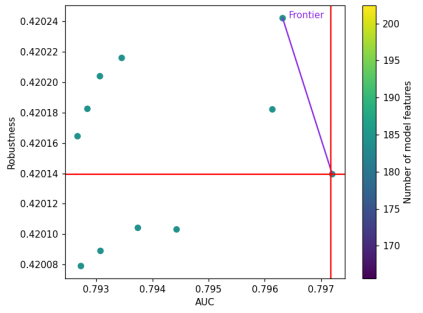
(a) Fairness



(b) Robustness

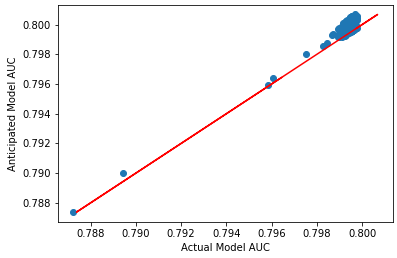


(c) Fairness, $n(S_{reselected}) = n(S_b)$

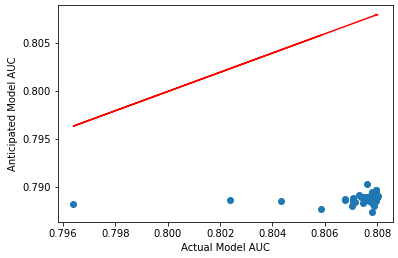


(d) Robustness, $n(S_{reselected}) = n(S_b)$

Figure 3: Alternate models found using REFRESH for two secondary performance characteristics: fairness ((a) and (c)) and robustness ((b) and (d)). Each point in the figure corresponds to a model trained using a different set of features. The intersection of the red lines is the baseline model. The reported metrics are the true measures and not anticipated values. The color of each point shows the number of features used to train the model. (b) and (d) show a subset of models from the fairness and robustness graphs (a) and (c) respectively, where each model has the same number of features as the baseline model.



(a) REFRESH (grouping features based on correlations)



(b) Without any grouping

Figure 4: Understanding the correlation grouping based SHAP approximation. Both graphs show the anticipated model AUC's against the actual model AUC. In (a), each point on the graph represents the anticipated versus actual AUC of a model trained with all features except all features from one group. In (b), each point on the graph represents the anticipated versus actual AUC of a model trained with all features except one feature (chosen at random) from one group. The red lines show the ideal plot (where anticipated AUC = actual AUC).

model outcomes depends on the correlation threshold for group formation. To study this, we find the difference in the anticipated and actual model AUC's for models formed by removing each of the groups. Fairness and robustness also depend on model outcomes, and a difference between true and anticipated values of these characteristics observe a similar effect to AUC, so these plots have been omitted.

Figure 5 shows the maximum difference between anticipated and actual AUC's of models when different correlation thresholds are used to form groups. As we can see, very low correlation thresholds would cause the approximation to suffer much more than choosing a very high correlation threshold. However, a high correlation threshold would result in more groups being formed which would result in more calculations for anticipated outcomes and hence

slower performance. Having a relatively higher (0.7) correlation threshold works the best, and this is observed across datasets.

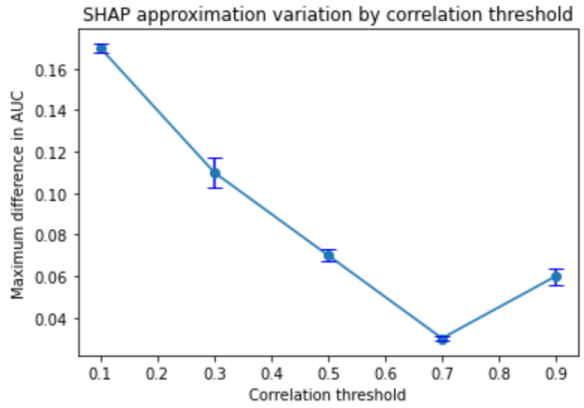


Figure 5: Analysing the proposed SHAP approximation (for the home credit default risk dataset) via plotting the difference (lower is better) in actual and anticipated AUC's versus the correlation threshold chosen to form groups.

4.4.2 Model hyperparameters. For the XGBoost model used for the home credit default risk dataset, 50 tree estimators are used with a maximum depth of 5. All other parameters are kept to default values for scikit learn's XGBoost model. For the COMPAS dataset, 2 estimators are used (since the dataset is very small) with a max depth of 3. For the HMDA dataset, 10 tree estimators are used with a maximum depth of 5.

As features are added or removed, hyperparameter tuning may have to be repeated. For the purposes of this paper, since we do not remove or add too many features, the hyperparameters are kept the same across different models since experiments showed that changing these had negligible impact on model performance. However, as more features are included or removed, tuning of parameters maybe required for optimal performance on alternate models.

4.4.3 REFRESH hyperparameters. Three hyperparameters are associated with REFRESH: the maximum number of inclusions, maximum number of removals, and number of inclusions per group. To show the difference in performance as these parameters vary, we report the AUC and fairness scores associated for models trained on the home credit default risk dataset for three different values associated with these parameters where the models are chosen such that they have the best secondary performance characteristic.

The results are shown in tables 1, 2 and 3. As seen, having a small value for maximum removals or maximum inclusions yields sub-optimal performance on alternate models found. Having a very high value for these parameters does not help with the best model being found and would just increase the number of models being trained. For the number of inclusions per group, having a low value may result in some helpful features (with respect to the secondary characteristic) being neglected. Having a very high value does not help and just adds to the number of features, since inclusions are performed from groups of correlated features.

4.4.4 Confidence intervals. The average standard deviations for AUC, fairness and robustness measures are reported in table 4. The values are low, showing that results are consistent across runs.

4.4.5 Experiments on COMPAS and HMDA datasets. Results for alternate models for the two datasets are shown in Figure 6. As can be seen, multiple alternate performance with different secondary characteristics can be found with just a few more models being trained.

Additionally, it is interesting to note that the best performance point in the COMPAS dataset with respect to fairness in figure 6 corresponds to just having one feature, which is the same feature found in [26] as the only feature being selected which is the most fair to judge recidivism (prior counts). Hence, REFRESH is able to automatically find feature sets that correspond to fairer features.

Finally, the COMPAS dataset has very few features, so finding more robust models is harder. This is shown in the robustness plot, where removing a few features resulted in robustness similar to the baseline model, but with a compromise on performance. However, the model is more robust when more features are removed. This analysis shows that eventually, the performance of REFRESH, just like any feature selection algorithm, is limited by the availability of features that can help with the secondary characteristic.

4.4.6 Experiment on neural network. To illustrate with an example that REFRESH is model agnostic, we perform an experiment on using a neural network with the HMDA dataset for the fairness characteristic. The neural network architecture is the same as in [48]. The results are shown in figure 7. As we can see, the results are similar to the results in 6. The key difference in implementation is in the use of KernelSHAP for the neural network as opposed to TreeSHAP for the XGBoost model.

5 DISCUSSION

This section is focused on discussions, including limitations, on the three novel components of this paper: feature reselection, REFRESH's methodology, and applicability of REFRESH based on regulations and insights from consumer lending [50].

5.1 Feature Selection and Reselection

Feature reselection is not introduced to replace responsible feature selection. Instead, it aims to provide an alternate efficient technique in cases where: a) models trained using a large set of features have already been deployed with selected features based on a primary characteristic and require re-evaluation for additional characteristics, b) new regulations require finding alternate models that improve based on secondary characteristics, and c) new research drives the need to evaluate models along different characteristics.

To achieve these objectives, REFRESH has been developed to aid model redevelopment. Since ranking of feature groups only depends on a score and not on the actual definition of the secondary characteristic, new secondary characteristic definitions can be readily incorporated to find alternate feature subsets. It does not replace the need for human insight on features that should be included or excluded, but is a tool that helps guide reselection based on desirable model characteristics.

Table 1: Varying the maximum number of removals hyperparameter for the home credit default risk dataset

Performance	Max removals =5	Max removals = 50	Max removals =100
SPD	-0.2689	-0.0267	-0.0267
AUC	0.796	0.788	0.788

Table 2: Varying the maximum number of inclusions hyperparameter for the home credit default risk dataset

Performance	Max inclusions =5	Max inclusions = 50	Max inclusions =75
SPD	-0.272	-0.0267	-0.0267
AUC	0.797	0.788	0.788

Table 3: Varying the maximum number of inclusions per group for the home credit default risk dataset

Performance	Inclusion per group =1	Inclusion per group = 3	Inclusion per group=5
SPD	-0.274	-0.0267	-0.02672
AUC	0.7955	0.788	0.788

Table 4: Average standard deviation for different performance measures for the home credit default risk dataset when results are average across three runs

Performance	Standard deviation
Accuracy	0.00823
SPD	0.00194
ROB	0.00042

5.2 Limitations of REFRESH

A limitation of this method is that the accuracy of the REFRESH approximation depends on the structure and correlations of the data itself, and the ability to find groups of features based on correlations, such that these groups are disjoint. This may not always be possible, and the approximation may perform worse in cases where the disjoint groups of features cannot be formed easily. However, the method could still yield insights into features that help improve secondary performance characteristics. We note that resorting to alternatives such as Conditional and Causal SHAP [1, 23, 29] could mitigate this problem. However, on top of the technical challenges of estimating a causal graph of the features, doing so could result in features not used by the model having a non-zero importance, an issue certainly no less important in the feature reselection setting. Additionally, some other feature attribution techniques cannot be compared to because they do not follow the additive property, fundamental to use the approximation in Equation 8. Additionally, REFRESH hyperparameters may also require grid search, causing the efficiency to decrease to find alternate models. We leave the investigation of techniques to make REFRESH more efficient as future work.

5.3 REFRESH and Regulatory considerations

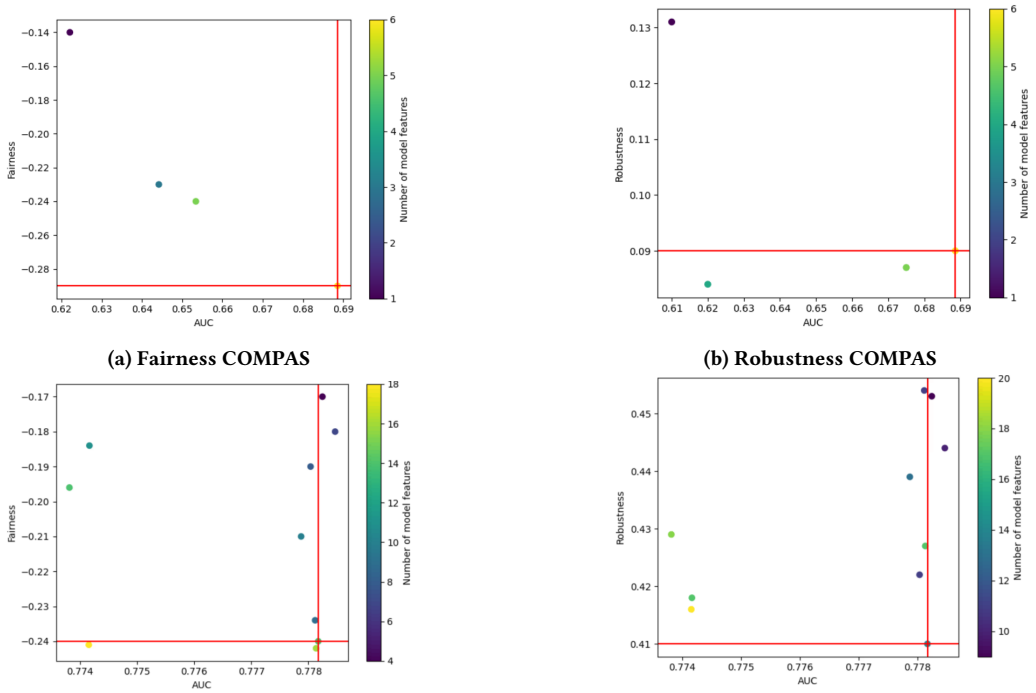
REFRESH is strongly motivated by findings from [50]. Regulations require that model developers do not use sensitive information in any model development procedure for critical applications. Additionally, there is a growing need to find less discriminatory alternative models for such applications, such as in home lending.

REFRESH helps provide less discriminatory alternatives without requiring access to sensitive information (and just requiring a score for fairness which can be computed by a third-party). Furthermore, providing additional constraints to control features that cannot be added or removed are in accordance with insights for explainability in [50]: features that can be explained by reason codes should be included.

Privacy based secondary characteristics [49] can directly be used in the REFRESH framework to select features that can cause the most leakage of data information, and these can be removed. Formally analysing privacy considerations for REFRESH is left as future work.

6 CONCLUSION AND FUTURE WORK

This paper introduces and motivates the problem of feature reselection. We then propose REFRESH: Responsible and Efficient Feature Reselection guided by SHAP values. REFRESH uses a combination of correlation analysis and the additive property of SHAP values to provide an approximation that can help find alternate models more accurately than directly using SHAP values. This can then be used to find models with improvements in secondary performance characteristics such as fairness and adversarial robustness. Experiments on three datasets, including a large-scale dataset in the finance domain, show that REFRESH can find several alternate models efficiently for multiple secondary performance characteristics. There are a plethora of possibilities that can be explored as future work. New methods can be created to deal with feature reselection, such that they could be more optimal with respect to the secondary performance characteristic. We choose SHAP values



(a) Fairness COMPAS

(b) Robustness COMPAS

(c) Fairness HMDA

(d) Robustness HMDA

Figure 6: Alternate models found using REFRESH for two secondary performance characteristics: fairness and robustness, and for two datasets: COMPAS (top) and HMDA (bottom). Each point in the figure corresponds to a model trained using a different set of features. The intersection of the red lines is the baseline model. The reported metrics are the true measures and not anticipated values.

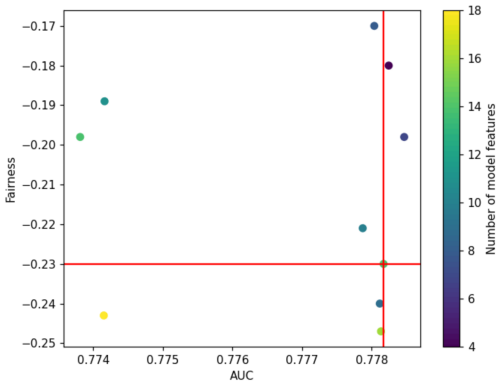


Figure 7: Results on fairness for a neural network trained using the HMDA dataset

because of their additive property, but other feature attribution techniques that follow this property can also be considered and compared to in the future. It would also be interesting to explore the ability to create groups of features that intersect inter-group so that the approximation is improved. Finally, the method can also be extended for experiments on additional secondary performance characteristics (eg. privacy).

ABSTRACT

Past research has demonstrated that the explicit use of protected attributes in machine learning can improve both performance and fairness. Many machine learning algorithms, however, cannot directly process categorical attributes, such as country of birth or ethnicity. Because protected attributes frequently are categorical, they must be encoded as features that can be input to a chosen machine learning algorithm, e.g. support vector machines, gradient boosting decision trees or linear models. Thereby, encoding methods influence how and what the machine learning algorithm will learn, affecting model performance and fairness. This work compares the accuracy and fairness implications of the two most well-known encoding methods: *one-hot encoding* and *target encoding*. We distinguish between two types of induced bias that may arise from these encoding methods and may lead to unfair models. The first type, *irreducible bias*, is due to direct group category discrimination and the second type, *reducible bias*, is due to the large variance in statistically underrepresented groups. We investigate the interaction between categorical encodings and target encoding regularization methods that reduce unfairness. Furthermore, we consider the problem of intersectional unfairness that may arise when machine learning best practices improve performance measures by encoding several categorical attributes into a high-cardinality feature.

1 INTRODUCTION

Anti-discrimination laws [3, 19, 20] prohibit the unfair treatment of individuals based on *sensitive attributes* (also referred to as *protected attributes*). The list of sensitive attributes varies per country, though these usually include gender, ethnicity, and religion [62]. Following such legal motivations along with societal expectations, many studies have looked into discrimination in machine learning and proposed various ways to promote fairness (e.g., [22, 44, 56, 65]).

Handling sensitive attributes throughout the machine learning pipeline is central to establishing fairness. An early common practice was removing data on sensitive attributes altogether. This technique has been questioned because sensitive attributes may be required for avoiding discrimination in data-driven decision models [37, 83]. Therefore, later work [30, 45, 79, 80] has aimed at how to obtain fairer models given the presence of sensitive attributes, formalizing the problem as an optimization trade-off between model quality in terms of performance and some fairness objective.

Sensitive attributes often come as categorical data. For instance, roughly 75% of the famous COMPAS dataset [35] consists of categorical attributes, including most of the sensitive ones (see Section 5.1.1 for more details). Many machine learning algorithms require categorical attributes to be suitably *encoded* as numerical data. Different ways of encoding categorical attributes into numerical features [32, 46, 49] have been proposed and extensively studied in the literature along with statistical regularization methods since the mid-1950s [54]. This has resulted in various methods that encode categorical attributes as numerical data to make them usable by popular machine learning models, such as support vector machines, gradient-boosting decision trees, or linear models.

In this paper, *we study the broader implications that encoding categorical sensitive attributes can have on model accuracy and fairness.*

Despite being a common machine learning practice, often within the data pre-processing step, the effects of categorical attribute encodings on fairness remain largely unexplored. For instance, prior works on fair machine learning [30, 79, 80] also use the encoding of protected categorical attributes without discussing its implications or the choices of encodings.

We focus on the two most widely used encodings: *one-hot encoding* and *target encoding* [49, 54, 58, 73]. *One-hot encoding*, an unsupervised technique, produces orthogonal and equidistant vectors for each category [49, 52], thereby considering the categories to be equally independent of each other and other attributes. However, when dealing with high cardinality categorical variables, one-hot encoding suffers from a lack of scalability and sparsity issues due to the creation of many orthogonal dimensions (later discussed in Section 2 and 3). *Target encoding* [46, 49, 54] is a supervised technique that replaces a categorical attribute with the mean target value of each corresponding category. Thus, it can handle all categories together in one dimension.[1]

The first problem of unfairness related to sensitive categorical attributes, which we call *irreducible bias*, is associated with the statistical differences between two highly populated groups: more data about the compared groups will not diminish this type of bias. The second problem arises because sampling from small groups may exhibit large variance leading to unfairness constituting *reducible bias*. Many datasets contain distributions of data that are imbalanced over different values of categorical attributes, often leading to performance degradation of the learned models (known as the *classes imbalance problem* [34]). Using encodings in such datasets may naturally introduce disparity per the observed class imbalance.

Moreover, when a dataset contains several sensitive categorical attributes, and these are merged to become one feature (a strategy often followed to improve model quality substantially [28]), encodings may create fine-grained, sparsely populated intersectional features [39, 40, 72] increasing the chance for both types of induced biases [23].

The effects of encodings on model quality and fairness under the interplay of different encoding and regularization techniques have not been studied in the literature. However, they affect very commonly used machine learning practices. For target encoding, we study two popular statistical regularization methods called *smoothing* and *Gaussian noise regularization*. These both regularization provide new avenues for analyzing the implications of categorical encodings on fairness. Through both a theoretical analysis as well as an empirical analysis using two real-world datasets, we find that suitable regularization can address unfairness arising from the target encodings with only marginal losses in accuracy.[2]

In summary, we make the following contributions:

- We compare the best-known categorical feature encoding methods, one-hot encoding, and target encoding against learning without protected attribute(s) in terms of model performance and fairness.
- We study the relationship between the regularization of target encodings and fairness by evaluating smoothing and Gaussian noise, two common techniques used for regularization by data preprocessing.
- We provide evidence that creating intersectional features can worsen discrimination. We show that a regularized target encoder can retain the benefits of intersectional features without increasing unfair discrimination.
- We provide a theoretical analysis studying two types of induced biases, irreducible and reducible, that arise while encoding categorical protected attributes.

2 BACKGROUND

2.1 Categorical attribute encoding

Handling categorical attributes is a common problem in machine learning, given that many algorithms use numerical data [49, 69]. There are many well-known methods for approaching this problem [4, 8, 9, 53, 70].

One-hot encoding (also known as dummy variables in the social sciences [74]) constructs orthogonal and equidistant vectors for each category. Given high cardinality categorical attributes, one-hot encoding suffers from shortcomings: (i) the dimension of the input space increases with the cardinality of the encoded variable, (ii) the derived features are rarely non-zero, and new and unseen categories cannot be handled [49, 68].

Table 1: An illustrative example of one-hot and target encoding methods over the same data sample.

Ethnic	Encoding	Label
African-American	1	1
Caucasian	1/3	1
Caucasian	1/3	0
Caucasian	1/3	0
Hispanic	0	0

(*a*) **Unregularized Mean Target Encoding**

Ethnic	African-American	Caucasian	Hispanic
African-American	1	0	0
Caucasian	0	1	0
Caucasian	0	1	0
Caucasian	0	1	0
Hispanic	0	0	1

(*b*) **One Hot Encoding**

Label/ordinal encoding [6] uses a range of integers to represent different categorical values. These are assumed to have no true order and integers are assigned in the order of appearance of the categories. Label encoding suffers less from higher cardinalities of attribute values, but imposes an artificial random order on the

[1] Target encoding methods have become an industry standard for high-cardinality categorical data [28, 49, 54, 60] with algorithmic procedures being implemented in many open source packages [14, 73]. One of the most common is the Python package called *category encoders* (https://pepy.tech/project/category_encoders). It achieves up to 1 million downloads per month. Target encoding is the default encoding method in some high-performance open-source software implementations such as *catboost* [17, 29] that has reached a total download of 74 million.

[2] In this work, we use the term "accuracy" in a non-literal sense to refer to the model performance, rather than the statistical evaluation metric of the same name. Section 5.1.3 discusses the appropriate evaluation metric for our scenarios.

categories, which may harm learning. This, in turn, obstructs the model to extract meaningful information from the categorical data.

Target encoding replaces attribute categories by the mean target value[3] of each corresponding category. Thus, the high cardinality problem is addressed, and categories are ordered in a meaningful manner [8, 46]. The main drawback of target encoding appears when the target values of a category with few samples are averaged. The model may overly rely on the resulting target value, potentially suffering from inherent variance in the small sample of data points from this category. To overcome this problem, several strategies introduce regularization terms in the target estimation [46, 49, 54].

In Table 1, we illustrate one-hot encoding and target encoding for the category ethnicity using a five person sample from the COMPAS dataset [35]. The problem of over-fitting is evident for the cases of *African-American* and *Hispanic* where their encoding is replaced directly with the target, creating a data leakage that can potentially cause reducible induced bias (cf. Section 5).

Even though early works that have studied preprocessing techniques for classification without discrimination [37] do not discuss the fairness effects of encoding categorical protected attributes. To the best of our knowledge, no previous work studies the different effects of regularization on target encodings nor the fairness implications of encoding categorical protected attributes.

2.2 Group Fairness

Various definitions of fairness in machine learning have been proposed (see, e.g., [2, 22, 44] for recent overviews). They can be categorized into notions of individual fairness and group fairness. While metrics of individual fairness judge whether *similar individuals are treated similarly* [18], metrics of group fairness measure the disparate treatment of groups, which are assembled according to shared categories of sensitive attributes of their individuals such as gender or race [64].

Different disparity metrics emphasize varying aspects of disparate treatment. For comprehensive understanding, we investigate the effects of encoding methods according to three common disparity metrics, i.e. equal opportunity, statistical disparity (demographic disparity) and average absolute odds (equalized odds). All three metrics indicate equal treatments of different groups by values close to zero and highly disparate treatments by values different from zero.

In this work, we distinguish and define two types of induced bias or discrimination that the encoding of categorical attributes introduces. Borrowing terminology used about different types of uncertainty [15, 26, 41], we use *irreducible bias* to refer to (direct) group discrimination arising from the categorization of groups into labels: more data about the compared groups do not reduce this type of bias. *Reducible bias* occurs due when the variance of categories with few instances cannot be well contained.

2.3 Addressing Intersectionality

It is a common trick for boosting model performance to concatenate multiple categorical variables and encode them into a single feature [28]. This feature engineering procedure, which includes target encoding, parallels a possible implementation of *intersectionality* when we concatenated two or more protected attributes. Intersectionality refers to when an individual that belongs to more than one protected group experiences discrimination at the intersection of these groups. It broadly refers to how different identities interact to produce a unique new form of discrimination [72]. Crenshaw [13], for example, studied how *black women* in the United States experience discrimination beyond being either black or women.

Although individuals often belong to multiple protected groups, intersectionality is largely understudied within algorithmic fairness. With some exceptions (e.g., [1, 24, 72, 76, 77]), most works assume the single binary protected attribute or disregard intersectionality entirely when handling multiple protected attributes [72], which is unrealistic and reductive. This is a pertinent issue as it is possible for individuals not to suffer from multiple discrimination but to suffer from intersectional discrimination [63, 75].

We address the intersectionality concerns linked to target encoding. On one hand, it can boost model performance; on the other hand, it can introduce new forms of discrimination. We add to this small but growing fairness literature by analyzing how target encoding can enable an implementation of intersectionality. In particular, we study how target encoding regularization can mitigate the potential biases induced by this feature engineering practice and compare it to the standard alternative of one-hot encoding.

3 FORMALIZATION AND REGULARIZATION OF TARGET ENCODING

Consider a categorical attribute Z with domain $dom(Z) = \{z_1, \ldots, z_c\}$, a binary target attribute Y with $dom(Y) = \{0, 1\}$, and the joint probability of $P(Z, Y)$ over the population of interest. Target encoding replaces Z with a continuous attribute $\bar{Z}$ with $dom(\bar{Z}) \in [0, 1]$. Values $z_i \in dom(Z)$, for $i = 1, \ldots, c$, are encoded to values $\bar{z}_i$ in a supervised way, as the posterior probability of positives:

$$\bar{z}_i = p_i \qquad \text{where } p_i = P(Y = 1 | Z = z_i) \tag{1}$$

However, since $P(\cdot)$ is typically unknown, an estimate of the posterior probability p_i is derived from a dataset $\mathcal{D}_{tr}$ (called the *training set*) of i.i.d. realizations of Z, Y. Let n be the total number of observations, n_i the number of observations where $Z = z_i$, and n_Y the number of observations where $Y = 1$, and $n_{i,Y}$ the number of observations where $Z = z_i$ and $Y = 1$. A candidate estimator consists of the observed fraction of positives among those with $Z = z_i$, hence encoding:

$$\bar{z}_i = \hat{p}_i \qquad \text{where } \hat{p}_i = \frac{n_{i,Y}}{n_i} \tag{2}$$

Such an estimator is unbiased, namely $E[\hat{p}_i] = p_i = P(Y = 1 | Z = z_i)$. More precisely, by Hoeffding bounds [33], for any $\epsilon > 0$, $P(|\hat{p}_i - p_i| \geq \epsilon) \leq 2e^{-2n_i\epsilon^2}$, which already points out the dependence of the estimate on the number of observations n_i of z_i. Formally , the variance of the estimator $Var[\hat{p}_i] = p_i(1 - p_i)/n_i$ is relatively large when n_i is small. Unregularized target encoding does not perform well on categories with little statistical mass [58] as it tends to overfit the training data, failing to generalize to new data. In the extreme case of only one observation, namely $n_i = 1$, it will replace the categorical value with the target of such an observation. Such an encoding will be unrepresentative of the category and introduces a sampling (or data collection) bias at the pre-processing stage. This

[3] Throughout the paper, we assume a binary target feature with values $\{0, 1\}$.

type of bias is what we define as reducible bias and can be left unnoticed because extremely small categories do not significantly impact the overall loss of the problem but can still impact fairness metrics. To avoid overfitting, practitioners regularize using either (i) smoothing towards the global mean or (ii) Gaussian noise, which adds normal (Gaussian) distribution noise to training data to decrease overfitting. Other smoothing techniques can be found in the literature but are either minimal variations of those two techniques or less popular [73].

3.1 Smoothing regularization

Smoothing towards the global mean leads to the following target encoding:

$$\bar{z}_i = \tilde{p}_i \qquad \text{where } \tilde{p}_i = \lambda(n_i)\frac{n_{i,Y}}{n_i} + (1-\lambda(n_i))\frac{n_Y}{n} \tag{3}$$

Here, the proportion of positives among the observations with $Z = z_i$ is interpolated with the proportion of positives among all observations. Formally, called $\hat{p} = n_Y/n$ an estimate of the prior probability $p = P(Y = 1)$, we have $\tilde{p}_i = \lambda(n_i)\hat{p}_i + (1-\lambda(n_i))\hat{p}$. The choice of the prior probability $P(Y = 1)$ is natural because, lacking a sufficient number of observations for $Z = z_i$, one resorts to the proportion of positives over the whole dataset of observations. The convex combination of the two estimators depends on $\lambda(n_i) \in [0, 1]$. The function $\lambda(\cdot)$ is assumed to increase with n_i. Intuitively, the larger the number of observations with $Z = z_i$, the more weight we give to the first estimator. Thus, the smoothed estimator is asymptotically unbiased. Conversely, the smaller the number of observations, the more weight we give to the prior probability estimator. Therefore, the smoothed estimator has a small variance for small values of n_i—yet, it is biased towards the prior probability.

3.2 Gaussian noise regularization

Gaussian noise regularization adds normal (Gaussian) distribution noise into training data after encoding the categorical attribute as in (2). The intuition is to perturb the data to prevent overfitting the target encoded attribute values. During the prediction stage, testing data are encoded as in (2) with no perturbation. Formally, called $z_{i,j}$ the j^{th} occurrence of z_i in the training set, $z_{i,j}$ is replaced by:

$$\bar{z}_{i,j} = \hat{p}_{i,j} \qquad \text{where } \hat{p}_{i,j} = \frac{n_{i,Y}}{n_i} + \epsilon_{i,j} \qquad \epsilon_{i,j} \sim N(0, \lambda^2) \tag{4}$$

where the $\epsilon_{i,j}$'s are i.i.d. with mean 0 and standard deviation λ. Typical values for λ are set between 0.05 and 0.6 [73].

4 THEORETICAL ANALYSIS

We present a theoretical analysis under a number of assumptions that make it reasonably simple. First, we assume that $\bar{Z}$ is the only predictive feature. Second, we consider a probabilistic binary classifier, which for an input $\bar{Z} = \bar{z}$ outputs a score $\hat{S}(\bar{z}) \in [0, 1]$, and a prediction $\hat{Y}(\bar{z}) = \mathbb{1}(\hat{S}(\bar{z}) > 1/2)$. Third, the score is expected to approximate a Bayes optimal classifier, i.e., $\hat{S}(\bar{z}) \approx P(Y = 1|\bar{Z} = \bar{z})$. For notational convenience, we write $a \bowtie b$ as a shorthand for $a > 1/2 \Leftrightarrow b > 1/2$, namely a and b are on the same side of the decision threshold $1/2$. We write $a \not\bowtie b$ when $a \bowtie b$ does not hold.

The case of perfect target encoding. Under the (theoretical) assumption of knowing the true values p_i's, the perfect target encoding would set $\bar{z}_i = p_i$ as in (1). The score $\hat{S}(\bar{z}_i) = p_i$ leads to the Bayes optimal classifier, hence maximizing AUC over the population and minimizing the classification error to the following:

$$\sum_{i=1}^{c} P(Z = z_i) \cdot min\{p_i, 1 - p_i\} \tag{5}$$

Consider now the equal opportunity fairness metric, namely:

$$P(\hat{Y} = 1|Y = 1, \bar{Z} = \bar{z}_i) - P(\hat{Y} = 1|Y = 1, \bar{Z} = \bar{z}_r) \tag{6}$$

where $\bar{z}_r$ is the encoding of the reference group in the protected attribute Z. By definition of $\hat{Y}$, $\hat{Y}(\bar{z}_i) = 1$ iff $\bar{z}_i = p_i > 1/2$, and analogously for r. Therefore, when both $p_i > 1/2$ and $p_r > 1/2$:

$$P(\hat{Y} = 1|Y = 1, \bar{Z} = \bar{z}_i) = P(\hat{Y} = 1|Y = 1, \bar{Z} = \bar{z}_r) = 1$$

and then the difference is 0. A similar conclusion is obtained when both $p_i \leq 1/2$ and $p_r \leq 1/2$. However, when the probabilities p_i and p_r lie on different sides of the threshold (i.e., $p_r \not\bowtie p_i$), the equal opportunity metrics is non-zero (either -1 or 1). In other words, the classifier is fair only if the prediction for the reference group is the same as for the protected group. But this will impact on accuracy. In fact, assuming a constant prediction over the groups, say $\hat{Y}(\bar{z}_i) = 1$, the classification error on the population becomes $\sum_{i=1}^{c} P(Z = z_i) \cdot (1 - p_i)$, which is clearly larger than (5).

In summary, even in the case of perfect target encoding and a Bayes optimal classifier, there is a tension between error and fairness metrics optimization: the amount of unfairness is *irreducible* as we assumed to know the posterior probabilities p_i's, unless we admit increasing the error by not using the protected feature Z in the classification problem.

The case of target encoding. Let us consider now the encoding using the (un-regularized) estimator $\hat{p}_i = n_{i,Y}/n_i$, i.e., (2). The score $\hat{S}(\bar{z}_i) = \hat{p}_i$ maximizes empirical AUC and minimizes the empirical error rate on the training set. When n_i is large, $\hat{p}_i \approx p_i$ (since variance of the estimator is low), and then the contribution to the classification error (5) and to the AUC are approximately the same as in the case of perfect target encoding. Regarding the fairness metric, we can reasonably assume that n_r is large for the reference group, and then $\hat{p}_r \approx p_r$. Therefore, the equal opportunity metric is unchanged w.r.t. the case of perfect target encoding.

When n_i is small, the estimate $\hat{p}_i = n_{i,Y}/n_i$ can be arbitrarily distant from p_i. The increment in classification error (5) is zero if $p_i \bowtie \hat{p}_i$, and it is $P(Z = z_i) \cdot |1 - 2p_i|$ otherwise. Also, the AUC will possibly be smaller due to wrong ranking of instances with $Z = z_i$. The equal opportunity metric is, instead, independent of $P(Z = z_i)$. Compared to the perfect target encoding case, its value is unchanged if $p_i \bowtie \hat{p}_i$. Otherwise, it can either decrease (if $p_r \bowtie \hat{p}_i$) or increase (if $p_r \not\bowtie \hat{p}_i$).

In summary, the variability of the estimator $\hat{p}_i$ for n_i small, negatively impacts on the performance metrics, and it propagates to the the fairness metrics, unpredictably increasing or decreasing it compared to the perfect target encoding case. The increase in the fairness metrics is *reducible* bias, which can be corrected by increasing the number of observations of $Z = z_i$.

The case of smoothing regularization. Let us consider now the target encoding with smoothing regularization (3). Let $\hat{S}()$ be the score function that minimizes the empirical error rate over the training set. When n_i is large, then $\tilde{p}_i \approx \hat{p}_i \approx p_i$, and then we fall back to the same situation as for (perfect) target encoding.

When n_i is small, we have $\tilde{p}_i \approx n_Y/n \approx p$, and then instances of the training set for which $Z = z_i$ are mapped close to $\bar{Z} = p$. This does not necessarily mean that the classification algorithm scores such instances as p – rather, it should score close to the mean target value of instances with $\bar{Z} = p$. Let us then be q such that $\hat{S}(p) = q$. We fall back then to the reasoning for the target encoding case. The increment in classification error (5) is zero if $p_i \bowtie q$, and $P(Z = z_i) \cdot |1 - 2p_i|$ otherwise. Compared to the perfect target encoding case, the fairness metric value is unchanged if $p_i \bowtie q$. Otherwise, it can either decrease (if $p_r \bowtie q$) or increase (if $p_r \not\bowtie q$).

In summary, the estimator $\tilde{p}_i \approx p$ for n_i small is stable, but nevertheless, it can affect the performance metrics (negatively) and the fairness metrics (increase or decrease). The increase in the fairness metrics is *reducible* bias. Notice that the magnitude of the impact depends on the choice of q by the machine learning algorithm under consideration, which, in principle, could be controlled for.

The case of Gaussian noise regularization. Let us now consider the Gaussian noise regularization (4). Its expectation is $E[\hat{p}_{i,j}] = E[\hat{p}_i] + E[\epsilon_{i,j}] = p_i$, hence the estimator is unbiased. Its variance is $Var[\hat{p}_{i,j}] = Var[\hat{p}_i] + \lambda^2$. From this, we have that: (1) the variance is larger than in the case of target encoding, and, a fortiori, of the smoothing regularization; (2) the larger the regularization parameter λ, the larger the variance. Let us consider a partition of the instances with $Z = z_i$ based on whether $\hat{p}_{i,j} \bowtie p_i$ holds or not.

For the subset $\hat{p}_{i,j} \bowtie p_i$, there is no change in classification error, nor in the equal opportunity fairness metrics, when compared to the perfect target encoding case.

Consider instead the subset $\hat{p}_{i,j} \not\bowtie p_i$. The increment in classification error (5) is $\sum_{\bar{z}} P(Z = z_i, \bar{Z} = \bar{z}, \bar{z} \not\bowtie p_i) \cdot |1-2p_i|$. For n_i small, this is lower than in the cases of target encoding and smoothing regularization. For n_i large, this is greater than in those two cases, where it is ≈ 0. However, since $Var[\hat{p}_i] \approx 0$, this case only occurs for a large λ^2 that causes crossing the decision boundary, i.e., for which $\hat{p}_{i,j} \not\bowtie p_i$. Compared to the perfect target encoding case, the fairness metric can either decrease (if $p_r \bowtie \hat{p}_{i,j}$) or increase (if $p_r \not\bowtie \hat{p}_{i,j}$). Again, for small n_i's the impact is smaller than for target encoding and smoothing regularization, and for large n_i's, this can only occur if λ^2 is large enough for crossing the decision boundary.

In summary, Gaussian noise regularization adds some controllable variability that impacts mainly on small n_i's and for a subset of the data distribution for which a random perturbation may cross the decision boundary. If this happen, there is an increase in classification error, and some chance to increase/decrease the equal opportunity fairness metric. The increase in the fairness metrics is *reducible* bias.

The case of one-hot encoding. Consider a variant of one-hot encoding setting $\bar{z}_i = 2^i$, i.e., mapping z_i into a binary number with the i-th digit set to 1 and all others set to 0. Such a variant keeps our assumption of one predictive feature only. The previous subsections on perfect target encoding and on target encoding could be repeated, almost unchanged, as they only require $\hat{S}(\bar{z}_i) = p_i$ and $\hat{S}(\bar{z}_i) = \hat{p}_i$ respectively, ignoring the form of the coding of $\bar{z}_i$. We would therefore expect that the behavior of one-hot encoding and (unregularized) target encoding be very similar. What can make a difference is that most machine learning algorithms treat one-hot encoding as a collection of i.i.d. features, ignoring their dependencies (i.e., that one and only one digit must be 1). This may lead to a greater classification error when compared to target encoding.

5 EXPERIMENTS

In this section, we study the implications of model accuracy and fairness when encoding categorical protected attributes. *(H1)* The first main hypothesis is that encoding the protected attribute helps to improve accuracy. *(H2)* The second main hypothesis is that fairness is worsened by encoding. To evaluate both (H1) and (H2) we compare two encoding methods, one-hot encoding and target encoding, versus not encoding the protected attribute. Our third hypothesis *(H3)* is that target encoding regularization can improve fairness without significantly impacting predictive performance, and we evaluate this by comparing two regularization techniques across various hyperparameters as part of the machine learning pipeline's preprocessing step. Additionally, in the last section, we explore the effects of intersectional protected categorical attributes, which augment the previous three hypotheses.

5.1 Experimental Setup

5.1.1 Datasets: COMPAS and FolkTables. We choose two datasets that happen to exhibit high-cardinality sensitive categorical attributes in a binary classification problem: COMPAS [35] and FolkTables [16]. We report our method and findings on the COMPAS dataset in the main body of this paper and apply the same methodology on FolkTables, but report findings from the latter in the appendix. Overall, the findings are very similar in both datasets.

COMPAS is an acronym for Correctional Offender Management Profiling for Alternative Sanctions, which is an assistive software and support tool used to predict the risk that a criminal defendant will re-offend. The dataset provides a category-based evaluation labelled as high risk of recidivism, medium risk of recidivism, or low risk of recidivism. We convert this multi-class classification problem into binary classification by combining the medium risk and high risk of recidivism and comparing them to low risk of recidivism. The input used for the prediction of recidivism consists of 11 categorical attributes, including gender, custody status, legal status, assessment reason, agency, language, ethnicity, and marital status. The sensitive attribute that we consider is *Ethnic* for the single discrimination case, whose protected group we define as the most represented group: African-American (cf. Figure 4).

To study fairness related to intersectional attributes, we created the variable *EthnicMarital*, engineered by concatenating *Ethnic* and *Marital* status. This new attribute has a high cardinality of 46 distinct values (cf. Figure 4). The most predominant category is *African-American Single*, and it will be the protected group (cf. Figure 4) for the intersectional fairness case. To compare disparate treatment between groups we will make use of *Caucasian Married* as the reference group. It is worth noting that the contribution of

the attributes to the model performance, based on attribute importance explanation mechanism [43, 47, 51, 59], is highly relevant. The available data is split into a 50/50 stratified train/test split, maintaining the ratio of each category between train and test set. In the Figure 4 of the appendix, we can see how the group distributions are unbalanced with two groups, *African-American* and *Caucasian*, that account for the +80% of the data. For the intersectional fairness case, the number of groups increases, making room for more distinct, disparate, and imbalanced groups [23].

5.1.2 Machine learning algorithms. Our experiments involve a logistic regression model, a neural network (Multi-layer Perceptron classifier), and a gradient-boosting decision tree. All models are trained on the training set. These three models provide examples of a model with large bias (the linear regression model), a highly complex model (the MLP classifier), and the extensively used, state-of-the-art gradient-boosting decision tree [7, 25, 48, 61, 82].

5.1.3 Choice of metrics and models.

Model performance metrics. Previous work on fair machine learning has evaluated their experiments on COMPAS using accuracy as a performance metric [78–80], but given that we want to study effects of group imbalance, we consider accuracy to be a less informative measure of model performance. Area Under the Curve (AUC) measures the diagnostic ability of a binary classifier as its discrimination threshold is varied. AUC is less susceptible to class imbalance than accuracy or precision and also accepts soft probabilities predictions [32]. An AUC of 0.5 is equal to random predictions.

Fairness metrics. We use three different metrics $\ell_{i,j}(f, X, y)$ to judge fairness of classifier f on data X between groups indexed by i, r and we denote $\hat{Y} = f(X)$ for simplicity:

- *Statistical Parity (Strong Demographic Parity)*: The difference between favourable outcomes received by the protected group and refernce group [12, 21, 38, 81]. DP ensures that a fair decision does not depend on the protected attribute regardless of the classification threshold used [11, 36]

$$\mathrm{DP}_{i,r} = d(P(\hat{Y}|Z = i), P(\hat{Y}|Z = r)) \tag{7}$$

  where $d(\cdot, \cdot)$ is a distance function. In this work, we use the Wasserstein distance as a measure between the two probabilistic distributions. The intuition behind Demographic Parity is that it states that the proportion of each segment of a protected attribute should receive a positive outcome at equal rates, a positive outcome is a preferred decision.
- *Equal opportunity fairness.* Following Hardt et al. [31]'s emphasis on ensuring fair opportunity instead of raw outcomes, we choose *equal opportunity* (EO) as a fairness notion and use the metric *disparate treatment* (difference between the true positive rates) to measure unfairness, which is estimated using the disparate treatment metric [78]. For simplicity, we refer to the interplay of these concepts as the *equal opportunity fairness (EOF)* metric. The value is the difference in the True Positive Rate (TPR) between the protected group and the reference group [50, 57]).

$$\mathrm{TPR}_i = P(\hat{Y} = 1|Y = 1, Z = i) \quad \mathrm{EOF}_{i,r} = \mathrm{TPR}_i - \mathrm{TPR}_r \tag{8}$$

  A negative value in (8) is due to the worse ability of a Machine Learning model to find actual recidivists for the protected group (i) in comparison with the reference group (j).
- *Average Absolute Odds (Equalized Odds)*: The sum of the absolute differences between the True Positive Rates and the False Positive Rates of the protected group plus the same ratio for the reference group.

$$\mathrm{FPR}_i = P(\hat{Y} = 1|Y = 0, Z = i) \tag{9}$$

$$\mathrm{AAO}_{i,r} = \frac{1}{2}(|FPR_i - FPR_r| + |TPR_i - TPR_r|) \tag{10}$$

  The intuition is that an $AAO = 0$ means the algorithm is fair because it results in the same False Positive Rate and True Positive Rate for the reference group as an protected group. If the algorithm causes a difference in either, then $AAO \neq 0$. A deviation in each term contributes equally to AAO, then False Positives Rates might have different social implications than True Positives Rates [44, 66, 71].

All three metrics indicate better fairness between groups i, j by values closer to 0. We calculate the overall fairness $\mathcal{L}$ of the model f on data of interest X given a fairness metrics ℓ, reference group i and other groups $\{i|i \neq r\}$ as:

$$\mathcal{L}(f, X, y, i, r) = \sum_{i \neq r} |(\ell_{i,r}(f, X, y)| \tag{11}$$

where each group i contributes equally to the overall metric, meaning these are not weighted by the number of individuals in each group.

5.2 Experimental results: encoding categorical protected attributes

In this section, we evaluate hypotheses (H1), (H2), and (H3). The trade-offs between fairness metrics and predictive performance metrics (AUC) are analyzed using two different encoding techniques (Section 2), with two different regularization techniques (Section 3) and two different estimators (Section 5.1.3). The ranges of the regularization hyperparameters are: $\lambda \in [0, 5]$ for the width of the Gaussian noise regularization; $m \in [0, 1000000]$ for the additive smoothing using the m-probability estimate function $\lambda(n_i) = n_i/(n_i + m)$ (see [46]). These hyperparameters will also be kept for the rest of the experiments for the COMPAS dataset.

Under **Gaussian noise regularization** (cf Figure 1 left images), evaluation supports our three hypotheses: (H1) predictive performance improves when encoding the categorical protected attributes. In all six experiments, the improvements reported are in the range of ~ 0.1 AUC. (H2) All the experiments exhibit fairness degradation up to one order of magnitude. (H3) We observe that within low regularization ranges of hyperparameters (lighter dots), fairness improves without compromising the predictive performance of the model. However, for higher levels of regularization (darker dots), fairness metrics have a plateau while predictive performance (AUC) keeps degrading. At the highest regularization penalty, target encoding often matches performance and fairness with "no encoding" while with no regularization matches "one hot encoding". Later in this section, we discuss this in depth.

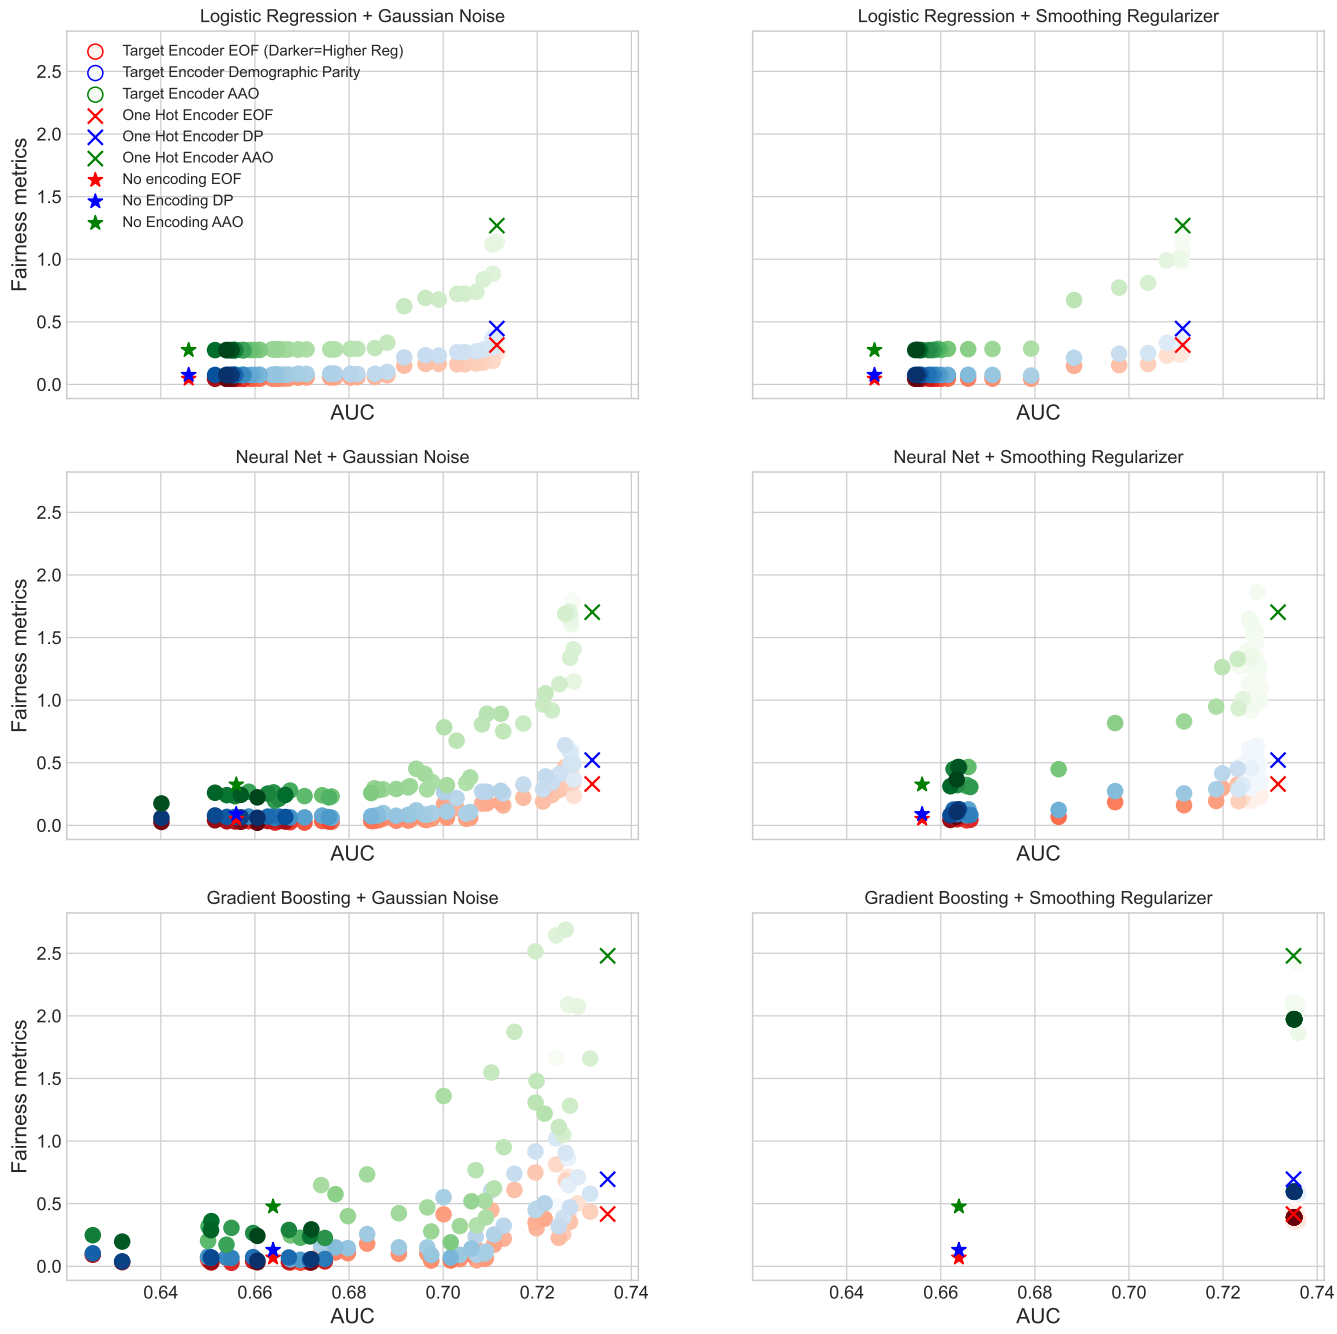

Figure 1: Comparing one-hot encoding and target encoding regularization (Gaussian noise and smoothing) for the Logistic Regression, Neural Network, and Gradient Boosting classifiers over the test set of the COMPAS dataset. Coloured dots regard different regularization parameters: the darker the red, the higher the regularization. Different colours imply different fairness metrics. Crossed dots regard one-hot encoding, and starred dots are the results of models that exclude the use of the protected attribute.

We find similar results in the case of **smoothing regularization** (cf Figure 1 right images). But not for our regularization hypothesis. While it should be for the linear regression and the neural networks, it does not work for the gradient-boosting decision trees, whose target encoding regularization effects are negligible in both fairness and model performance. These can be due to smoothing producing

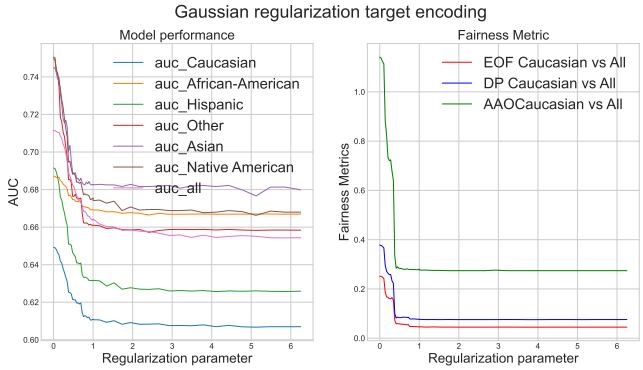

Figure 2: Impact of the Gaussian noise regularization parameter λ on performance and fairness metrics over the test set of the COMPAS dataset using a Logistic Regression with L1 penalty. In the left image, the AUC of all the protected groups over the regularization hyperparameter. On the right, the equal opportunity fairness, demographic parity and average absolute odds variation throughout the regularization hyperparameter.

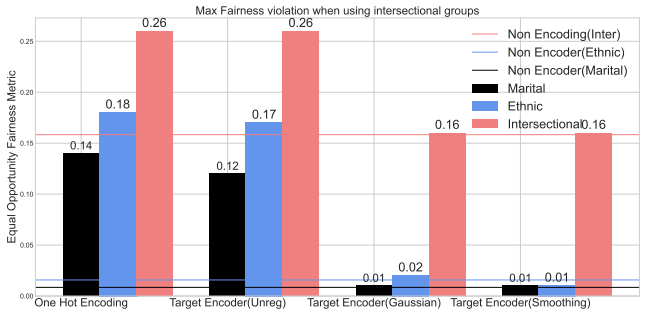

Figure 3: Equal opportunity fairness implications of encoding categorical protected attributes and their regularization effects on the Compas Dataset. Horizontal lines are the baselines where the protected attribute is not included in the training data. Regularized target encoding does not harm fairness metrics, but it can improve predictive performance on this dataset.

a shrinking effect where decision tree-based models are generally not affected by monotonic attribute transformations [10].

In Figure 2, we analyze the target encoding hyperparameter fairness-accuracy trade-off deeper. We can see that there is an optimal trade-off value around 0.3, where the equal opportunity fairness and demographic parity have dropped down toward the fairness plateau, and the model performance has only slightly decreased. The predictive performances (AUC) of different groups have different negative slopes, ethnic groups as *Asian* or *Native-American* have a drastic drop in performance while groups as *African-American* have only a small performance decay. *African-American* represents the 44.4% of the data while *Asian* or *Native-American* do not even achieve a statistical representation of 1%.

Concerning the across-model comparison, the predictive performance of the gradient boosting decision tree model is best, followed by the neural network and then the linear model [5, 27]. From the fairness perspective, more complex models have a stronger fairness violation.

5.3 Experimental results: engineering intersectional fairness

Our intersectional fairness hypothesis are that (i) the engineering of intersectional features degrades fairness, (ii) that encoding the categorical protected attribute increases discrimination and (iii) that by regularizing target encoding, we can reduce intersectional discrimination to no-encoding levels.

To provide evidence of the potential effects of encodings on intersectional fairness, we concatenate *Ethnic* and *Marital* status of the COMPAS dataset. We select *Caucasian Married* as the reference group and compare the maximum fairness violation w.r.t. all other groups. For visualization purposes, we choose the generalized linear model or the previous section and focus on the notion of Equal Opportunity Fairness since we have seen in the previous experimental section that the three fairness metrics exhibit the same behavior.

In Figure 3, we see how attribute concatenation creates intersectional attributes and boosts fairness violations. Validating our first hypothesis that fairness metrics increase just by the engineering of intersectional discrimination. Even when there is no-encoding the protected attributes (horizontal lines), the maximum fairness violation between groups is increased by an order of magnitude from 0.015 for *Ethnic* or 0.08 for *Marital Status* to 0.16 for the intersectional attribute of both. The increase of discrimination when engineering intersectional protected attributes align with the social findings presented originally back in 1958 when Kimberle Crenshaw [13] wrote her critique of the anti-discrimination doctrine, feminist theory, and anti-racist politics, to describe how different forms of oppression intersect and compound one another, increased discrimination for marginalized groups.

Our second hypothesis is validated as both encoding techniques achieve a higher equal opportunity violation than no-encoding of the protected attribute. Finally, we can see that fairness can be improved by regularizing the target encoding of protected attributes. This is not surprising, and, in general, attribute concatenation can worsen fairness both on the side of irreducible bias (because p_i and p_r become more distant) and on the side of reducible bias (because n_i becomes smaller) as we have seen in the theoretical section.

6 CONCLUSION

In this work, we have focused on how the encoding of categorical attributes can reconcile model quality and fairness. We have provided theoretical and empirical evidence that encoding categorical attributes could induce two different types of bias: an *irreducible bias*, due to the learning of discriminant information between the protected and reference groups, and a *reducible bias* due to the large variance of samples found in small protected groups.

Through theory and experiments, we showed that the most used categorical encoding method in the fair machine learning literature, one-hot encoding, consistently discriminates more than target encoding. However, we found some promising results using target encoding. Target encoding regularization showed fairness improvements with the risk of a noticeable loss of model performance in the case of over-parametrization. We also found that the type of regularization chosen is relevant depending on the algorithm used. These results support our view that (regularized) target encoding can be useful for fair machine learning. Furthermore, we discussed how attribute engineering could boost the performance of machine learning algorithms but can lead to fairness violations increase, potentially due to both reducible and irreducible biases.

These experiments aim to motivate industry practitioners, where in many situations, the usage of the protected attribute is not strictly prohibited, and with slight changes in the encoding of the protected attribute, improvements in fairness can be achieved without any noticeable detriment to predictive performance.

Limitations and disclaimer: In this work, we have used two models, two encodings, two regularization techniques, and two datasets. To make a large-scale comparison, we must choose a single scalar metric that accounts for the trade-off between model accuracy and model fairness. Also, encodings are more impactful when the protected attribute is related to the target variable. This work aims to show what are some of the implications of encoding categorical protected attributes. At all times, it is important to understand that simply encoding categorical protected attributes may not necessarily lead to improved fairness metrics. We strongly advocate considering the effects of encoding regularization not only on predictive performance but also along the fairness axis. Using fair AI methods does not necessarily guarantee the fairness of AI-based complex socio-technical systems [42, 64, 67].

Reproducibility Statement

We make our results open-source and reproducible: original data, data preparation routines, code repositories, and methods are all publicly available at https://github.com/nobias-project/FairEncoding. Note that throughout our work, we do not perform any hyperparameter tuning (except on the regularization); instead, we use default `scikit-learn` hyperparameters [55].Our experiments were run on a four vCPU server with 15GB of RAM.

ACKNOWLEDGMENTS

This work has received funding from the European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie Actions (grant agreement number 860630) for the project: "NoBIAS - Artificial Intelligence without Bias". Furthermore, this work reflects only the author's view, and the European Research Executive Agency (REA) is not responsible for any use that may be made of the information it contains. We acknowledge the support of the Stuttgart Research Focus *Interchange Forum for Reflection on Intelligent Systems (IRIS)*. The authors thank Gourab K. Patro for his early-stage contributions.

APPENDIX: EXPERIMENT RESULTS

Data: Compas data overview

In Figure 4 we complement the experimental section on the main body of the paper by showing the distributions of the ethnic groups. There are two groups (*African-American* and *Caucasian*) that account for the 80% of the data, while there are less represented groups such as Asian or Arabic that have a less significant statistical weight. For the intersectional fairness case, the number of groups is increased to 46 distinct groups, making room for more distinct, disparate, and imbalanced groups[23].

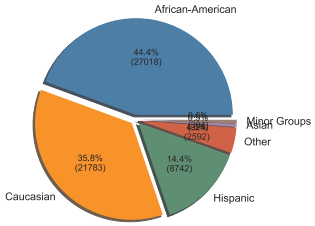

Figure 4: Distribution of the protected attribute categories to be encoded and regularized for the COMPAS data [35]. Predominant *Ethnic* categories are *African-American* and *Caucasian*

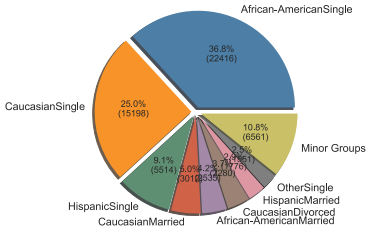

Figure 5: Distribution of the intersectional protected attribute *Ethnic-Marital* to be encoded and regularized for the COMPAS data [35]. Predominant categories is categories distribution are *African-American Single* and *Caucassian Single*

Data: US Census Income

In this section, we provide experiments on the Adult Income data set[4] derived from the US census data [16]. Folktables package provides access to data-sets derived from the US Census, facilitating the bench-marking of fair machine learning algorithms. We select the data from California in 2014 that covers 60,729 individuals including their race, that has 8 unique groups. Aiming to predict whether an individual's income is above 50, 000. The data is split into a 50/50 train/test split, maintaining the ratio of each category between the train and test set.

	Distribution	Ratio
White	117209	0.66
Asian	28817	0.16
Other	20706	0.11
Black	8435	0.05
Native	1121	0.005
Hawaiian	612	0.003
American Indian	379	0.002

Table 2: Statistical distribution of the protected attribute *Race* on the US census dataset.

Figure 6: Comparing one-hot encoding and target encoding regularization (Gaussian noise and smoothing) for the Logistic Regression classifier over the test set of the US Income dataset. The Reference group is *White*. Coloured dots regard different regularization parameters: the darker the red, the higher the regularization. Different colours imply different fairness metrics. Crossed dots regards one-hot encoding, and starred dots not including the protected attribute in the data.

Under **Gaussian noise regularization** (left images of Figure 6), for the logistic regression, we can validate our three hypotheses: (H1) first that predictive performance improves when encoding the categorical protected attributes, in this case, respect to the results on Compass dataset, the AUC improvements are smaller, this can be due to the lack of predictive power of the categorical protected attribute. (H2) that fairness metrics are worsened by the encoding of the protected attribute, the differences between no-encoding

[4]Please see the ACS PUMS data dictionary for the full list of variables available https://www.census.gov/programs-surveys/acs/microdata/documentation.html

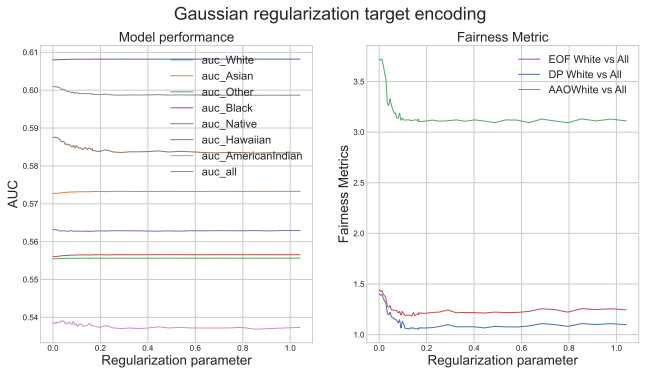

Figure 7: Impact of the Gaussian noise regularization parameter λ on performance and fairness metrics over the test set of the US income dataset using a Logistic Regression with L1 penalty. In the left image, the AUC of all the protected groups over the regularization hyperparameter. On the right, the equal opportunity fairness, demographic parity and average absolute odds variation throughout the regularization hyperparameter.

versus one-hot encoding or non-regularized target encoding are substantial.

Our last hypothesis (H3) is that through regularisation predictive performance can be improved without compromising the fairness of the model. We can observe that during the low regularization range of hyperparameters (lighter dots), there are high fairness violations with only a small improvement in predictive performance. On the other side, for high regularization (darker dots), fairness metrics have a smaller value. At the highest regularization penalty, target encoding often matches performance and fairness with "no encoding" while with no regularization matches "one hot encoding".

Machine Learning practices and infrastructures

ABSTRACT

Machine Learning (ML) systems, particularly when deployed in high-stakes domains, are deeply consequential. They can exacerbate existing inequities, create new modes of discrimination, and reify outdated social constructs. Accordingly, the social context (i.e. organisations, teams, cultures) in which ML systems are developed is a site of active research for the field of AI ethics, and intervention for policymakers. This paper focuses on one aspect of social context that is often overlooked: interactions between practitioners and the tools they rely on, and the role these interactions play in shaping ML practices and the development of ML systems. In particular, through an empirical study of questions asked on the Stack Exchange forums, the use of interactive computing platforms (e.g. Jupyter Notebook and Google Colab) in ML practices is explored. I find that interactive computing platforms are used in a host of learning and coordination practices, which constitutes an infrastructural relationship between interactive computing platforms and ML practitioners. I describe how ML practices are co-evolving alongside the development of interactive computing platforms, and highlight how this risks making invisible aspects of the ML life cycle that AI ethics researchers' have demonstrated to be particularly salient for the societal impact of deployed ML systems.

1 INTRODUCTION

It follows from the notion that Machine Learning (ML) systems ought to be thought of as *sociotechnical* systems [122]—i.e. systems that are socially constructed, requiring both human actors and machines to work [36]—that the social context in which an ML systems is researched, developed, and deployed is likely to shape the characteristics of that system. Given the increasing rate of ML system deployment in high-stakes domains, and widespread evidence of ML systems failing to meet societal expectations [e.g. 25, 69, 94, 123], a key question for ML field relates to infrastructuralisation and its implications for ML practices and deployed ML systems. This paper begins to address this question, by attending to one aspect of social context—interactions between ML practitioners and the tools they use to research, build, and deploy ML systems—and demonstrating the relevance of this context to concerns raised by AI ethics researchers.

The social context of ML system development has been studied in AI ethics [e.g. 15, 33, 55, 80]. However, relatively little attention has been paid to tracing the relationship between specific material features of this context and the characteristics of ML systems that are developed [72]. That is, the role of material things (e.g. software tools, office layouts, computer interfaces, network connections), which themselves are socially constructed, alongside social things (e.g. people, beliefs, norms) in shaping ML systems merits closer scrutiny. In this paper, I consider one aspect of this sociomaterial context of ML system development: the use of interactive computing platforms (e.g. Jupyter Notebooks and Google Colaboratory) during ML model development and evaluation. I explore the structure of these platforms and their use by ML practitioners, and consider the ways in which this use may contribute to conventions of ML practices. This exploration serves to illustrate the importance for the AI ethics field of attending both to the sociomaterial context of ML system development generally, and to the role of interactive computing platforms, in particular. The research question to which this exploration is addressed is: *how are interactive computing platforms used in ML practices?*

To answer this question I developed a probabilistic topic model of user-contributed questions on the Stack Exchange forums related to ML and the use of interactive computing platforms. Stack Exchange forums were selected due to their wide use by data and computer scientists, software engineers, and technologists generally [6, 10]. Alongside this I undertook qualitative text analysis of a small sample of Stack Exchange questions. I find that interactive computing platforms are used in a range of ML practices, particularly in the data curation and processing, and model training and evaluation stages of ML system development. I highlight the role of interactive computing platforms in learning practices, and in practices of coordination across multiple infrastructures. To interpret these findings I draw on sociological studies of infrastructures and practices, particularly the work of sociologists Susan Leigh Star [20, 129–131] and Elizabeth Shove [124, 125, 145], and cultural anthropologist Brian Larkin [73, 74]. I conclude that learning and coordination roles are indicative of an infrastructural relationship between ML practitioners and interactive computing platforms, which renders some of the aspects of ML systems development that

AI ethics discourse has highlighted as particularly consequential (e.g. the importance of training dataset provenance [32, 40]) as invisible to ML practitioners. As such, this paper contributes an empirical snapshot of the use of interactive computing platforms in ML practices, and argues for a renewed focus in the field of AI ethics on the emergence of digital platform infrastructures in the ML ecosystem.

2 RELATED WORK

2.1 The sociomaterial context of Machine Learning practices

As ML systems have become objects of sociological interest [e.g. 26, 35, 67, 83], the social context in which ML systems are researched, developed, commissioned, and deployed has garnered increased attention in diverse fields from Human-Computer Interaction [54, 84], to Science and Technology Studies [28], to public policy [71]. In this paper, I refer to *sociomaterial* context rather than *social* context to signal a particular focus on the intertwining of socially-constructed material things—specifically, interactive computing platforms—in ML practices. As Paul Leonardi et al. [76–78] have argued, a sociomaterial perspective highlights how the material is socially constructed, and the social is enacted through material forms. A sociomaterial perspective invites us to consider the material things that ML practitioners enrol in their day-to-day work, alongside other aspects of the social context, and the contribution of these things to the stablisation of ML practices. In this context, *material* refers to the "properties of a technological artifact that do not change, by themselves, across differences in time and context" [78, p.7]—for interactive computing platforms, and software generally, this includes their user interfaces and layouts, their core capabilities, and their dependencies [110]. My understanding of *practices* is informed by social practice theory [18, 116, 128], which conceptualises *practices* as routinised ways of understanding and performing social activities [58], and highlights that multiple practices can coexist within the same cultural setting [116, p.646]. *Machine Learning practices* are thus the constitutive matter of 'doing' ML. Some practices (e.g. Agile meeting processes) may be widely shared across cultures and organisations, and others (e.g. the use of specific software) may vary dramatically from practitioner to practitioner.

In the field of AI ethics, a sociomaterial perspective has been used to highlight the challenges of translating AI ethics research into ML practices. Michael Veale and Reuben Binns [140], for instance, studied how statistical measures of fairness can be implemented within the practical constraints of limited access to data on protected characteristics, finding that new institutional arrangements will be necessary to support industry implementation of statistical measures of fairness that depend on access to sensitive data [cf. 16, 17]. Veale and Binns argue for future empirical research on the "messy, contextually-embedded and necessarily sociotechnical" challenge of building 'fairer' ML systems [140, p.13]. Veale et al. [141] subsequently conducted an empirical study of ML practitioners in public sector organisations and their engagement with ethics issues during ML system development for high-stakes decision making, finding that while practitioners have a high degree of awareness regarding ethical issues, they lack the necessary tools and organisational support to use this awareness in their ML practices. Mona Sloane and Janina Zakrzewski [128], who also situate their work within social practice theory, provide a more expanded overview of AI ethics practices, through an empirical study of the operationalisation of ethics in German AI startups. Sloane and Zakrzewski develop an anatomy of AI ethics practices, which they suggest can be used as a framework to inform improvements to ML system development practices. Relevantly, the anatomy includes 'ethics materials', defined as "concrete objects, processes, roles, tools or infrastructures focused on 'AI ethics"' [128, p.5]. Holstein et al. [54] provide further support for the importance of ethics materials, through their empirical study of ML practitioners working in product teams in large technology firms to develop 'fairer' ML systems, which found that practitioners lack the tools needed to identify and address ethics issues that arise during ML system development. Finally, Will Orr and Jenny Davis [96] highlight how ML practices include the diffusion of responsibility for ethics during ML system development. Orr and Davis found a "pattern of ethical dispersion" amongst practitioners: practitioners perceive themselves to be the inheritors of ethical parameters from more powerful actors (regulators, clients, employers), which their expertise translates into the characteristics of systems they develop, which are then handed over to users and clients, who assume ongoing responsibility [96, p.7]. These studies, along with other empirical explorations of ML practice [e.g. 55, 64, 71, 108, 119, 139] and several workshops focused on the research-to-practice gap [9, 12, 133], have prompted calls for better support for practitioners attempting to operationalise AI ethics principles in their ML practices [88, 120, 121].

This study complements and inverts these empirical studies of AI ethics in ML practices. Rather than moving from the social to the sociomaterial, this study moves from the material to the sociomaterial. That is, rather than starting with interviews [e.g. 54, 55, 96, 108, 119, 128, 141] or surveys [e.g. 71, 139] of practitioners to explore their understanding and operationalisation of AI ethics in ML practices, the study begins with material artefacts that practitioners use and produce in the course of their ML practices, and explores what light these artefacts may shed on the translation of AI ethics to ML practices. A similar approach is followed by Max Langenkamp and Daniel Yue [72] in their study of open source ML software use, which consists of a review of code repositories on GitHub to establish the breadth of open source use followed by interviews with practitioners to provide further context. That study takes a broad perspective, exploring trends across open source software use. In contrast, this study takes a narrow perspective, exploring how a specific category of software tool is used in ML practices.

2.2 Interactive computing platforms and Machine Learning practices

The specific material artefacts this study starts with are *interactive computing platforms* (ICPs), also referred to as 'computational notebooks' [27, 118], 'literate programming tools' [100] or 'integrated development environments' [150]. Two widely used ICPs are the open-source Jupyter Notebook and Google Colab, Google's

extension of Jupyter Notebook, designed to integrate with other Google services.[1] Figure 1 shows an example Jupyter Notebook.

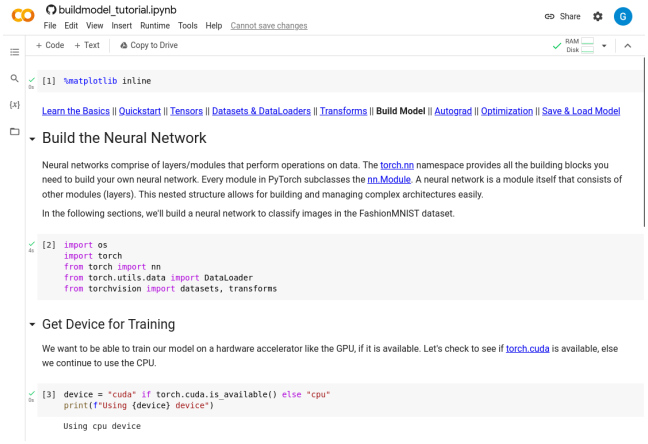

Figure 1: A screenshot of a Google Colab notebook maintained by PyTorch as part of their onboarding documentation. The notebook can be accessed at: https://pytorch.org/tutorials/beginner/basics/buildmodel_tutorial.html. The numbered grey cells are code cells. Immediately above each code cell is a natural language cell, which contains explanatory text. Immediately below each code cell is the output from running the cell's code.

Technically, an ICP is an interactive shell for a programming language, such as Python [98]. The shell enables users to write and interact with code fragments—called 'cells'—alongside natural language, and to assemble series of cells into a *notebook*, which can be shared with others—much in the same way that a word processor enables a user to assemble an editable document and share that with others. The notebook can be thought of as a computational narrative, which enables one to read and interact with a sequence of code alongside a narrative description of what the code does [68]—hence, the terms 'literate programming tools' and 'computational notebooks'. However, crucially, an ICP presents itself as only a shell: all but the most rudimentary code fragments depend on access to libraries of existing code, which a user must import into the shell environment. Similarly, particularly in the context of ML, data must be imported into the shell for the code to operate on and a compute resource must be accessed to process operations. Numerous digital infrastructures support importing code into a notebook, including the code repository GitHub,[2] in which many repositories include a notebook to demonstrate common use cases of the code [118], PyPi,[3] which indexes and hosts Python-based code packages, and HuggingFace,[4] which indexes and hosts ML training and evaluation datasets and models. In this study, *interactive computing platform* is thus preferred, as the infrastructural implications of 'platform' are a critical aspect of what defines these tools: ICPs are highly networked arrangements, one part of a circular web of infrastructures and inter-dependencies (the Internet, cloud computing, programming languages and libraries).

Interactive computing platforms pre-date the widespread adoption of ML techniques in applied settings. Indeed, their motivating design goal was to support reproducible science [45, 68, 98] (see, e.g. [13, 109] for discussions of their effectiveness at meeting this goal). However, as ML techniques have become ubiquitous, and data scientists have become widespread in industry, interactive computing platforms have become widely enrolled in ML practices. Commentators thus describe ICPs as the "tool of choice" for data scientists [99], and practitioners vigorously debate the merits and drawbacks of using ICPs in applied settings [e.g. 21, 48, 56, 90, 138].

Interactive computing platforms have also become objects of study in several fields adjacent to AI ethics. Human-Computer Interaction studies have developed empirical accounts of the way users interact with ICPs, focusing particularly on the role of ICPs in collaborations [143, 150] and in data science [65, 118]. Of particular relevance, Adam Rule et al. [118] conducted three studies of the use of ICPs by data scientists, which included a large-scale review of notebooks on GitHub and interviews with data scientists and found that ICPs tend to be used by data scientists during data exploration phases of a project, rather than for constructing and sharing detailed explanations of data analysis. Studies in the field of Software Engineering have also focused on documenting the use of ICPs, focusing particularly on ICPs as a site to study trends in code use [144] and reuse [70, 100], and on the their potential as educational tools [135]. Similarly, in the field of Computational Science, several studies have considered the role ICPs can play in supporting reproducible science [13, 24, 63]. This study provides a different perspective on ICP use, by considering ML practices in particular, and interpreting these practices through the lens of sociological studies of infrastructure, which shifts the focus of the study away from the individual user-notebook relationship and towards the broader relationship of ML practitioners to the suite of infrastructures involved in ML practices.

3 STUDYING INFRASTRUCTURES & PRACTICES

Studying the relationship between practices and infrastructures can be vexed. Infrastructures may be functionally invisible to the social groups who make use of them in daily practices [130], as I consider further in Section 6.2. Further, infrastructures often span multiple practices across different social groups, which, particularly in the context of digital infrastructures, may not be geographically proximate [19]. And, practices themselves are not purely infrastructural—as Shove et al. [126] argue, they bring together infrastructures and other materials, competencies, and ways of knowing.

Sociological studies of infrastructures have orientated themselves around the broad aim of rendering infrastructures, and their sociopolitical commitments, visible [19]. Ethnographic methods–historically, fieldwork and participant observation; more recently, multi-site studies–have been used to empirically document infrastructures [127]. Star [130], for instance, advocates studying moments of breakdown in infrastructures, seeing these as instances where infrastructures become visible to social groups. Star [130]

[1] Available at https://jupyter.org/ and https://research.google.com/colaboratory/.
[2] See https://github.com/.
[3] See https://pypi.org/.
[4] See https://huggingface.co/.

also observes that infrastructures are often learned as part of group membership, directing attention to moments of transience in social groups (discussed further in Section 6.1). However, digital infrastructures present particular challenges: one cannot physically access online communities, and the number of physical sites is at least as large as the user-base of the infrastructure [19].[5]

In this study, I build on Star's insights by focusing, as a path towards understanding ICPs and their relationship to ML practices, on moments where ML practitioners are either experiencing ICP breakdowns or limitations in their own ICP capabilities. In particular, and reflecting the challenge of direct observation of digital infrastructure use, the primary data source used are the questions asked by ML practitioners on popular online forums. This is supplemented with analysis of ICP affordances and inter-dependencies. This approach follows in the spirit of other studies of digital infrastructure, such as Plantin et al.'s [102] analysis of the documentation and inter-dependencies of the Figshare platform and Andre Brock's [22] analysis of Black Twitter through analysis of Twitter interfaces and user generated content, although the study presented here is narrower in scope.

4 METHOD

This study consisted of an empirical study of user-generated content on the Stack Exchange forums, supported by a close reading of a small number of exemplars texts [61]. In particular, a Structured Topic Model (STM) [111–114] of user-generated questions about ML and the use of interactive computing platforms on Stack Exchange forums was estimated.[6] A similar approach has been used in a number of studies of Stack Exchange forums [2], for instance to identify challenges practitioners face in developing ML systems more generally [3] or themes in questions asked by mobile application developers [115] or themes in privacy-related [134] or security-related questions [149].[7]

4.1 Corpus development and description

English-language Stack Exchange community forums, specifically Stack Overflow, Cross Validated, Data Science, Computer Science, and Software Engineering were mined for relevant questions. Stack Exchange claims to be the world's largest programming community.[8] As of October 2022, its most popular forum, Stack Overflow, had over 19 million registered users, who contribute, edit, and moderate questions and answers on the forum.[9] Previous research demonstrates that Stack Overflow is enmeshed in software engineering and data science practices [e.g. 1, 5, 8, 38, 91, 136], and that ML techniques are a rapidly growing topic of discussion on the forum [3]. The Stack Exchange forums share data structures[10] and interface layouts, with annoymised user questions, answers, and comments from all Stack Exchange forum made available for querying and research through the Stack Exchange Data Dump [e.g. 3, 115, 149].[11]

Questions related to ML and interactive computing platforms were extracted from the Stack Exchange forums listed above on 23 November, 2022. Four example questions are shown in Figure 2. To identify relevant questions the topical tags associated with every question were leveraged. Through manual review of the forums, and queries of the Stack Exchange Data Dump, 10 ICP tags and 32 ML related tags were identified.[12] These tags are listed in Appendix A. Having identified relevant ML and ICP tags, two datasets were extracted from the Stack Exchange Data Dump: all questions on the selected forums with at least one ML related tag (a large dataset consisting of 485, 053 questions), and all questions on these forum with at least one ICP related tag (a smaller dataset of 75, 639 questions). The ML tagged questions were filtered by the presence of an ICP term (leaving 36, 940 questions), and ICP tagged questions were filtered by ML terms (leaving 9, 634 questions). This procedure resulted in two datasets with some substantial overlap. After de-duplication, a final dataset of 21, 555 ML and ICP related questions was left; this dataset became the corpus used to estimate a STM topic model..[13]

4.2 Estimation of the topic model

STM is a probabilistic, mixed-membership topic model, which extends the widely-used Latent Dirichlet Allocation model by enabling the inclusion of metadata—here, the tags associated with questions and question creation date—in the model training process (see [82, 114] for introductions to STM). To prepare the corpus for topic modelling, pre-processing was undertaken using the *stm* R package [112] (see [46, 147] for discussion of pre-processing procedures). Title and body fields for questions were concatenated into a single column. Questions on Stack Exchange forums are formatted using markdown, and often include large snippets of computer code. All code snippets and markdown were removed from questions. Code snippets were retained for subsequent analysis. Html symbols (e.g. '"'), special characters (e.g. '''), punctuation, and superfluous white spaces were removed from questions. Questions were converted to lowercase. Frequently occurring words with little topic predictive value ('stopwords') were removed from questions. Words in the questions were stemmed (i.e. converted to

[5] Although outside the scope of this paper, an additional emerging challenge is automated personalisation of digital infrastructures, which makes obtaining a general view of the infrastructure challenging [137]. ICPs do not currently afford personalisation in this way.

[6] See [59, 82, 87, 93] for overviews of topic modelling in the social sciences, and [11, 23] for more critical perspectives.

[7] Code to reproduce pre-processing steps and the topic model described below, are available at https://github.com/gberman-aus/aies_23_topic_modelling.

[8] See https://stackexchange.com/ to access Stack Exchange and its forums. Stack Overflow is broadly focused on computer programming. Cross Validated is a more specialised forum, focused on statistics and data analysis. Software Engineering is a similarly specialised forum, focused on software systems development. Finally, Data Science and Computer Science are relatively small forums, focused on data and computer science respectively. However, reflecting the ubiquity of ML techniques in computing, questions related to ML occur in all of these forums, and, as all of these forums are user-moderated, their boundaries and scope are dynamic.

[9] This estimate is based on a query of the Stack Exchange Data Dump. See [8, 10] for studies of Stack Overflow usage.

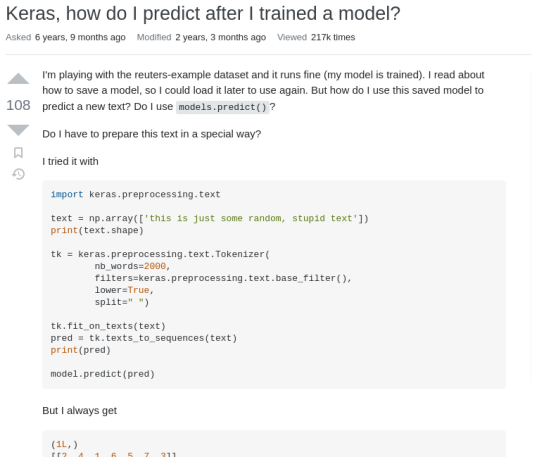
[10] A detailed description of the database schema used across forums is provided by Stack Exchange on their forum about the Stack Exchange network, appropriately named Meta Stack Exchange, accessible at https://meta.stackexchange.com/questions/2677/database-schema-documentation-for-the-public-data-dump-and-sede.

[11] The Stack Exchange Data Dump can be accessed at: https://archive.org/details/stackexchange. The database is updated weekly.

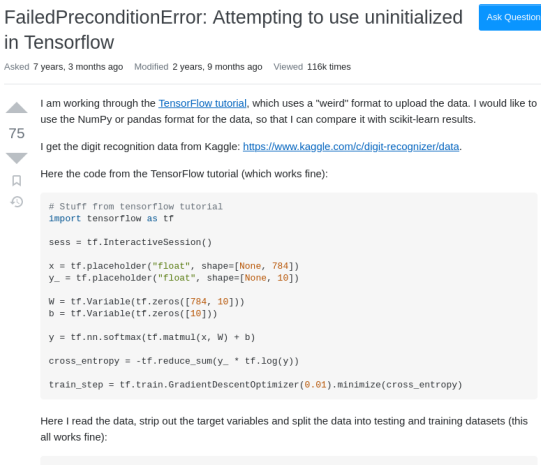
[12] In studies of more niche topics only one tag has been used [134], however, as in [3], manual review demonstrated that there are no over-arching ML or ICP tags.

[13] A significant advantage of the *stm* R package relied upon is that it enables manual setting of the random seeds used during the model training process—ensuring a higher degree of reproducability is possible.

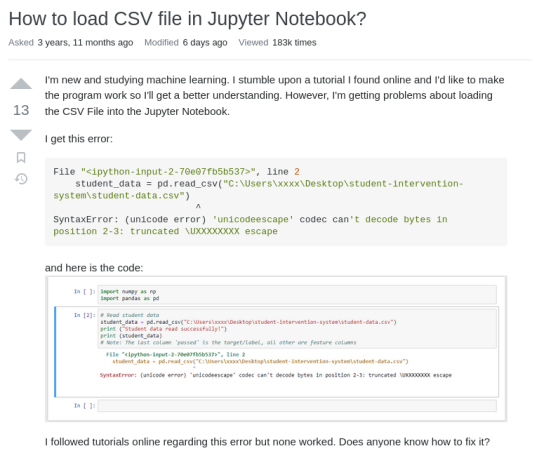
(a) Topics: 13 (28.1%), 5 (24.5%), and 23 (13.3%). The infrastructure and inter-dependencies cluster.



(b) Topics: 19 (15.6%), 21 (11.2%), and 16 (10.3%). The data manipulation cluster.



(c) Topics: 25 (48.2%), 4 (9.6%), and 8 (7.3%). The model training cluster.



(d) Topics: 13 (44.2%), 5 (31.4%), and 12 (6.6%). The infrastructure and inter-dependencies cluster.

Figure 2: Screenshots of four highly viewed questions on the Stack Overflow forum. The top three topics identified by the topic model and the cluster are reported in the caption of each image.

their root form). The creation date of questions was converted into a numerical format.

STM requires the researcher to set the number of latent topics (k) to identify in a corpus. As such, selecting the optimal value for k is an important decision, and requires testing a wide range of values [47]. Additional hyper-parameters can also be optimised, and different pre-processing regimes can also be tested against each other [46, 85]. Given the preliminary nature of the study, k values from 10 to 60, at intervals of 5 were experimented with. The *stm* package's built in multi-model testing feature was used: for each value of k, up to 50 model runs, with a maximum of 100 iterations each, were tested to ensure model stability.

To select an optimal value of k two evaluation metrics were used: *exclusivity* and *semantic coherence* [114]. *Exclusivity* is a measure of the difference in key words associated with each topic, whilst *semantic coherence* is a measure of how internally consistent each topic's key words are [147]. These measures tend to pull in opposite directions: exclusivity is likely to be optimised by increasing the number of topics, whilst semantic coherence can be optimised by decreasing the number of topics [114]. An optimal number of topics for social science research can be found by plotting exclusivity against semantic coherence for a range of k values, and then choosing a value at which neither measure dominates [114]. However, there is no 'right' value for k [107]; the aim is to find a value of k that enables meaningful interpretation [47, 114, 132]. In this instance, as can be seen in Figure 4 in the Appendix, models with k values of around 25 represented an optimal trade off between exclusivity and semantic coherence. After inspection of keywords

associated with each topic and representative questions, the model with a k value of 30 was selected.

4.3 Interpretation of the topic model

To interpret the results of the topic model Yotam Ophir and Dror Walter's [95, 142] three step process was followed. First, I qualitatively interpreted the topics identified through review of the most probable words associated with each topic (Figure 3a). Second, I analysed the relationships between topics by calculating their correlation, with a positive correlation indicating a high likelihood of two topics being found together in the one Stack Exchange question [111, 112]. Third, I used a community detection algorithm to identify clusters of topics and broader themes across the corpus (Figure 3b). In particular, I used the Newman-Girvan method for community structure detection [92], with the result being three clusters of topics. After review of the probable terms associated with topics within each cluster and representative questions, I labeled these clusters: *infrastructure and inter-dependencies*, *data manipulation*, and *model training*. As an additional final step, I made use of STM's ability to calculate the impact of covariates on topic prevalence to analyse the expected proportion of individual topics (Figure 3c) and clusters of topics over time (Figure 3d).

Throughout the above steps I moved between analysis of the topic model itself and deeper review of full Stack Exchange question and answer threads that are representative of particular topics or clusters of topics. Here, I adapted the approach of Paul DiMaggio, Manish Nag, and David Blei [34], who, after training a topic model, identify topics of interest and then undertake analysis of the most representative texts for those topics. In particular, I identified the 10 Stack Exchange questions with the highest probability for each topic, and the 10 questions with the combined highest average probability across topics within each cluster. For these highly representative questions, within each topic cluster I further sorted the questions by their view count on the Stack Exchange forums (Figures 6 - 8 in the Appendix), enabling me to identify questions that were both highly representative of a given topic cluster and highly viewed on the Stack Exchange forum.

5 FINDINGS

The topic model of Stack Exchange questions discussing interactive computing platforms and ML demonstrates that interactive computing platforms are implicated in a wide range of ML practices. ML practices are often conceptualised within a life cycle framework, with stages of ML development moving from problem formulation, to data curation and processing, to model training and evaluation, to model deployment and ongoing monitoring [e.g. 7, 75, 88, 105, 106]. Figure 3a shows the most probable terms associated with each topic, and the expected proportion of each topic across the corpus. Unsurprisingly, given the corpus focus on ICPs, the two topics most widely represented in the dataset—13 and 5—are associated with Google Colab and Jupyter Notebook respectively. The most probable terms for most other topics are associated with many of the ML development stages, particularly data curation and processing (e.g. see key terms for topics 28, 4, and 21), and model training and evaluation (e.g. see key terms for topics 19, 11, 7, and 12). The deeper review of identified topics and representative questions highlights two inter-related themes, which address the study's research question regrading use of ICPs in ML practices: the use of ICPs as *learning laboratories*; and, their role as *coordination hubs* across ML infrastructures.

5.1 Learning laboratories for Machine Learning

Interactive computing platforms serve as ML practice *learning laboratories*: they enable users to experiment with each other's code and publicly-available datasets, learn how code functions through line-by-line interactions, and redeploy code in their own use cases. ICPs are thus part of the sociomaterial context for what Louise Amoore has described as the "*partial, iterative and experimental*" nature of ML practices [4], which is also reflected in Langenkamp and Yue's broader study of open source tools [72].[14]

Figure 1 shows an example of an ICP used as a learning laboratory, drawn from a tutorial for PyTorch, an ML-focused high-level programming language. Figure 2b shows an example of a Stack Overflow question, titled '*Keras, how do I predict after I trained a model?*", which also reflects the use of an ICP as a learning laboratory. This is one of the four most viewed questions from the data manipulation cluster of topics. The author of this question appears to be engaged in a learning practice: they describe themselves as "*playing with*" the dataset, and write that they have "*read about*" saving a trained model, but are now struggling to use the saved model in a prediction task. Not shown in Figure 2b are the community answers the author received.[15] Each answer also includes a code snippet, demonstrating a solution. Similarly, the question "*FailedPreconditionError: Attempting to use uninitialized in Tensorflow*" (Figure 2c), one of the most viewed questions in the model training cluster, includes a code snippet that is "*from the TensorFlow tutorial*", which the author is attempting to use with "*digit recognition data from Kaggle*". In both these questions users' learning is through an ICP, and is focused on understanding how to achieve a specific task using the Application Programming Interface (API) of a particular high-level programming library.

When ML practitioners use interactive computing platforms as learning laboratories they engage in practices of code and data reuse. The author of the Stack Overflow question discussed above notes they are "*playing with the reuters-example dataset*", which is a publicly-available dataset used in topic modelling and text classification tasks [79], and provides a code snippet to illustrate the point at which they require assistance. Within ML practices reuse of publicly available datasets, such as the Reuters dataset for text classification or the ImageNet dataset for computer vision is well documented [32]. Patterns of dataset reuse can be found across the corpus: the Reuters dataset is referend in 11 questions; ImageNet dataset is mentioned in 436 questions; and, the MNIST handwritten digits dataset is mentioned in 834. Indirect evidence of code and data reuse in ML practices can also be found by reviewing the code snippets included in questions in the corpus. As discussed in Section 4, during pre-processing code snippets were isolated from the text of questions on which the topic model was trained. Of all questions, 89.7% include a code snippet. Because the corpus

[14] For an extended description of the relationship between learning practices and digital infrastructures see [49].

[15] The full question, including community provided answers can be seen as: https://stackoverflow.com/questions/37891954/keras-how-do-i-predict-after-i-trained-a-model.

consists of questions about using ICPs, many of these code snippets represent the point at which a user of an ICP has become stuck while trying to attempt to an ML related task. This is illustrated by the question titled "*How to load CSV file in Jupyter?*", shown in Figure 2d. Here, the author of the question has included in the body of their question a screenshot of their Jupyter Notebook. As can be seen, the first cell in this notebook begins with the *import* function, which is how specific programming libraries or sub-libraries are imported into the ICP. In this case, the author has imported *numpy*, a mathematical functions library, and *pandas*, a data analysis library. More broadly, the code snippets included in questions shed light on the substance of code that is entered into ICPs during ML related tasks. By calculating the frequency of the terms that immediately follow the *import* function, widely used programming libraries can be identified (see Figure 5 in the Appendix). Among the 15 most frequently mentioned programming libraries in code snippets are: 'Sequential', 'Dense', and 'Model' (specific components from Keras, a high-level library for deep learning); 'cv2' (a computer vision high-level library); and, 'PyTorch' (an alternative to TensorFlow).

The code snippet in the question titled "*FailedPreconditionError: Attempting to use uninitialized in Tensorflow*", shown in Figure 2c, illustrates the significance of *import* functions for extending the abilities of ICPs both as learning laboratories and more generally. The code snippet includes the line:

$$train\_step = tf.train.GradientDescentOptimizer$$

Across the corpus, 120 questions reference TensorFlow's *GradientDescentOptimizer*. Gradient Descent is a type of optimisation algorithm used during training of a neural network [117]. This line of code enables the user to access the TensorFlow library's operationalisation of gradient descent algorithms through its API—alleviating the need for the user to code their own gradient descent algorithm. While TensorFlow is only one of a number of similar software libraries available, the volume of posts (38.6% of all questions) in the corpus in which TensorFlow is mentioned, and the two most probable terms in topic 15 ('import' and 'tensorflow'), provides some indication of its widespread use in ICPs and ML practices.

5.2 Coordination hubs for ML infrastructures

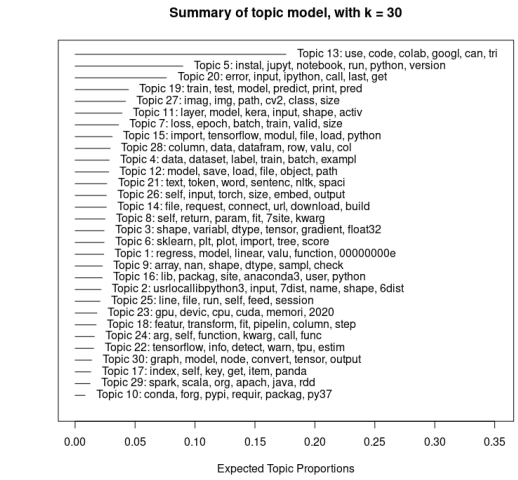
Assembling an ML workflow is a complex task, requiring coordination of multiple infrastructures. Interactive computing platforms serve as *coordination hubs*, through which networks of infrastructures are assembled to support ML practices. Reflecting this, as shown in Figure 3d, the cluster of topics associated with infrastructure and inter-dependencies accounts for a significantly greater proportion of questions in the corpus than the cluster of topics associated with model training. The most viewed questions within the infrastructure and inter-dependencies cluster reveal the infrastructural coordination that is at the heart of many ML practices.

One of the most viewed questions within the infrastructure and inter-dependencies cluster is titled "*Can I run Keras model on gpu?*" (Figure 2a).[16] Keras is a high-level API designed to support deep learning techniques.[17] Keras is integrated into TensorFlow, and enables users to build a wide range of neural networks—Keras makes it easier and more efficient to complete deep learning tasks within TensorFlow. A GPU—Graphics Processing Unit—is a specialised microprocessor, which in many computing systems works alongside the more general-purpose Central Processing Unit (CPU) microprocessor. Whilst the GPU-CPU arrangement predates the emergence of Deep Learning, it turns out that GPU microprocessors are better suited to performing many of the computations required to train a neural network than CPUs. The author of this question is attempting to assemble a system that consists of a "*Tensorflow backend*" and a "*Keras model*", interacted with through a "*Jupyter notebook*", and run on their computer's GPU. The highest scoring answer recommends installing CUDA, which is an additional parallel programming platform designed to enable GPUs to be used for non-graphics processing tasks, such as model training. This answer provides hyperlinks to additional resources for installing CUDA and checking that TensorFlow is running properly on a GPU. Above this answer are two further user comments also linking to additional resources. As such, the author of this question is assembling a system that involves at least five interdependent layers: GPU, CUDA, TensorFlow, Keras, Juypter Notebook. The author is fortunate, however, as their aim is to train their model within "*36 hours*", which suggests that either they have access to a powerful GPU, or they are training a model with a relatively small dataset (for instance, as part of a learning exercise). In industrial or research settings, training a neural network requires access to much greater compute resources, which requires users to access a cloud resource, such as Amazon Web Services, and adds at least one additional layer of complexity to the system.

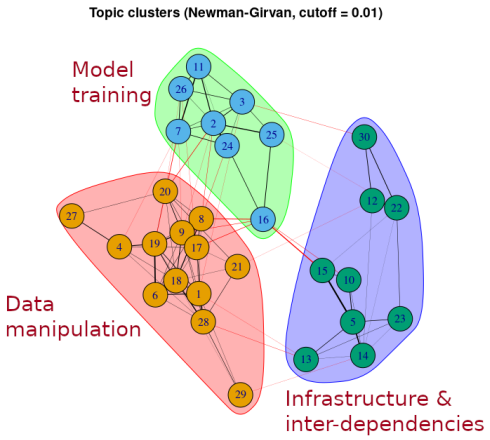
The key words associated with topics within the infrastructure and inter-dependencies cluster (shown in Figure 3a) provide an additional perspective on the infrastructural coordination required to support ML tasks. In descending order of representation in the corpus, these topics are: 13, 5, 15, 12, 14, 23, 22, 30, and 10. As already observed, topics 13 and 5 relate to Google Colab and Jupter Notebook, two ICPs. Meanwhile, topic 15 includes 'import' and 'tensorflow' as the two most probable terms. Topic 23 includes 'gpu', 'cpu', and 'cuda' as probable terms. Topic 22 includes 'tensorflow' and 'tpu', which is a reference to Tensor Processing Units, which are a new generation of GPUs specifically designed to support TensorFlow. The presence of these topics, and their close correlations, as shown in Figure 3b, indicate that coordination between infrastructures is widely discussed on Stack Exchange. Finally, Figure 3d shows the expected proportion of topic 13 (Google Colab) compared to topic 5 (Jupyter Notebook) over time. The topic model estimates that since 2017 questions related to Google Colab have increased compared to questions related to Jupyter Notebook. Significantly, a key point of difference between these two platforms is that Google Colab has been designed to integrate directly into Google's cloud compute infrastructure, and is used as the platform of choice in TensorFlow and Keras tutorials.

[16] See https://stackoverflow.com/questions/45662253/can-i-run-keras-model-on-gpu for the full question and its answer thread.

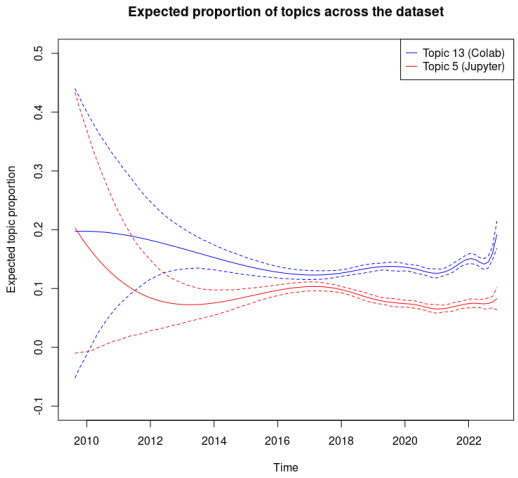
[17] See https://keras.io/ for an introduction to Keras.



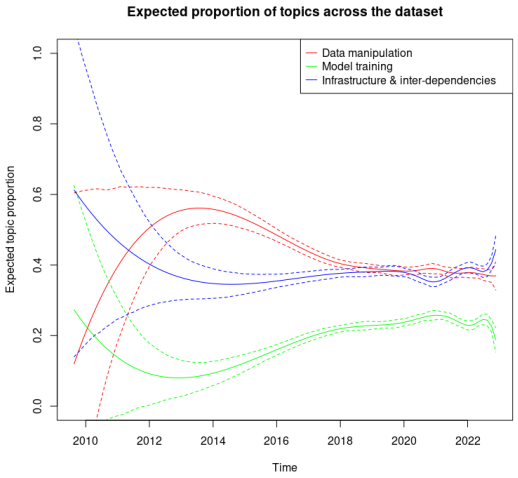
(a) Expected distribution of all topics across the corpus, with the most probable word associated with each topic.



(b) Topic correlation network, using the Newman-Girvan method, with a minimum correlation threshold of 0.01.



(c) Comparison of the expected topic proportions in the corpus over time for topics 13 (Colab related questions) and 5 (Jupyter related questions). Dashed lines represent a confidence interval of 0.95.



(d) The expected topic proportions over time, with the three communities identified in Figure 3b treated as groups of topics. Dashed lines represent a confidence interval of 0.95.

Figure 3: Visualisations of the estimated topic model.

6 DISCUSSION

In this study, the intertwining of interactive computing platforms in ML practices was explored. The findings indicate that ICPs are learning laboratories—tools by which users experiment with and learn ML practices through line-by-line interaction with others' code and publicly available datasets, facilitated by the APIs provided by high-level programming languages. The findings show also that ICPs are coordination hubs—sites at which multiple different infrastructures are brought together to support ML practices, such as model training or data processing. Given the role ICPs play as coordination hubs for ML practices, they can be conceptualised as an emerging form of 'digital infrastructure'—an essential and widely participated in sociotechnical system [19, 104]. Conceptualising ICPs in this way enables existing theorising about infrastructures to inform consideration of the sociopolitical significance of ICP use in ML practices, and helps connect ICP use to concerns raised in AI ethics discourse. To illustrate this, in the following subsections I consider how Brian Larkin's review of anthropological practices for studying infrastructure [73] and Susan Leigh Star's description of the properties of infrastructure [130] can apply to ICPs. In each subsection I conclude with a brief reflection on implications for AI ethics discourse.

6.1 An emerging infrastructural relationship

As material objects, Larkin describes infrastructures as "*built networks that facilitate the flow of goods, people, or ideas*" [73, p.328]. At the same time, infrastructures are systems that support the functioning of other objects, and it is these objects that users of an infrastructure experience; we experience hot water, not plumbing [73, p.329]. Star describes this characteristic of infrastructure as 'transparency': for users of an infrastructure, the tasks associated with it seem easy and straightforward—transparent [130]. Star, however, understands infrastructures as relational. Transparency is not an inherent characteristic of a sociotechnical system, but rather a characteristic of an infrastructural relationship between a sociotechnical system and its users.

The topic model of Stack Exchange questions is a snapshot of an emerging infrastructural relationship: as ML practitioners use ICPs as coordination hubs, facilitating flows of data and code across networks of disparate resources (compute capacity, programming languages, datasets, etc.), they are forming an infrastructural relationship with the platform. The platform itself recedes into the background and the objects that the platform enables to function—predictive models—come into the foreground. This is why ICPs excel as learning laboratories for ML. The affordances of the ICP, however, continue to have efficacy even as the platform itself becomes transparent: the affordances enable and constrain users, and in doing so help configure practices associated with the ML techniques that the platform enables [30, 31].

Star's understanding of infrastructures as relational also highlights the relationship between infrastructures and groups: infrastructures are "*learned as part of membership*" [130, p.381]. This conceptualisation of the relationship between infrastructures and group membership appears to align closely to the burgeoning infrastructural relationship between ML practitioners and ICPs. As the topic model interpretation illustrates, ML practitioners learn to use an ICPs as part of the process of becoming 'ML practitioners'. Star highlights that shared use of common infrastructures among practitioners helps reinforce their identity as a distinct group [130]. Non-members, meanwhile, encounter infrastructures as things they need to learn to use in order to integrate into a group. Note, for example, the author's phrasing in the Stack Overflow question shown in Figure 2d: "*I'm new and studying machine learning... I'm getting problems about loading the CSV File into the Jupyter Notebook*". 'ML practitioner' is an ill-defined term frequently used in AI ethics discourse as a catchall for describing the data scientists, software engineers, and product managers who work on the research and development of ML systems. From an infrastructural perspective, however, the term can also be thought of symbolising a new set of infrastructural relations: where previously data scientists, software engineers, etc., each worked within their own suites of tools, increasingly they use shared infrastructure, such as ICPs, enabling the collapsing of distinctions between these professional roles that is indicated in the term 'ML practitioner'.

6.1.1 Implications for AI ethics. A stream of AI ethics research has focused on the development of software and management tools to support ML practitioners (see [88] for an overview). For this stream, ICPs may be a constraint, in so far as tool adoption is often held to be dependent on integration with existing ML infrastructure and practices [e.g. 40, 50]. Alternatively, the affordances of ICPs may offer new opportunities for future tool development. The grammar of ICP interactions may be applied to the design of tools intended to prompt practitioner reflection. The open source Fairlearn library, for example, provides example ICP notebooks[18] to demonstrate library uses.

More broadly, however, as ICPs contribute to the configuring of ML practices, they shape the space in which AI ethics are situated. Here, Britt Paris's [97] reflections on the relationship between Internet infrastructure and constructions of time are instructive. ICPs, like the Internet at large, imagine particular temporal relations. ICPs, in particular, are premised on speed: the staccato call-and-response of user inputs and computer outputs helps configures a working environment in which the value of ML practices resides in their speed and efficiency. In this sense, conceptualising ICPs as ML infrastructure presents as a challenge to calls from AI ethics researchers for greater reflexivity in ML [e.g. 37, 146].

6.2 Visible and invisible infrastructures

As material objects, infrastructures are designed, and reflect, at least in part, the intentions of the designer. Yet, at the same time, infrastructures are "*built on an installed base*", often following paths of development laid down by preceding infrastructures [130, p.382]. And, infrastructures are often caught in circular webs of relations with other infrastructures: computers rely on the electricity grid to function, and the functioning of the modern electricity grid is reliant on computers [73]. Infrastructures therefore cannot be understood in isolation, in the same way that they cannot be designed in isolation. The role ICPs play as coordination hubs reflect this: they are built on top of the networked and decentralised infrastructures of the Internet, programming languages, and computing. In doing so, ICPs augment and extend these pre-existing infrastructures, both following path dependencies established by these infrastructures and charting new paths for future infrastructures [cf. 148].

Larkin highlights that infrastructures also serve a 'poetic' function [73]. Larkin draws on linguist Roman Jakobson's concept of poetics [62], which holds that in some speech acts the palpable qualities of speech (roughly, sound patterns) have primary importance over representational qualities (i.e. meaning). Infrastructures, argues Larkin, can have a poetic function, not reflected in the declared intentions of designers, nor in their technical capabilities [73]. Researchers of infrastructure, then, must take seriously the aesthetic aspects of infrastructure, and consider how infrastructures not only reflect the declared intention of those who build them, but also their (undeclared) interests. Larkin's description of the poetics of infrastructure mirrors Jenna Burrell's critique of blithe descriptions of algorithms as 'opaque', which ignore the ways the appearance of opaqueness in an algorithmic system can reflect the politics of the institutions who operate them [26]. In this context, a significant line of future inquiry pertains to the different politics and interests reflected in the two ICPs identified as widely used by the topic model: Jupyter Notebook and Google Colab.

For Larkin, the aesthetic aspects of infrastructure include the way infrastructures may at times appear transparent or invisible [73]. Here, Larkin takes issue with Star's description of infrastructures

[18] See https://fairlearn.org/v0.8/auto_examples/index.html.

as 'invisible'. Star describes this characteristic of infrastructure as "*becoming visible upon breakdown*" [130, p.382]. By standardising interactions between material objects, users, and other infrastructures, infrastructures become transparent to users, and, when this transparency becomes routine, the infrastructure itself appears invisible. Questions asked on Stack Exchange can thus be interpreted as instances of ML infrastructure becoming visible. To Larkin, however, the claim that infrastructures are invisible can only ever be partially valid: what the affordances of infrastructures make visible and invisible is both an outcome a system's technical capabilities and its poetic functions. Larkin and Star's debate on invisibility thus helps shed light on the mechanism by which ICPs become implicated in the characteristics of ML systems that are developed through their use. As infrastructural systems, ICPs standardise a particular form of presenting and interacting with code—the 'notebook' layout of descriptive and computation cells described in Section 2.2—and this standardisation renders some aspects of ML system development more visible to ML practitioners than others.

Shifts in the aspects of ML system development that are transparent to ML practitioners can have significant impacts on practitioners' understanding of ML technologies. As discussed in Section 5.1, ICPs support iterative experimentation with the APIs of high-level programming languages, which often occurs through probing and re-purposing of code written by others. Iterative experimentation with the API of a high-level programming language, however, is unlikely to reveal the full range of decisions that the creators of an API have made in operationalising a particular ML algorithm or technique. The point of Keras' *Tokenizer* function (shown in the code snippet in the Stack Overflow question in Figure 2b) is that it enables users to convert the text in a corpus into a series of integers ('embeddings'), so that computations (e.g. topic modelling) can be run on the corpus. The function enables users to choose whether or not to convert text to lowercase, but because the function has a default setting, this choice is not necessary—by default any call of the *Tokenizer* function will convert text to lowercase before conversion to numerical form.[19] This may seem inconsequential, but it can have a significant downstream impact: converting a corpus to lowercase means that the verb 'stack' and proper noun 'Stack' will be embedded as semantically identical.

As APIs of high-level programming languages become more sophisticated, particularly as they start to incorporate pre-trained models for common ML tasks (e.g. image classification, object detection and labelling, sentiment detection), the choices obfuscated by the API become more consequential. The TensorFlow Object Detection notebook[20] uses a CenterNet pre-trained model which was trained on the Common Objects in Context dataset [81]. This dataset includes labels for 91 categories of objects, including 'plate', 'cup', 'fork', 'knife', 'spoon', and 'bowl' (but not, for instance, 'chopstick'), and it is these objects that the CenterNet model can detect in images. This sequence of choices, and the constraints each choice imports into the ML system, are not surfaced by experimentation with the API in an ICP; the infrastructural relationship between ML practitioners and ICPs renders transparent code reuse, but leaves detailed code knowledge opaque.

[19] See https://www.tensorflow.org/api_docs/python/tf/keras/preprocessing/text/Tokenizer for the *Tokenizer* documentation.
[20] Accessible at https://www.tensorflow.org/hub/tutorials/tf2_object_detection.

6.2.1 Implications for AI ethics. At stake in AI ethics discourse are questions of legitimacy. Arising from the recognition that code operationalises and reifies particular interpretations of essentially contested social constructs [20, 60, 89] is the challenge of locating where and how coding decisions are currently made, and where they ought to be made. What, if any, categories of gender ought to be included as labels in an image dataset [66]? High-level APIs, interacted with through ICPs, obscure these decisions, and in doing so further entrench them in ML practices: what is unknown to ML practitioners is unquestioned. In this sense, the infrastructural relationship between practitioners and ICPs is an example of social arrangements helping configure ML practices as 'black boxes' [26], and is thus a new challenge to the efforts of AI ethics researchers to embed accountability for decision making in ML development [29].

6.3 Development of infrastructures over time

The role of coordination hub lends ICPs and the web of other infrastructures they are related to (compute resources, code repositories, etc.) a semblance of hierarchical coherence. But, while infrastructures may be presented as coherent, hierarchical structures, they are rarely built or managed in this way. Indeed, Jupyter Notebook began life as an open-source project focused on scientific computing within the Python programming language, before being adopted and adapted by ML practitioners and industry [45]. In this sense, the emergence of ICPs as infrastructure reflects a familiar process of adaptation and translation [cf. 57]. Relevantly, Star highlights that infrastructures are fixed in modular increments [130, p.382], with "*conventions of practice*" co-evolving alongside the development of the infrastructure itself [130]. Here, Elizabeth Shove's work on the co-evolution of infrastructures and practices offers a potential framework by which to explore how ICPs and ML practices co-evolve [124, 125].

Watson and Shove argue that infrastructural relations and practices co-evolve through processes of aggregation and integration [145]. Aggregation refers to "*the ways in which seemingly localised experiences and practices combine and, in combining, acquire a life of their own*" [145, p.2]. Individual ML practitioners, for example, each develop their own approach to coordinating the different layers of infrastructure needed to support ML tasks. However, as individuals share their approaches, and these coalesce into conventions, the conventions themselves shape future infrastructure development. The convention of using GPUs for model training, for example, creates the demand needed to justify the development of more specialised TPUs. Integration refers to ways that policies, processes, and artefacts at the level of the overarching infrastructure are "*brought together in the performance of practices enacted across multiple sites* [145, p.2]. Google, for example, sets various policies regarding the availability of Google's GPU resources to users of Google Colab. These policy decisions (e.g. the decision to offer limited free access to GPUs) in turn are integrated into individual users' ML practices—top-down policy decisions help inform the future development of conventions of practice, but do not determine them. For the field of AI ethics, the framework of aggregation and integration offers a path towards understanding how norms in ML practices, such as the use of particular operationalisations of fairness metrics, co-evolve as a product of both

the integration of particular fairness approaches into high-level programming languages and the aggregation of local approaches to 'managing' ethics issues into shared practices.

6.3.1 Implications for AI ethics. Conceptualising interactive computing platforms as an emerging form of 'digital infrastructure' situates them alongside other digital 'platforms' that have coalesced into infrastructures (e.g. WeChat [101], Facebook [51, 52, 103], and Google [103]). The prominence of these digital infrastructures in mediating contemporary life has led to the development of the platform governance field [43].[21] Platform governance researchers have explored how digital infrastructures attempt to exercise governance over their users, and how digital infrastructures themselves can be more effectively governed. Robert Gorwa, for example, has studied the governance of online content, particularly user-generated content on digital platforms [42]. As Gorwa argues, there is an increasing nexus between AI ethics discourse and platform governance discourse: algorithmic systems, particularly predictive ML systems, are core components of the governance regimes of digital infrastructures [44]. Tarleton Gillespie, for example, critiques the positioning of ML tools as the solution to social media content moderation [41]. ICPs advance this nexus, but in the reverse direction: as the platforms have developed from software tools for scientific computing to general purpose coordination hubs for ML practices they have begun to integrate affordances more commonly associated with digital platforms. Google Colab, for example, integrates directly into Google Drive—a widely used cloud storage and file sharing platform. We can interpret this integration as an effort to cultivate network effects [14]: if I care about sharing my notebook with others, then it makes sense that I will seek out the ICP that integrates directly with the file sharing system most of my colleagues use. But, to the extent that a notebook is 'content', and the extent that this content may include ML models that have been shown to cause significant social harm, ICP operators have so far eluded responsibility for this content. For the field of AI ethics, then, the potential for ICP operators to exercise governance functions over ICP users may be worth further consideration.

7 LIMITATIONS

Conceptually, as Eric Baumer and Micki McGee [11] argue, topic modelling risks using a statistical model of a corpus to speak on behalf of a social group. This risk is compounded by the fact that the social group who generates content that enters a corpus (in this study, people who ask questions on Stack Exchange forums) may not be representative of the social group of interest to the study (here, ML practitioners). Relevantly, among the Stack Overflow user base, as of 2016, only 5.8% of contributors were female [38]. Additionally, while there are versions of Stack Overflow in multiple languages, only the English-language version has been used in this study. As such, future research will need to validate the extent to which the practices identified in this study are representative of ML practitioners.

The focus of Stack Exchange questions also presents a fundamental limitation for studies of ML practitioners. Stack Exchange questions are points of trouble—they represent moments when a user has been unable to complete a task. As such, it may be the case that there are a range of practices that are not represented in the Stack Exchange corpus, simply because they are practices so familiar they do not necessitate asking any questions. Given the discussion on transparency and infrastructures in Section 6.1, this means Stack Exchange questions can only offer a partial account of infrastructural relationships. There are also limitations inherent in the pre-processing and model training process outlined in Section 4.2. In particular, stemming of words may have reduced the semantic depth of the topic model, as may have removal of code snippets from the corpus. The validation of topic models is an ongoing area of research [46, 85]. As this is a preliminary study, no attempt has been made to externally validate the accuracy of the topics identified (e.g. through comparing the latent topics identified by the topic model to coded themes identified by expert human reviewers of the same corpus, as in [86]). More broadly, the approach taken in this study will benefit from complementary qualitative studies to both validate and contextualise findings (e.g. ethnographic studies of practitioners in multiple social contexts [39]).

8 CONCLUSION

Interactive computing platforms, such as Jupyter Notebook and Google Colab, are widely used by ML practitioners. In this paper, I conducted a topic model analysis of user-contributed questions on the Stack Exchange forums related to interactive computing platforms and ML. I found interactive computing platforms are used by ML practitioners in two categories of practices: in learning practices, particularly to support probing and reuse of others' code; and, in coordination practices, to help marshal the various infrastructures needed to enact ML tasks. I argued that these practices constitute an emerging infrastructural relationship between ML practitioners and interactive computing platforms, in which both the platforms and ML practices are co-evolving. I highlighted several consequences of this infrastructuralisation, in terms of configuring the space in which AI ethics operates and responds to, designing interventions in ML practices, making visible the operationalisation in code of social constructs, and the platform power of ICP operators. As the ML field advances, a pressing issue is therefore the relationship between the social context ICPs form part of and the characteristics of ML systems that are developed. Tracing these relations is critical for resisting the enclosure of AI ethics by a set of social arrangements that may themselves be contributing to the production and deployment of harmful ML systems.

ABSTRACT

Fairness toolkits are developed to support machine learning (ML) practitioners in using algorithmic fairness metrics and mitigation methods. Past studies have investigated practical challenges for toolkit usage, which are crucial to understanding how to support practitioners. However, the extent to which fairness toolkits impact practitioners' practices and enable reflexivity around algorithmic harms remains unclear (i.e., distributive unfairness beyond algorithmic fairness, and harms that are not related to the outputs of ML systems). Little is currently understood about the root factors that fragment practices when using fairness toolkits and how practitioners reflect on algorithmic harms. Yet, a deeper understanding of these facets is essential to enable the design of support tools for practitioners. To investigate the impact of toolkits on practices and identify factors that shape these practices, we carried out a qualitative study with 30 ML practitioners with varying backgrounds. Through a mixed within and between-subjects design, we tasked the practitioners with developing an ML model, and analyzed their reported practices to surface potential factors that lead to differences in practices. Interestingly, we found that fairness toolkits act as double-edge swords — with potentially positive and negative impacts on practices. Our findings showcase a plethora of human and organizational factors that play a key role in the way toolkits are envisioned and employed. These results bear implications for the design of future toolkits and educational training for practitioners and call for the creation of new policies to handle the organizational constraints faced by practitioners.

1 INTRODUCTION

It is now well-known that machine learning (ML) applications employed for decision-making might cause or reinforce distributive unfairness and other harms [3, 67, 69, 73, 100]. As a result, over the years, a great amount of theoretical research in ML has focused on conceptually understanding potential harms and on developing algorithmic methods to build ML systems that are less harmful [28, 100]. These methods, better known as algorithmic fairness metrics and unfairness mitigation methods, have lately been packaged into various *fairness toolkits* [6, 10, 23, 87, 97] to make it easier for their adoption by those who develop ML models (ML practitioners). A parallel line of research has investigated the practices of these ML practitioners, studying how they make use of proposed methods and what challenges they face. These studies are extremely important to understand how to further support practitioners.

Considering that the fairness toolkits are becoming a defacto standard means of tackling questions pertaining to algorithmic fairness[1] and potentially of teaching "ethical ML" to practitioners [13, 65], it is important to understand the extent to which practitioners rely on such toolkits, and whether and how toolkits shape their practices. Addressing this knowledge gap is a crucial step towards questioning the broad impact of fairness toolkits. A majority of past studies [24, 45, 57, 60, 77, 84, 85, 99] that have focused on the practices and challenges of practitioners in using the fairness toolkits have already identified a number of limitations of the toolkits in terms of design and technical specifications, that might hinder their adoption. However, such studies fall short in two major ways.

Fairness toolkits allow one to implement algorithmic methods for handling algorithmic unfairness. Yet, it is now well understood that these methods bear conceptual limitations [3, 43, 52, 58, 69, 88, 102]. Algorithmic unfairness observed in the outputs of an ML system is only a simplified representation of distributive unfairness in the world (what the metrics aim at quantifying), mitigation methods might themselves cause harm or not address the root causes of

[1] https://www.borealisai.com/research-blogs/industry-analysis-ai-fairness-toolkits-landscape/; https://www2.deloitte.com/de/de/pages/risk/solutions/ai-fairness-with-model-guardian.html

distributive unfairness, and other harms (beyond distributive unfairness) caused or reinforced by the use of ML systems are not accounted for by this framework (e.g., the purpose of the system itself might considered harmful, independently of the system's outputs being fair or not)[2]. None of the studies around practices and toolkits has however investigated how ML practitioners might conceive and overcome these limitations. It is especially unclear whether the toolkits narrow down practitioners' activities towards algorithmic unfairness and broader harms. These insights are necessary to envision where to focus future research efforts in terms of algorithmic harms beyond algorithmic fairness.

Additionally, prior studies do not report on differences of practices and challenges across practitioners, and the factors that cause these differences. Yet, identifying these differences, and grounding these differences into the *factors* that impact the fragmentation would allow one to identify the root causes of potential flawed practices and of certain challenges. This would allow one to envision more appropriate future solutions. In other words, explicitly looking into factors would allow one to answer the following questions: should fairness toolkits be our object of study to foster practices for handling algorithmic harms, i.e., are toolkits really the most important factor that supports and impacts practices around algorithmic harms (they would be if we would find a coherent set of practices across practitioners using a toolkit in comparison to those who do not)? Or are they only technical mediators of practices, that are impacted by deeper factors beyond the availability and design of the tool?

Hence, in this study, we ask the following two research questions: 1) How effective are toolkits in enabling practitioners to reflect about algorithmic harms and to handle them? 2) Which are the factors that affect the (in)effectiveness of toolkits in shaping practitioners' practices around algorithmic harms?

In order to answer these questions, we conduct 30 semi-structured interviews[3] with practitioners of various backgrounds. We compare practices before and after a practitioner is introduced to a fairness toolkit (within-subject experiment), and practices between practitioners who do not use a fairness toolkit to those who do (between-subject experiment), in order to understand the potential role of toolkits in shaping up practices. Besides, we further analyse qualitatively the interviews, and compare practices across practitioners, and across the two toolkits selected for this study, in order to identify potential additional factors that might impact practices.

For the participants of our study, we find that toolkits do increase awareness and use of algorithmic methods towards algorithmic fairness, do not impact considerations of algorithmic harms, yet can foster a checkbox culture with absence of reflexivity around the limitations of algorithmic fairness. More than solely toolkits, we also find that various human factors, such as types of training, and psychological and socio-demographic traits, as well as contextual factors, and especially organisational incentives, interact to shape up how practitioners make use of the toolkit, how reflexive they are around the limitations, and whether they conceive and tackle broader algorithmic harms. These factors, while they have been mentioned scatteredly across research publications that deal with perceptions of algorithmic harms [47] or the governance models of organizations around algorithmic fairness [84], had not been analyzed in detail in terms of their impact on the practices for the development of ML systems (with harms in mind). We then further discuss the implications that our findings bear when fostering reflexivity among practitioners towards avoiding algorithmic harms, e.g., in the form of design guidelines for fairness toolkits, as well as educational programs, and for further enforcing policy efforts towards making algorithmic systems less harmful.

[2]In the remaining of the paper, we use *algorithmic harms* to refer to any harm that ML systems might cause or reinforce, among which are *distributive unfairness* harms (related to the unfair ways in which resources are allocated following the recommendations made by the outputs of an ML system). We use *algorithmic unfairness* to refer to the limited conceptualisation of distributive unfairness in the lens of algorithmic metrics and methods developed by the scientific community.

2 RELATED WORK

2.1 Fairness Toolkits for dealing with Algorithmic Unfairness

2.1.1 Algorithmic Unfairness. Each step of the machine learning (ML) lifecycle might create or reinforce *distributive unfairness* [67, 94]. Theoretical works have primarily developed *algorithmic fairness* metrics [100] that aim at measuring distributive unfairness in the outputs of the final model or in a dataset. These works also propose algorithmic unfairness mitigation methods [4, 28] that ought to improve the model's algorithmic fairness as defined by the metrics. Facing the diversity of metrics, the challenge for a practitioner is to choose the appropriate one for their task.

Several studies have investigated how ML practitioners work with algorithmic fairness metrics and mitigation methods. Topics of focus revolve around general challenges met by practitioners [22, 45, 60, 71, 74, 77, 84, 89, 99, 103], and obstacles and limitations for the application of algorithmic fairness methods. Findings outline the need to support practitioners to concretely use fairness methods, as this use is challenging due to the context dependence of methods, the current lack of guidance [45, 60], and the need for adapting methods that are incompatible with targeted tasks [45].

2.1.2 Effectiveness of Fairness Toolkits. To facilitate the adoption of algorithmic fairness metrics and mitigation methods, various companies and public institutions have built fairness toolkits. These toolkits are typically code repositories that allow for an easier implementation of the metrics and methods. Examples of these toolkits are FairLearn [10], AIF360 [6], Aequitas [87], Themis-ML [5], ML-Fairness Gym [23], TensorFlow Fairness Indicators [107], etc.

Various works [24, 57, 85] have shown through interviews the beneficial use of toolkits by practitioners for developing fair models and learning about algorithmic fairness. Yet, they also show their limitations in terms of support provided to practitioners for designing the right algorithmic fairness evaluation, noting that participants often inappropriately change their modeling task definition to fit existing tools. These works also identify obstacles to the application of the toolkits in terms of compatibility with other ML frameworks and usability, summarized into toolkit checklists that should inform the design of future toolkits. We will show that our results corroborate and complement these insights. Indeed, to the best of our knowledge, our work is the first to investigate

(or report) whether the toolkits do impact practices contrary to a situation where no toolkit would be available, whether there are differences in practices of different practitioners using a same toolkit, or whether different toolkits lead to different practices.

2.2 Fairness Toolkits for reflecting on Harms Beyond Algorithmic Unfairness

2.2.1 Algorithmic Harms. A few theoretical works have looked beyond algorithmic fairness to identify other harms of ML [3, 69]. We now present a few of these harms that are highly worthy of consideration according to the literature. Algorithmic fairness metrics and methods bear conceptual limitations, that do not allow one to comprehensively gauge the distributive unfairness they are aimed at addressing. By limiting harms to the frame of output distributions (also termed distributive justice fairness), algorithmic fairness cannot reflect the contextual factors that influence what is considered fair. For instance, it assumes that parity is always desired in the model outputs [58], it does not account for the impact one same output has on different receivers of this output [69], nor for the indirect impact on non-data subjects [52]. Looking at the process to reach algorithmic fairness (termed procedural justice), the metrics and mitigation methods do not make sure that the way in which the unfair situation is addressed is aligned with moral principles [102]. For instance, individuals or groups might see low disparate accuracy by all receiving unjustified treatment [72], or by all being treated differently (e.g., post-processing methods allocate different decision thresholds for different groups) which consists in direct discrimination [35].

Three other categories of harms have also been discussed. First, ML requires to use *datasets* whose schemas and sampling can be harmful. For instance, certain attributes and their values might be offensive [11, 108] or inappropriate [67], e.g., use of non-volitional or privacy-infringing attributes [39, 95]. Second, research questions the *desirability of the ML model* in the first place, its use for undesired applications [46, 48, 69, 70], and how it impacts structures in place [27]. Using ML for certain tasks might be questioned, for instance because it means making decisions for people by comparing them to others instead of following the principle of individual justice [9, 26], or because it reproduces historical, potentially harmful, data patterns [81]. Third, certain researchers question the *negative externalities caused by the production process* of ML applications, such as the environmental impact of data centers and model training [7, 17], the poor labor conditions of crowd workers [86, 105, 109, 111], the privacy-infringing training data [82], etc.

2.2.2 Effectiveness of Fairness Toolkits. Besides investigating the effectiveness of toolkits in enabling reflexivity around algorithmic unfairness, it is important to acknowledge the known limitations of the algorithmic fairness methods and the existence of other algorithmic harms that ML systems might pose. To the best of our knowledge, no work has investigated practices in relation to these limitations. We do not know to what extent the use of fairness toolkits —that foster the use of the algorithmic fairness methods— impacts considerations of algorithmic harms and of the limitations of algorithmic fairness (that are typically obfuscated from the toolkits). It is unclear whether fairness toolkits, that do not deal with these harms, might lead practitioners to "forget" them.

2.3 Factors Affecting the Usage of Toolkits

The effectiveness of fairness toolkits in enabling reflexive practices among ML practitioners around algorithmic unfairness and harms is conditioned by factors that shape the usage of these toolkits. Research into the characterization of these factors is still scarce. It is important to understand which factors make practitioners choose one metric or the other, and more broadly, to identify the factors that impact the decision of practitioners to try quantify unfairness, and later to mitigate it. The factors that lead a practitioner to handle broader algorithmic harms have also not been investigated in the past. Knowledge of these factors could allow one to better understand the deeper nature of the challenges faced by practitioners, and to provide more personalised support to these practitioners.

Up to now, studies have solely identified organisational factors, that are further shown to be obstacles for practitioners to develop fair models [60, 62, 84, 99]. Contrary to our work, previous studies had not accounted for human factors in their study design or in their result analysis, such as Deng et al. [24] who only reported on coarser-grain practices (e.g., they reported that the practitioners they interviewed recognize the limitations of their knowledge and wish to receive help from domain experts, but do not specify any difference across these practitioners). In our study, we find such factors, and also investigate the existence of technical ones.

3 METHODOLOGY

To characterize the effectiveness of fairness toolkits in enabling reflexive practices, and to identify the factors that might impact and fragment those practices, we adopted an empirical and qualitative approach via 30 semi-structured interviews with ML practitioners. By comparing practices within-subjects (participants are observed before and after receiving an introduction to fairness toolkits), we observe the extent to which toolkits enable or hinder reflexivity. Additionally, by comparing practices in-between subjects who bear different characteristics (e.g., background and prior experiences) and who use different toolkits, we characterize the fragmentation and delve further into the contributing factors.

3.1 Participants

We recruited our participants in the period of April-June 2022, by means of personal networks, targeted requests on social media, calls for participation on the official Discord or Slack communication channels of the toolkits, LinkedIn, and snowball sampling. The participants received no financial compensation, and their contributions were voluntary (they typically participated to learn more about algorithmic harms, and to help science progress). Our institution's ethics committee approved the study. All participants signed an informed consent form acknowledging the risks involved with participating, as well as agreeing to the interview being recorded (all interviews were conducted online), transcribed, anonymized, destroyed, and consented to the results being used in scientific publications.

A total of 30 participants were recruited across research and industry institutions, and across application domains such as healthcare, finance, and predictive maintenance (cf. supplementary material). Manual sampling was performed to make sure that all participants have responsibilities in ML model development, deployment,

or evaluation; varying levels of prior experience with ML, ranging from 2 to 15 years; and varying practical experience with algorithmic fairness and fairness toolkits (11 participants already had experience with FairLearn, and 9 with AIF360). The resulting participants differ in terms of demographic background (nationality, gender, and age), level of highest education, educational background, and type of training received around ML. Besides, participants already experienced with algorithmic fairness presented variations in terms of how they learned about the topic, the kind of experience they have had, and for how long they have worked with these issues (from 0 to 18 years).

3.2 Interview Procedure

The interviews with participants already familiar with a toolkit lasted one hour each, going through Task T1. The interviews with the other participants lasted around two hours each, through three stages (Task T1, a tutorial about one fairness toolkit, and Task T2). These three stages were designed to identify how the use of toolkits might impact practices around algorithmic harms. Comparing practices between participant groups with or without prior familiarity with the toolkits allowed us to unveil other influential factors, such as the type of training received around harms. In total, we collected 2207 minutes of recording. In Figure 1, we show the workflow of the interviews with the questions asked in each stage, for the two kinds of participants. We asked three types of questions: background experience questions (demographics, experience with ML and algorithmic fairness); reflection questions around algorithmic fairness, harms, or toolkits, and around general comments, wishes, doubts, and challenges the participants might have about their workflow or harms; and process questions to understand the reasoning behind each participant's activities during the tasks (cf. supplementary material for details on tutorial and questions).

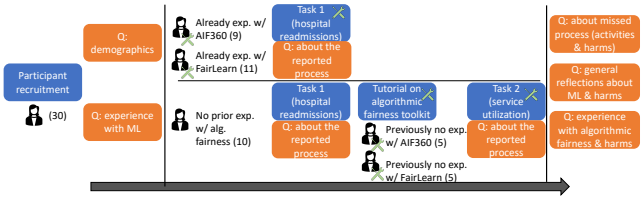

Figure 1: Interview procedure for the participants already experienced with a fairness toolkit, and for the participants who did not have any prior practical experience with algorithmic fairness. In blue: the main steps of the procedure; in orange: the questions posed in each step.

3.3 Materials

Use-Cases. We chose two use-cases, the first one involving the prediction of *hospital readmissions* within 30 days for individual patients [93], referred to as Task T1, and the other involving the prediction of low or high *medical services utilization* [42], referred to as Task T2. Using these tasks instead of discussing the participants' own use-cases was important to be able to rigorously compare practices over the same case and to surface the factors that impact practices for a same use-case. We pre-processed the two corresponding datasets for them to have similar characteristics (number of attributes and of records), and to be prone to similar harms (cf. supplementary material). By employing comparable domains and datasets without re-using the exact same use-case for the two tasks of the interviews, we aimed to minimize learning effects. We chose the domain of healthcare because it is prone to various harms, requires expertise to be handled correctly (i.e., we could check whether the participants mentioned the limits of their knowledge [24]), several corresponding datasets were available, and these are not the most frequent use-cases in the algorithmic fairness literature which allows us to minimize the confounding effect of familiarity with the domain of application. Our choice also allows us to mimic a realistic situation, where oftentimes, practitioners have to develop or deploy models without having extensive expertise in the domain of application. In such cases, practitioners' decisions might lead to harms, that fairness toolkits are meant to empower practitioners to reflect about.

Tasks, Toolkits, and Notebooks. For each task, we shared a Google Colab notebook with the participants, which included a design brief with one of the two datasets pre-loaded. The design brief mentioned that a hospital (or an insurance company) wanted to optimize their cost and services (or their prices), and therefore wanted to investigate whether ML could help them predict readmissions (or utilization, respectively). The institution tasked the participant to investigate this feasibility possibly using the dataset they had collected, and to report on their findings by speaking outloud. Along the investigation, when participants mentioned some code-based exploration, we shared corresponding code snippets prepared before the interviews to speed up the process.

For the interviews with practitioners who had used a fairness toolkit in the past or with the ones we introduced to a toolkit, we loaded a specific toolkit (FairLearn [10], or IBM AIF360 [6]) into the notebook, that they were most familiar with. We consider these toolkits because they contain a large number of functionalities around algorithmic fairness; they are the most studied toolkits in research [24, 57] and appear to be popular among practitioners. Cf. supplementary material for details about our interview materials.

Analysis of the Transcripts. We analysed the transcripts using a combination of inductive and deductive coding. The first author identified the segments discussing the main themes we wished to discuss (e.g., the harms, their conceptions, identification, and handling, and toolkit use), and coded any other emerging themes (e.g., other factors that practitioners trade-off when developing ML models) in collaboration with four other researchers. Then, the author in discussion with the other authors, reconciled redundant codes. Finally, this first author studied each of these codes based on their associated participants. While we cannot certainly identify which factors cause observed variations in terms of conceptions and practices based on our qualitative study, certain practitioners explicitly mentioned potential factors that we report. We also explore quantitative differences based on the background information we have about the practitioners (yet, all the factors are impacting practices in different ways, that we cannot explore within our study).

4 RESULTS

4.1 On the Effectiveness of Toolkits

In terms of algorithmic unfairness, practitioners reported the toolkits to be extremely useful for them to quantify and mitigate unfairness, what was confirmed by our observations. Yet, we also identify drawbacks of the toolkits for distributive unfairness, that we describe next. In terms of algorithmic harms beyond distributive unfairness, we did not note any evidence of positive or negative impact of the toolkits on practitioners' considerations and practices.

4.1.1 Effectiveness of Toolkits. Among toolkit-inexperienced practitioners, toolkits fostered a positive shift in practices around algorithmic fairness between task T1 and their introduction in task T2. Before being introduced to the toolkits (T1), it was not natural for the practitioners to reflect about algorithmic fairness. After our tutorial (T2), they began discussing potential unfairness caused by the outputs of their models and trade-offs between different fairness metrics and with accuracy, to judge which model is satisfactory (even if superficially on occasion). They also started envisioning approaches to mitigate the potential issues with the outputs. Hence, toolkits, for these practitioners, represent a means to foster awareness around distributive unfairness and its causes. *P19: "Just seeing how it worked, made me realize that it's not only about the dataset, but there's bias everywhere."* It also represents a means to learn about existing solutions to mitigate unfairness, and a prompt to start actively tackling the issue (being readily-available code repositories, toolkits lower the entry-barrier to the problem). *P17: "If it's quick and easy, run a quick check. 'Oh, there is something there I didn't think of. I need to explore that.' I could see that happening."*

As for toolkit-experienced practitioners, they primarily use toolkits to speed-up their processes around algorithmic fairness, and to foster communication with other stakeholders. *P11: "I talk to business people and this is how they can connect to this topic from the technical side because they can't code or anything."*

4.1.2 Undesirable Consequences of Toolkits: Reducing Harms to Algorithmic Fairness. Despite their perceived utility, toolkits can be misleading, and create a gateway to a narrow view on distributive justice. 6 out of 10 participants who were inexperienced with fairness, 4 out of 9 relatively more experienced ones, and 2 out of 11 very experienced ones took the toolkits at face value. They applied all fairness metrics available through the toolkits without considering their meaning and appropriateness, declared a model satisfying if certain values of (often arbitrarily picked) fairness metrics were reached (sometimes operating a non-informed balance between accuracy and fairness metrics) without reflecting on their limitations. *P13: "With the use of toolkit, I don't think my view changed. [Before having the toolkit,] I already believed in what the techniques could do. So if the toolkit correctly implements techniques, I have faith in it."*

55% of practitioners who were more experienced with fairness explicitly expressed concerns surrounding the toolkits. Toolkits might narrow down critical thinking around what is measured in relation to distributive fairness and be misleading, limit reflections on broader socio-technical concepts, and foster techno-solutionism triggered by the development of unfairness mitigation methods. *P22: "You cannot rely on the toolkit. You need to understand the problem and the domain knowledge. I can easily see these toolkits like before metrics like precision, recall were just thrown at random without knowing the actual meaning. Things like statistical parity difference, as they become more common, I can see them being misused because a lot of people don't even know their definitions. It's easy for people to misinterpret them."* Practitioners also felt that toolkits encode biases in their setup. *P23: "These libraries can introduce some biases that you are not aware of, so you don't need to put all the chances on those libraries, you should look into data yourself to see what type of bias data contains."* All in all, toolkits might illegitimately serve as a checkbox. *P3: "Fairness for many companies is just a small checkbox, and sometimes people put their mark without any question. I hope there will be a time when they understand that fairness is not about code and just picking up one toolbox. [..] The toolkits would constrain your view if you're using them blindly."* This is in direct contradiction with the way a few participants perceive the toolkit as an opportunity to realize and convey the complexity of the distributive justice problem *P21: "The recurring theme of our conversation is that fairness is difficult, and this realisation is what the toolkits achieve. They give a large variety of options to make fair models, but their biggest positive impact is helping practitioners realize that this is not a topic where we just do the same five steps and we have a fair model, but it's something that requires a lot of consideration."* This is evidence that beyond the toolkit itself, there are additional factors that impact practices –we discuss them next.

4.1.3 Technical Factors: Differences across Toolkits. We do not find any notable difference in the conceptions of harms between practitioners who used different toolkits, irrespective of their experience with fairness. While in practice some functionalities (metrics and mitigation methods) are only supported by one of the toolkits, this did not appear to be a major obstacle to the practitioners, who seemed to use other methods when needed (some practitioners also mentioned having to design novel methods to tackle their problems). This could however potentially be dangerous for beginner practitioners who learn about algorithmic fairness solely through the toolkits, and may revert to sub-optimal metrics and methods.

Practitioners did mention factors that impact the adoption of toolkits: compatibility with existing frameworks and code, frequency of maintenance and open source nature, ease of adoption and learning curve, transparent implementation and documentation, amount of functionalities and adaptability to various use-cases, and socio-technical questions the toolkits foster (cf. supplementary material for details about these factors and the others we identify). Interestingly, these mainly refer to non-functional requirements. While practitioners agree on these requirements, the evaluation of the satisfaction of a requirement for a toolkit was sometimes contradictory across practitioners when choosing one toolkit over the other (oftentimes, practitioners did not know both toolkits, but used similar arguments for explaining the choice of one over the other), e.g., they mentioned choosing AIF360 or FairLearn both because of their compatibility with existing coding frameworks.

4.2 Human Factors

Finding out that the toolkits are not the only factor that substantially fragments practices, we turn to the human factors and the specificities of each practitioner to understand observed variations.

4.2.1 Experience in Algorithmic Harms. As already mentioned, the amount of prior experience with algorithmic fairness (which includes experience with fairness toolkits) seem to impact practices on average. Relatively inexperienced practitioners typically think of fewer harms and reflect on issues with less critical attitude, and more often solely relying on their intuition, than the more experienced practitioners. Most participants who are just entering the realm of distributive fairness through a toolkit are not very critical about algorithmic fairness. *P20: "Using it this way seems to be one of the best ways, taking into account what I knew before, and what I learned today about the toolkit."* They become more critical if they accumulate more practical experience and knowledge by further exploring the toolkits' guidelines. Hence, more than the mere amount of experience, the type of prior experience with algorithmic fairness is a factor that seems to strongly impact practices. For instance, practices among the most experienced practitioners do vary, with some also relying solely on sometimes flawed intuitions (e.g., removing samples with missing values always improves the ML model performance), while others systematically involved external sources of information and rigorous computations (e.g., other stakeholders, laws, guidelines, business) and potentially make use of statistical tests.

4.2.2 Ways of Learning about Algorithmic Harms.

Types of Interactions with Others. The practitioners who displayed a more critical attitude discussed having learned about distributive fairness through interactions with various stakeholders. For instance, half of the participants who have learned about the metrics primarily through the code and 70% of the inexperienced participants who only briefly learned about the metrics during our interview discussed observing all metrics without reflecting on their meaning, while all the ones who have had more interactions with the research community (7 participants) or other interdisciplinary teams (3 participants) judged choices based on use-cases. These interactions (discussions, workshops, and conferences) often involve colleagues, clients, or researchers in AI ethics that highlight potential limitations and critical attitude to keep, or illustrate the subjectivity of the topic. *P3: "We invited one developer of FairLearn to run workshops. Her message was clear: you can ingrain fairness in code, but if you don't understand what you're doing, you will be in the world where we are already."* Similarly to previous results showing that discussions can positively impact fairness considerations [66, 79], the participants we introduced to the toolkits also mentioned the benefits of our discussion (to make them conscious of potential harms and of the limitations of their own, often non-critical practices), more than the one of the toolkits. *P20: "[Do you feel like your perspective on algorithmic harms changed after after seeing the toolkit?] Yes, I mean more after this discussion altogether. I personally wouldn't have taken some of them into account myself if I weren't pointed in the right direction by your questions."* Our participants reflected about the choice of fairness metrics and mitigation methods, once we explicitly prompted them about specific use-cases and actual meaning of different choices. *P28: "You also mentioned proxy. And I realized that just protecting some variables doesn't mean that you have removed completely that bias."*

Types of Courses. Other practitioners learn about various harms and algorithmic fairness by reading literature (e.g., P9 mentions the diagram from the Algorithmic Justice League) or by following courses on ML in general, on AI ethics, or on ethics of technology. The way the course is taught seems to impact practices, as one practitioner discussed having been trained through use-cases and was able to identify a number of harms, while four others mentioned a few ML ethics courses with toolkits introduced during the courses but did not reflect on any harm during the interview.

Importance of the Design of the Learning Material. While practitioners learn and develop their experience with ML and algorithmic harms via various means, leading to various practices, they also seem to interpret differently the same material, sometimes leading to misconceptions. While we discuss in a later subsection relevant human factors, we emphasize here the importance of the framing of the materials around harms. For instance, certain initiatives, although having a legitimate aim —warning against issues or proposing relevant approaches— sometimes had the inverse effects, and narrowed down the view of the practitioners towards related harms. This was especially the case for the recent "data first" approach advertised by different research communities [2], that led certain practitioners not to understand that model design might also create algorithmic unfairness; *P22 "I talk about the data quality first like Dr. Andrew Ng says. Data-driven ML is becoming very prominent."* Similarly, P9, P16, P23 learned about model energy-consumption issues by reading the "Stochastic Parrot" paper [7], leading them to acknowledge these issues solely for large language models, but not for other types of simpler ML models.

Next to the framing of harms, the vocabulary employed (e.g., "bias", "sensitive feature", "protected attribute") also revealed to be a source of confusion and flawed practices. For instance, certain fairness-inexperienced practitioners only conceived "biases" as statistical skews without relations to, e.g., sensitive attributes or harms *P30 "with medical instruments, for a specific machine, there is some specific noise in the data. If you know which machine measured the blood pressure, then you know the bias in the data."* Some expert practitioners even warned about issues with loaded terms.

4.2.3 Disciplinary Experience.

ML Experiences. The amount of experience with ML also seem to be an impacting factor for practices around algorithmic harms. We observed that practitioners who have longer experience with ML (independently of having experience or not with algorithmic harms) reflect about more harms, more in-depth, and often envision more diverse mitigation methods than less experienced practitioners. For instance, three of those practitioners without experience around fairness were able to envision potential harms from the model design, and naturally evaluated the model based on subgroups of population without knowing the concept of equalized odd, whereas practitioners relatively inexperienced in ML with some algorithmic fairness training often did not account for this. Three participants who had extensive experience with data science but were inexperienced with fairness and three mildly experienced ones were also more critical about the toolkits. *P18: "You always need to question existing tools and practices to be able to improve and innovate."*

Experiences with other Fields. Three practitioners who have not only studied ML or data science emphasized the potential benefits of their background: a participant trained as an ethicist; another trained in industrial design *P1: "This is my industrial engineering background talking. Let's map out the process to see, if we would be using a model, where it would fit in the current process and what requirements might be there? Is this supposed to be a fully automated system? How are people going to use this system? [..] For that, I talk to people. Can you imagine yourself saying that? [sarcastic remark about computer scientists]"*; and a last one in sociology *P29: "that's why they hired me: someone who's both good on the computer science side and on this sociology side."* These participants indeed identified more relevant harms and presented a more critical attitude towards their own activities, reinforcing the importance of involving multiple stakeholders with a diversity of backgrounds when the ML practitioners themselves do not have the relevant education.

4.2.4 Personal Factors. As we hinted at earlier, practitioners might behave differently even when presenting similar prior training and experience, within similar contexts. This hints at the existence of additional human factors that impact practices. Especially, non-volitional, socio-demographic factors were explicitly reported by practitioners as drivers of certain practices, such as gender, nationality, and culture that impact their ways of perceiving harms. Belonging to a minority might also change the lived experiences and efforts put onto harm mitigation. *P13: "I felt my obligation because I participate in many unprivileged classes. So I would like another person to do it for me."*

Although not always directly observable via our interviews, other factors (e.g., psychology traits, abilities, and the resulting personal interests) appeared to be at play. For instance, when asking the practitioners to envision potential limitations of fairness metrics and mitigation methods, many of them could neither envision any conceptual one, nor see the potential risks of distribution shifts (that is a more technical and well-known topic –mentioned by only 20% of the participants). Similarly, when we prompted the participants to reflect broadly about their approaches, many did not envision or acknowledge any potential limitation. Yet, some participants showed more reflexivity, accurately recognized being biased and having to make subjective, uninformed choices, and acknowledged the complexity and subjectivity of the choices they make. *P20: "I'm sure that there is a possibility to create bias if I create features based on my interpretation of the data or what I think in my subconscious about people that get ill."* A few (also recognized not really knowing the potential impact but potentially keeping the benefice of the doubt. *P4: "For hyperparameters like learning rate, I can't see the connection with how it might harm people because it just influences accuracy. But I'm hesitant to say it doesn't affect it at all because you never know with these things, so you should always be cautious."*

4.3 Contextual Factors

Along the interviews, practitioners also mentioned a number of organisational factors that represent obstacles or impetus towards handling questions of algorithmic harms.

4.3.1 Incentives and Support. Several participants discussed monetary incentives (financial compensation) and non-monetary incentives and opportunities (possibility to get dedicated time for investigating harms), or the lack thereof, provided by their organization, that impact their considerations and actions. *P14: "the challenge is that, from a legality compliance and the organization perspectives, the appreciation should be there for you to spend the time."* Several participants mentioned engaging in volunteer work in their organization, in order to setup trainings and tools for tackling harms, or directly investigate harms for their own ML projects.

Others also reported on the material support (or the lack thereof) provided to them to facilitate tackling algorithmic harms. They especially mentioned the access to convenient tools (such as the fairness toolkits), and education around the topic (e.g., via the participation to workshops and seminars ordered by the organisation). Human support was also reported, especially the facilitation of the access to various relevant stakeholders (e.g., domain experts, decision-subjects, researchers) who might be able to give indication on the existence of potential harms and the way to solve them.

4.3.2 Procedural Obligations. Procedural obligations were also reported by participants, as wishes to foster algorithmic harm considerations. In terms of requirements or guidelines for the ML system to be built, they reported that, oftentimes, the organisation did not specify any harm-related requirement, and that certain requirements would come in opposition to the mitigation of harms (due to existing impossibility results; limited access to data, e.g., due to cost, etc.) —a clear hindrance towards harm mitigation. For instance, P16 and P19 described that their decision to develop a system is based primarily on the system's usefulness (time and cost saved) for the business that requires it, leaving out questions about harms towards data subjects *P16: "It's appropriate and relevant for the business. They want to save money or to reduce time of work."* Subjective norms (the vision that the society might have on the organisation, or the belief that the organisation has on the way of handling harms of other organisations) also played a role in the establishment of requirements by the organisation. In certain cases, it made the organisation push the practitioners towards investigating harms, while in other cases it refrained them to do so —for instance, P13 mentioned that if the public knew about a certain harm mitigation approach, they would not accept the ML system deployment *P13: "[talking about post-processing methods that flip certain model outputs] They imply a bias in the process. It would be a problem for the company to say that they are doing this: if I am a company and I am saying publicly that I am imputing bias on my model, how would society react to it?"*

Next to inexistent, ambiguous, or contradictory requirements, the allocation of responsibilities towards harms was described as structurally unclear for the practitioners. Very few practitioners mentioned clear allocation of responsibilities by their organisation (e.g., existence of an ethics committee). This represented one more challenge for the practitioners, as that did not necessarily provide them with the needed power to make choices towards harm mitigation. Particularly, participants often discussed that they can strive to make harms transparent within their projects, but that the model requesters have the final say in deployment decisions.

4.4 Interactions between Factors

Here, we provide a short description of the main interactions we identified between factors, that reveal the importance of psychological traits and other human factors, and reinforce the need to account for the entangled nature of these factors.

4.4.1 Perceived or Actual Responsibility. We described that organizational factors might leave responsibility around harms ambiguous. In such situation, different practitioners react differently (hinting again at the importance of human factors): they perceive their responsibility differently, and engage to different extents in activities that are not promoted by the organizations in order to tackle harms. Certain practitioners argued that as data scientists that know the most about the system, they are the ones responsible for identifying and reporting harms (if not also for making decisions on system requirements and deployment) *P17: "It needs to be the responsibility of the developer, or have a developer that is some sort of fairness compliance person, that's doing some peer reviews of code, because once you get to the developers' boss, they don't know code."*; that the model requesters are the ones deciding for any requirement; that the C-level and managers should be responsible to incentivise the engineers and to make choices where practitioners do not have knowledge *P19: "As much as I would probably want to, I don't think I have all the necessary background for that."*; or that a committee within the organization should be responsible as it would gather more diverse expertise *P16: "We have a committee of ethics. If we have any questions, we can go there to understand their opinion, it will not be the decision of one person but a collective decision."*

4.4.2 Obstacles and Efforts. We mentioned that practitioners might lack resources (e.g., access to relevant stakeholders) and knowledge to tackle harms. In such cases, we identify different attitudes towards the challenge. While it is well-known that collaboration in the ML lifecycle is often needed for the practitioners [24, 51, 80, 110], prior work and our study both show that tackling questions around algorithmic harms is still predominantly the job of ML practitioners alone. Except for certain highly-ML experienced practitioners, most of them did not mention putting proactive extensive effort into reaching out to relevant stakeholders. In terms of knowledge, many of the participants who admitted lacking knowledge to identify or mitigate harms, concluded by reporting that they consequently do not put effort into acting on harms. *P10: "I am slightly aware of it but I wouldn't be able to say how to make changes towards that. I don't have any experience."* Instead, others mentioned searching into research papers to identify appropriate methods. For instance, P15, P18, P24, P27 proposed to look into research that trades-off model size (assuming a smaller model would be less energy-consuming) and accuracy performance to reduce environmental impact. Some practitioners explained potentially having a higher propensity to put effort onto fairness challenges because they have research experience, and hence can search within publications for relevant methods *P7: "I'm interested in research. When you try to apply these tools, that is connecting the academic world to the business side."* Similarly, when participants mentioned that no method exists yet to tackle a harm, certain would attempt to create a new one, while others would wait for research to progress.

5 DISCUSSION & IMPLICATIONS

5.1 The Renewed Importance of Factors

5.1.1 Summary of our Findings. In our study, we found that a complex set of interdependent human and organisational factors interact, and result in diverse practices of machine learning (ML) practitioners around algorithmic harms. For instance, we identified that, overall, practitioners who have little experience with ML and have not received practical and critical training around algorithmic fairness often stop at the application of a few fairness metrics and mitigation methods. The more experienced practitioners and those with an interdisciplinary background present a more critical attitude, attempt to go beyond what fairness toolkits permit (e.g., by envisioning non-algorithmic ways to avoid algorithmic unfairness), especially when they had opportunities to discuss these topics with experts. Next to these prior experiences, organizational constraints and incentives also represent drivers or obstacles towards deeply tackling harms, that, in interaction with psychological and sociodemographic traits, result in a diversity of trade-offs made between algorithmic harms and other business considerations.

While it is natural that such types of factors impact practices in the context of ML model development and algorithmic harms, no investigation of such factors had been performed. This study provides a first qualitative investigation that bear broad implications, and whose output validity should be later investigated through quantitative studies. As toolkits cannot serve as straightforward recipes for the practitioners, practitioners should also be supported in exercising due diligence. We argue that this should go through the development of better means for knowledge dissemination and training, the design of supportive materials and new organizational processes, and the consideration of organizational factors.

5.1.2 A Lukewarm Perspective on Toolkits. Our results bring evidence confirming the results of prior works on the use of various documentation and code toolkits, that have shown that these toolkits can indeed support ML practitioners in finding more algorithmic harms than without a toolkit [16, 24]. Yet, our results also bring more nuance to the benefits of toolkits, and show the risks of using those. These nuances had not been demonstrated in prior, empirical works on toolkit practices, as they did not focus on the impact of toolkits on algorithmic harms, but only on the correct implementation of algorithmic fairness methods. Our results also provide empirical evidence for prior broader works that argued against the techno-solutionism of algorithmic fairness [34], demonstrated the potential dangers of ethics washing [8], and more broadly warned against automating ML processes, e.g., through AutoML [106].

Prior work [24] had not discussed major differences in usage of different fairness toolkits. We corroborate such findings. Besides, the factors we find practitioners mentioning as important for selecting a toolkit are well aligned with the insights of prior works on the use of these toolkits [24, 57, 85]. These works have developed, among others, rubrics for the design of better toolkits, including similar functionalities (compatibility with various models, inclusion of diverse fairness metrics, guidance along the entire ML lifecycle, facilitating interdisciplinary conversations, etc.) and non-functional requirements (e.g., learning curve, compatibility with common coding frameworks, etc.). We especially echo the recommendations

they make to better guide practitioners along socio-technical considerations [104], in order to avoid the pitfalls emphasized by our participants. These prior works however had not discussed the contradictory evaluation of toolkits by practitioners, that we found in our interviews, and that would merit further investigation.

5.1.3 The Importance of Human Factors. Although prior works have sparsely investigated human factors that impact attitudes towards algorithmic fairness, we find a number of prior results that align with ours, and hint at the validity of our results. While these studies do not investigate ML practitioners specifically (but computer science students, or decision subjects), they are still relatable, as perceptions of fairness impact follow-up practices towards harms. Besides, our work expands on these prior results in that it looks at a broader range of harms, and at different types of individuals.

- *Toolkit.* A few works [24, 57] show the potential usefulness of toolkits and their current practical limitations. No study mentions potential negative impact that we identified.
- *Experience.* Kleanthous et al. [50] identified the impact that the level of computer science education has in understanding fairness issues along an ML pipeline, that we also identified. Yet, no study reveals the importance of the type of educational background and the type of prior ML experience and fairness training.
- *Socio-demographic factors.* Quantitative studies [47, 79] have shown the impact of gender on students' considerations of ML fairness, privacy, and non-maleficence. Prior work has also shown the effect of gender and race on judgements of fairness metrics [37, 41]. While this is not a result we could explore due to the imbalanced distribution of participants we had, all our female participants also displayed a critical attitude towards their practices and acknowledged various harms, whereas the results were more disparate across male participants.
- *Non-volitional factors.* Others [38, 66] found that non-volitional factors, e.g., political views and experiences with identity-based vulnerability, are relevant. Our results also hinted at the importance of non-volitional factors, as multiple practitioners referred to their personal interest in the topic, or being part of discriminated minorities, as motivating factors.

While the studies above align with our work, other studies seem contradicting. Some studies have not found impact of socio-demographic or other human factors on the perception of different fairness metrics [22, 37, 91], and the results of other studies are contradicting each other in terms of fairness perceptions, as detailed in [41]. For example, Wang et al. [101] identified that people with higher computer literacy perceive algorithmic decision-making fairer than what people with lower levels of literacy perceive, and that age, gender, race, and education level do not have a significant impact. Contrary to these findings, others [47, 79] pointed to the impact of gender, and our work showed the variability in perceptions of fairness among all our participants who were highly computer literate. We argue that these contradictions are due to the absence of detailed investigation of the impact of the human factors we identified, or to the lack of relevant intersectional considerations across factors.

5.1.4 Contextual Factors: Obstacles or Vectors. Our study identified various clashing constraints and objectives that practitioners have to take into account during the ML lifecycle. Some of these points have already been highlighted in previous empirical works, such as the conflict between business goals (e.g., the system should work for a majority of cases but not necessarily for edge cases to have a competitive advantage) and practitioners' goals (making sure to have high accuracy on all kinds of population) [61, 75, 78], or the lack of organisational support [84] (time and cost allocated, development of tools and guidelines, etc.), that result in individual efforts instead of organizational processes. Other factors had not been discussed until now to the best of our knowledge, in the context of practices for handling algorithmic harms.

5.2 Reflexivity via Renewed Experiences

Facing the importance of various factors, one should take those into account in the future development of support structures for ML practitioners to tackle algorithmic harms. Support should be personalised to the relevant types of practitioners we identified.

5.2.1 Guidelines for the Design of Toolkits. While fairness toolkits mildly contribute to enacting reflexive practices around algorithmic harms, they still represent an almost inevitable medium for algorithmic fairness. They appear as double-edge swords according to our results. This is where the danger of breeding a "*Checkbox Culture*" can manifest among practitioners with respect to handling algorithmic harms. Our work especially shows the need for pointers to relevant activities and resources within toolkits [56], while emphasizing the complexity of the problem and its context-dependence. Toolkits should also be adapted to the type of stakeholders that use them, based on their prior training, experiences, and other human factors, showing pop-up warnings, enforcing attention checks towards harms, allowing for different functionalities, or proposing trainings before using the toolkits. This will be a challenge as existing warnings in FairLearn [10] do not seem to always be considered by the practitioners. Besides, we need to make sure the toolkits do not become new checkboxes, but instead foster critical thinking.

5.2.2 Due Diligence through Education.

Topical Education. Since our results highlighted the importance of the type of training and experience practitioners have received about ML and harms, we join prior studies in advocating for more education of ML practitioners [24, 51, 89]. Many works [12, 14, 19, 29, 31, 44, 49, 65, 83] have discussed ways to provide a responsible AI education to developers, and we recommend to refer to their insights (e.g., modular approaches to responsible AI education for easy integration into courses, including events reported in news articles). We also recommend to rely on insights from farther domains such as data science teaching [32, 54, 92] (perhaps even more worrying than our results, low-ML-experienced practitioners also failed into well-known, non-harm-related traps, such as not reflecting on the limitation of accuracy as a performance metric), ethics and HCI [20, 25, 30], or even ethics of long-established fields such as medicine [21], which have tackled tangential questions. We emphasize the importance of accounting for the breadth of the topic (only Garrett et al. [31] noticed the absence of certain harms like environmental impact from existing courses), its complexity, and the importance to raise awareness about the issues and to train on tackling them.

Change of Attitudes. Next to teaching about algorithmic harms, it is important to develop the moral sensitivity [14], the critical attitude, and the reflexivity of future practitioners [68][4], in this highly-subjective context (Green and Viljoen [36] talk about an algorithmic realism approach, acknowledging the contextual, porous, and political nature of these harms and objectives) where no easy solution to algorithmic harm can be prescribed. Three concrete mediums of good practices surfaced from our interviews: discussions with diverse stakeholders to develop awareness around the subjectivity of the problem, warnings to develop a critical attitude towards existing theories and tools, and use-cases to experience potential challenges in the responsible use of tools. These should be incorporated in the trainings. We envision that trainings using close-to-real-world use-cases, starting from the beginning of the ML lifecycle (problem formulation) to the end (deployment and monitoring), with various stakeholders to interact with, and varying degrees of challenges (e.g., having all harm-related and other constraints explicit or proactively identifying them), could be beneficial. Markus and al. [64] insist on accounting for organisational dynamics in such trainings.

Terminological Considerations in Education Material. The terminological confusions we identified align with prior works [72] that highlight disciplinary confusions in the task of making a model fair, and works that studied the impact of terminological choices [53] on one's perceptions of an ML system. Mulligan et al. [72] promote the value of shared vocabularies and reconciling taxonomies that facilitate discussions. We echo these recommendations and the ones of P29 who suggested to move away from loaded terms towards more specific words, e.g., characterizing the type of bias in relation to the harm it creates, arguing that these materials should not only contain definitions such as it is currently done [59], but should also make concepts clear to the extent of pointing out to the different related theories behind them.

5.2.3 Acknowledging Contextual Factors. While these factors are often unspoken in the research community, they have to be accounted for by practitioners, as they are inherently in tension with handling algorithmic harms, but most practitioners currently face the dilemmas alone. We argue that the research community and policy makers should account for these factors further, and support —sometimes empower— practitioners in the decisions they have to make along the ML pipeline. Interdisciplinary research is needed to understand how to prioritize tackling the different harms (beyond distributive fairness), accounting for realistic trade-offs that have to be made across stakeholders and acknowledging practical constraints. Relevant directions are the understanding of preferences of stakeholders beyond well-studied preferences across fairness metrics [37, 41], the development of frameworks to uncover and negotiate preferences between stakeholders [18, 55, 96], and the creation of guidance for practitioners to navigate the trade-offs.

Knowledge and due diligence are not enough when practitioners do not receive structural incentives. P18 mentioned *"Practice is different from the ethical goals of the world. I had an interview. I said it's important to recommend people music that is worthwhile listening to. The manager told me these are idealistic thoughts, not how the real world operates, this company is all about revenue. So fairness at a company level, it depends on the culture and ethics of the people."* Hence, we join [84] in the idea of developing organizational processes to foster the development of good practices: the design of guidelines [63], e.g., for identifying responsibilities and appropriate requirements, the facilitation of interdisciplinary collaborations [83, 104], and the establishment of structural incentives and principles such as slowness [76]. Development of regulations, that explicitly account for organisational obstacles (e.g., making sure some employees of an organization are well-equipped to investigate algorithmic harms, have time dedicated for it) could also incentivise these organizations [33, 90, 98].

[4]Miceli et al. [68] refer to Bourdieu's notion of reflexivity [15] that would apply to ML practices "an analytical tool to sensitize researchers to "the social and intellectual unconscious" that condition their thoughts and practices in research, and is, therefore, an integral part of and a "necessary prerequisite" for scientific inquiry".

5.3 Rigorously Investigating the Factors

The factors we identified should be quantitatively explored in the future to validate our results (identified conceptions for each harm could serve as dependent variables). This would inform the design of trainings and supportive tools (e.g., the categories of individuals to tailor them to), and the constitution of ML development teams, accounting for the perceptions and abilities of each member. We foresee challenges in the design of a rigorous experimental setup: difficulties to quantify human factors, need to account for interactions between them, and need for specific scales around each harm, their different perceptions, and mitigation approaches. Apparent contradictions among results of prior works seem to be due to subtle differences in what is measured, who is the experiment subject, and potential interactions between multiple factors, which are differences that one should aim at controlling in future studies.

Existing research could be used to overcome these challenges. A measurement has been developed to quantitatively measure undergraduate student's attitudes towards the ethics of AI [47], that could be useful to evaluate how these factors are impactful. Yet, one should first complete this instrument to account for the types of harms that are currently left out from the instrument and for which we identified a variability of conceptions, and not only for attitudes towards harms but also towards their mitigation. The insights and methods from social psychology studies about human processes of taking actions, such as the theory of reasoned action or the theory of planned behavior [1, 40], could also be adapted to further analyse results, as they hint at a diversity of factors and their co-existence, for action taking. We already see correspondences, for instance in the subjective norms and perceived control mentioned by these theories, and that our interviewed practitioners also discussed, e.g., when mentioning the image ML ethics give to an organization.

6 LIMITATIONS

While we strived for recruiting a diversity of participants in terms of demographics, experience with ML and fairness, we could not obtain a significant sample for combined categories. Impossibility came from the relatively small amount of practitioners tackling these issues in the world (e.g., few practitioners could be found working regularly with the AIF360 toolkit), the duration of our interviews, and the controversial character of the topic. Yet, since several of our observations are corroborated with previous studies, one

can suppose some generalisability of our results. This also indicates future challenges in quantitatively investigating the factors.

Due to time considerations, practitioners could not extensively explore the toolkits beyond our tutorial. Letting them familiarize themselves further with algorithmic fairness before conducting task T2, would possibly provide a few different results on the impact of experience and toolkits on practices as practices evolve long-term. For instance, FairLearn provides warnings about algorithmic harms that the participants did not see during the interviews, but that could change their attitudes. Yet, the interviews with practitioners experienced with toolkits allowed us to somewhat control for this, and did not show related differences.

Finally, our participants were not placed into a specific organization and did not have access to different stakeholders. While this was useful for us to fairly compare practices across participants, we foresee the importance of further studies, e.g., with the practitioners' own projects, to identify additional factors.

7 CONCLUSION

Our study led to an extended characterization of the complex, intertwined, factors (toolkits, human, and organizational) impacting the differences of conceptions and practices about algorithmic harms that surface across ML practitioners. These results do not only align with prior works that surfaced a few factors in relation to algorithmic fairness, but also extend and complement these works with information around a more comprehensive consideration of algorithmic harms. Particularly, we found that the use of fairness toolkits does not necessarily lead to its envisioned impact, and can at times promote a checkbox culture, if it is not accompanied by a distinction of the background and prior training the user of the toolkit received, as well as of the pressures their organisations puts on them. In summary, our study constitutes a strong testimony that ML practitioners are not as much "ethical unicorns" [83] (i.e., practitioners who ensure a comprehensive handling of algorithmic harms of the ML systems they work on), than *subjective unicorns encaged in an organization*. Such findings bear strong implications for future research opportunities around the refinement of the toolkits and of educational programs, accounting for these human factors, and for potential regulations to address organizational concerns.

ACKNOWLEDGMENTS

This work was partially supported by the HyperEdge Sensing project funded by Cognizant. We would like to thank all the participants of our studies, without whom this work would not have been possible. Besides, we would like to thank Pablo Biedma Nũnez, Eva Noritsyna, Harshitaa Pandey, and Ana-Maria Vasilcoiu, who participated in interviewing participants.

ABSTRACT

Intersectionality is a critical framework that, through inquiry and praxis, allows us to examine how social inequalities persist through domains of structure and discipline. Given AI fairness' raison d'être of "fairness," we argue that adopting intersectionality as an analytical framework is pivotal to effectively operationalizing fairness. Through a critical review of how intersectionality is discussed in 30 papers from the AI fairness literature, we deductively and inductively: 1) map how intersectionality tenets operate within the AI fairness paradigm and 2) uncover gaps between the conceptualization and operationalization of intersectionality. We find that researchers overwhelmingly reduce intersectionality to optimizing for fairness metrics over demographic subgroups. They also fail to discuss their social context and when mentioning power, they mostly situate it only within the AI pipeline. We: 3) outline and assess the implications of these gaps for critical inquiry and praxis, and 4) provide actionable recommendations for AI fairness researchers to engage with intersectionality in their work by grounding it in AI epistemology.

1 INTRODUCTION

Artificial intelligence (AI) fairness research is critical to the development of just AI. Work in this space consistently urges researchers and engineers alike to consider notions of fairness defined over model predictions. These notions vary across conceptualization (e.g., group, individual fairness [8]) and operationalization (e.g., pre/in/post-processing [2]) [54]; nevertheless, the literature generally agrees on the goal of minimizing negative outcomes across demographic groups, including groups associated with multiple, "intersectional" demographic attributes (e.g., Black women) [92]. However, Kong [66] observes that AI fairness papers often narrowly interpret intersectional subgroup fairness as intersectionality, the critical framework from which the term originates [29, 67]. This myopic conceptualization of intersectionality has non-trivial consequences for just AI design and epistemology (i.e., ways of knowing).

The term *intersectionality* describes a traveling framework of critical inquiry and praxis (i.e., practical action beyond mere academic theorizing) intended to examine interlocking mechanisms of structural oppression (e.g., racist policy [60]) which produce inequality [29]. Critical inquiry into the formation of inequalities generates knowledge that can inform strategies for combating them, which is often referred to as praxis. Generating knowledge that illuminates the underlying mechanisms of oppressive systems is a shared objective among critical disciplines, such as feminist, antiracist, and decolonial studies, and is rooted in a history of resistance [28]. Critical disciplines thus do not decouple reclaiming knowledge from reclaiming power. This is in contrast to disciplines rooted in colonial epistemology, e.g., science. Upon initial examination, science offers universal, empirically-grounded explanations for natural phenomena; however, science is rooted in colonialism through its imposing of a "a positivist paradigm[1] approach to research on the colonies and other oppressed groups" [21]. According to scientific colonialism, the researcher has "unlimited rights of access to source[s] of information belonging to [a] population," where data collection and knowledge formation reflects *the one reality* the researcher understands [20, 34]. Indigenous knowledge is erased as dominant knowledge systems are imposed, preventing Indigenous people from creating and sharing their own knowledge and perspectives. Consequently, disciplines rooted in colonial epistemology often assimilate prevailing knowledge systems that perpetuate the erasure of knowledge [21, 33, 42].

[1]Knowledge as a result of "neutral" and quantifiable observation. This paradigm strictly relies on only measurement and reason [77].

The epistemologies of AI research are not divorced from scientific colonialism's legacy. Intersectionality may be used to critically examine AI research methodologies, so that "the world-views of those who have suffered a long history of oppression and marginalization are given space to communicate from their frames of reference" [21]. Intersectionality promotes grappling with "how individuals and groups who are subordinated within varying systems of power might survive and resist their oppression," thereby empowering communities to criticize the injustices they experience [28]. In the face of epistemic violence (e.g., the erasure of Indigenous knowledge), intersectionality erects a new form of epistemic resistance: knowledge production. Frameworks to articulate social inequalities have been integral to the survival of communities at the margins. Similarly, intersectionality, by enabling researchers to observe and articulate disparities, may break the epistemic molds "researchers are placed in so they may operate differently" [21].

In the context of AI fairness, intersectionality is less about getting technology right (e.g., establishing fairness constraints for a model); it is more about interrogating the social reality which drives AI oppression, so we can then make technology better. Crenshaw uses the term intersectionality as a metaphor to speak on how "different systems of oppression overlap," but more importantly emphasizes that neglecting the convergence of these structures would cause rhetorical and identity politics to abandon issues and people who are actually affected by these intersecting "systems of subordination" [6]. Intersectionality thereby challenges the sociopolitical amnesia which frames subgroup fairness as solely a technical problem [92]. We do not reject subgroup fairness outright; rather, we share this example to challenge the AI fairness community to expand its engagement with intersectionality. To operationalize AI fairness with an intersectional lens, it is vital to first illuminate underexplored gaps between intersectionality and existing AI fairness literature. To this end, we ask: (1) how is intersectionality discussed in AI fairness literature?; (2) to what extent does this discussion change based on computer science (CS) methodology?; (3) where are the largest gaps in conceptualizing and operationalizing intersectionality for advancing social justice?; (4) what tensions exist in leveraging these gaps for just AI design?; and (5) what do these findings tell us about opportunities for more just AI? To answer these questions, we contribute the following:

(1) Identify a growing body of AI fairness papers related to intersectionality (§4) and examine their conceptions of the critical framework in contrast to core intersectionality literature (§3).
(2) Create guiding questions to critically assess the use of intersectionality as a lens to operationalize AI fairness (Table 2).
(3) Use our findings to analyze where gaps remain in AI fairness papers' use of intersectionality, provide recommendations towards addressing these gaps, and comment on the structural forces that may contribute to these observed norms (§5, §6).

The majority of the papers we review approach intersectionality from the narrow perspective of subgroup fairness. Through a deductive lens in §5, we find that intersectionality engagement varies significantly depending on how it is situated within the AI pipeline, how sources of biases are described, and what CS research epistemologies are invoked. Inductively in §6, we find that even when researchers center intersectionality literature, there is little engagement with the framework itself, evidenced by a lack of described social context, little discussion of power and relations between structures, questionable citational practices, and a disjointed sense of social justice praxis.

Our paper does not concern itself with claiming that intersectionality must take a particular form within AI fairness. Rather, we center intersectionality as an "analytical sensibility" [22, 29], which when activated, can sharpen and transform the tools in the AI fairness researcher's toolbox. This, we argue, is key to justice-centric AI development. We further seek to dispel the misconception that social science disciplines have no place in STEM [72, 79]. Educated in CS, we equip the AI fairness researcher of similar training who is committed to justice with concrete ways of using their training in AI to exercise critical praxis. In this way, we hope to disrupt deep-rooted indifferences to social reality, "a powerful force that is perhaps more dangerous than malicious intent" [5].

Positionality Statement All but one author of this paper are formally trained primarily as computer scientists, with additional training in gender theory, criticial social theories, criminology, linguistics, and related fields. One author is a social scientist who confronts issues of social inequities in both everyday life and their scholarship, necessitating an intersectional and life course perspective. All authors have informal training in queer studies through activism and advocacy. As such, our backgrounds influence this work's design, decisions, and development. All authors are located in the US or Europe, but have diasporic links to other social contexts; we do our best to position our work in a global context. We write this to empower individuals across both academia and industry research to critically engage with AI fairness paradigms. Therefore, our recommendations are articulated in a way that can be operationalized, though they are transferrable to other audiences. We position ourselves within a social justice ethos informed by decolonial theory, and that champions equity over equality as well as reparations to correct historical injustices.

2 RELATED WORKS

We are not the first to champion or critique intersectional praxis in AI fairness, let alone more broadly. Several works across disciplines including psychology and CS have advocated the use of intersectionality frameworks or discussed the misappropriation thereof [4, 14, 16, 24, 52, 56, 80, 82, *inter alia*]. Furthermore, AI ethics researchers have addressed the narrow perspective of intersectionality as intersectional subgroup fairness (e.g., Kong [66]); our review points to this too, although our scope is wider and considers numerous gaps in AI's operationalization of intersectionality.

A few papers have reimagined intersectionality in AI [9, 23, 88], pushing for intersectional practices to be woven into the full AI pipeline, and arguing for a joint interrogation of culture, technology, and solutionist framings of fairness (e.g., critical technocultural discourse analysis [15]). Constanza-Chock [31] illuminates the lack of critical praxis in AI, drawing upon Collins's matrix of domination to encourage researchers to reflect on how AI relates to "domination and resistance at each of these three levels (personal, community, and institutional)" [26]. Davis et al. [37], inspired by Crenshaw [36],

argue for AI to be reparative and aware of social and historical context. Klumbyte et al. [63] facilitate community-based critical analysis of the "tensions and possibilities" of integrating intersectional knowledge into machine learning systems. With a shared goal of intersectional AI, we complementarily gauge the epistemic alignment of AI papers related to intersectionality with Collins' intersectionality tenets [29]. We go beyond the scope of papers like Birhane et al. [12], which is not explicitly about intersectionality and focuses on evaluating discussion of social context and power.

3 INTERSECTIONALITY OVERVIEW

Crenshaw coined the term "intersectionality" in her 1981 paper [35], and expanded on it in [36]. In the context of violence against Black women, these works study the interactions of race and gender, as well as racism and patriarchy as systems of subordination. Her work is grounded in "a bottom-up commitment" to address the needs of those who are "victimized by the interplay of numerous factors," with the explicit goal of obtaining political and social justice. Thus, praxis has been an important facet of intersectionality from its inception; what constitutes praxis is broad and contextual, including "movements for economic justice, legal and policy advocacy, state-targeted movements for prison abolition" [22].

While various definitions of intersectionality have emerged, they all center a need to examine power relations across structures, disciplines, domains, and location [1, 25, 53]. We draw upon broad intersectionality scholarship in our paper to enrich our own observations. To ground our review methodology and analysis in the following sections, we base our evaluations on Collins and Bilge [29]. This work details six core tenets of intersectionality (drawing from an in-depth genealogy of intersectionality) that lend themselves to an *analytical language* and *cognitive organization* around how forms of oppression are co-created, operated, amplified, and interact with social and structural disparities. These tenets are: social justice, social inequality, relationality, social power, social context, and complexity. We describe each tenet below, its connections to AI fairness, and how we interpret the tenet for advancing social justice in AI fairness. These descriptions further inform the construction of 3-4 guiding questions per tenet to assess how well the works in our critical review engage with the **tenets** (Table 2).

Social Justice. Intersectionality emerges as a synergy between inquiry and praxis, where praxis is action to advance social justice that is informed by inequities identified via critical inquiry (e.g., via the tenets). Collins and Bilge [29] caution that inquiry alone does not further social justice; intersectionality "demands more than simply being critical and entails turning critical analyses into critical praxis" [29]. In AI fairness, social justice praxis spans numerous practical approaches to fairness, e.g., debiasing techniques, fairness metrics for multiplicative groups; however, its effectiveness depends on authors' social context. Intersectionality widens these practical approaches; this does not remove researchers from the AI fairness domain, but rather deepens our ability to engage with the domain. Overall, intersectionality enables the creation of new forms of knowledge which are informed by a critical examination of how AI systems reproduce inequalities. Therefore, our social justice guiding questions assess how works commit to advancing justice and center the perspectives of subordinated communities.

Social Inequality. Intersectionality rejects the inevitability of inequality as "hardwired into the social world, into individual nature" [28]; rather, the framework emphasizes the study of how social inequalities are fundamentally formed and reinforced through saturated centers of power. Dismantling inequalities requires locating these centers. In AI fairness, inequality is often measured via quantities like demographic parity and disparate impact [54]. Hence, these metrics ground the practice of harm reduction; however, static measures pointing towards equality rather than equity do not resolve complex and wide-reaching inequality. Instead, intersectionality asks us to center the social and historical context of those at the margins to inform praxis. As such, our inequality guiding questions assess the depth with which researchers situate their work in social inequality.

Relationality. Relationality enables us to examine power and inequality by centering relational thinking. This functions to unveil how concentrations of power take shape, are situated in a broader social context, and perpetuate inequalities. Relationality comprises: addition (what happens when we *don't* consider the intersections of social categories), articulation (how relations impact the growth or dissolution of such intersections), and co-formation (e.g., of social categories as phenomena) [29]. In the context of AI fairness, relationality involves examining the relations between decisions we make as researchers, the technical artifacts we produce, and whom they impact (e.g., how the Eurocentrism of auditing frameworks makes them fail to capture inequalities in globally-deployed AI). Hence, our relationality guiding questions assess works' intention and inquiry across technological structures and social context.

Social Power. Intersectionality uses relationality to tie "intersecting power relations" to how power "produce[s] social divisions of race, class, gender, etc." [29]. Intersectionality is predicated on understanding that systems of power "co-produce each other in ways that reproduce unequal material outcomes and the distinctive social experiences [within] hierachies" [28]. In AI fairness, power is concentrated in *human* choices: system design, data collection, deployment, operationalizations of fairness. These choices impact resource allocation for communities at the intersections of the "structural, disciplinary, cultural, and interpersonal" domains [3, 26, 31]; thus, power should be discussed at all stages of the AI pipeline. Our power guiding questions therefore assess the extent to which researchers reflexively comment on or situate their work in the power relations in which they participate.

Social Context. Intersectionality centers "context-specific [...] historical particularities and the increasing significance of a global context" [29]. When engaging with intersectionality in different (especially global) contexts, inquiry and praxis take different forms; consequently, one must practice epistemic, personal, and critical reflexivity to be cognizant of context, in order to effectively and holistically advance justice. In AI fairness, social context informs AI context through researcher training and background, model training and deployment, language choices, etc. Hence, self-reflexively acknowledging that one operates in the Global North informs *who* is centered in fairness tasks. Conversely, fairness works that flatten social context (e.g., by optimizing for "Indigenous people" broadly) informs who drives knowledge production. As a result, our social context guiding questions assess the extent to which context is deliberately referenced and informs research processes.

Complexity. Complexity is key to a "creative tension" between critical inquiry and praxis, which results in new forms of social action to combat inequality [29]. Complexity necessitates relational thinking and situational awareness. In AI fairness, complexity is often conceptualized as minimizing unfairness across a large number of social groups. However, complexity is more expansive; for example, it entails co-designing with groups who have been harmed by AI systems rather than using preconceptions of excluded groups to remedy exclusion. Our complexity guiding questions probe how works contend with model requirements, community needs, and centers of power that influence AI design. This notion of complexity is distinct from how complexity is used in the complex systems discipline, or runtime complexity in CS.

4 CRITICAL REVIEW METHODOLOGY

4.1 Paper Inclusion Criteria

To gauge how AI fairness research conceptualizes and operationalizes intersectionality, we curate 30 papers by: 1) querying "intersectionality machine learning" on Google Scholar to obtain 75 relevant papers, and 2) filtering those to papers published in AI venues including symposiums, conferences, journals, and books. We choose to query "machine learning" as AI fairness research tends to center machine learning. Our process simulates how researchers might discover AI fairness literature related to intersectionality when grounding their own work. Papers are tagged as including intersectionality if they cite intersectionality scholarship that centers critical inquiry. We restrict our sample to 30 papers to ensure that we can annotate each paper (some papers by multiple authors) for engagement with intersectionality. We document all the papers we review in Tables 4 and 5, and provide statistics thereof in Table 1.

4.2 Review Methods

Our annotation scheme is based on the tenets and corresponding guiding questions discussed in §3. All questions reflect three axes of reflexivity: epistemological, personal, and critical [78]. For each paper, for each guiding question (e.g., "Do the authors mention power?"), we annotate whether or not the authors of the paper explicitly or implicitly answer the question. Then, for each tenet, we annotate that the paper has characteristics of the tenet if it explicitly or implicitly answers at least one of the guiding questions corresponding to the tenet. Importantly, our questions are not a checklist to determine whether researchers have "truly" engaged with intersectionality; rather, they reveal where efforts in AI fairness are concentrated and help us reimagine our practices towards advancing social justice in AI. We share all our guiding questions in Table 2. We further break down our methodology for creating questions in Appendix §B.

11 out of the 30 papers were evaluated by 3 annotators, and we present our tenet-level interannotator agreement for these papers in Table 3. The scores in Table 3 indicate moderate to high interannotator agreement. The remaining 19 papers were each evaluated by at least 1 annotator. We expand on our annotation methodology in Appendix §C and provide our annotations at https://tinyurl.com/intersectionality-annotations.

Given the nature of intersectionality, engagement therewith cannot be captured solely through quantitative means; therefore, we also qualitatively mine intersectionality-related themes from our sample of papers. With these deductive (i.e., using our guiding questions) and inductive (i.e., qualitative coding) analyses, we supply a bird's eye and granular view of engagement with intersectionality in AI fairness. As praxis, we translate our inductive findings to recommendations for deeper engagement with intersectionality. These recommendations are tailored for AI fairness researchers with any level of training in AI, in academia, industry, or both. We urge readers to take their own identity, capacity, and power into account when considering our recommendations, as these will affect what they can do and potential consequences.

In our analyses, we acknowledge that papers are products of varied epistemological contributions, relations between authors and reviewers, and power dynamics. Thus, our critical review is not so much a criticism of AI fairness researchers as it is a reflection of broader systems, such as the incentives and infrastructural forces that govern publishing in CS and enacting change in corporations, as well as the types of knowledge production that are valued or even simply considered legitimate in the field. Papers do not reflect everything that goes into a research project, and they are also merely static snapshots in time that researchers grow beyond.

4.3 Investigating Intersectionality Within the AI Fairness Research Paradigm

Reflexivity enables AI fairness researchers to engage in praxis; as Mohamed et al. [72] comment, "deciding what counts as valid knowledge, what is included within a dataset, and what is ignored and unquestioned, is a form of power [...] that cannot be left unacknowledged." To interrogate knowledge and inspire reflexivity, we texture our deductive analysis of intersectionality in AI fairness via four methodology lenses: where intersectionality is situated in the AI development process, how papers describe sources of bias, types of CS papers, and (inter)disciplinary relationality (i.e., synergy). These methodologies speak to both the research process and structures which researchers navigate in their work. We document the methodology tags for all the papers we review in Table 4.

4.3.1 Operationalization of intersectionality. We observe how papers engage with and operationalize intersectionality in the AI pipeline. Papers are tagged as pre-processing (i.e., pre-training interventions), in-processing (i.e., training-time modeling choices), post-processing (i.e., test-time interventions of model predictions), full pipeline, or processes. "Full pipeline" situates intersectionality (for empirical work) across the pipeline, while "processes" situates intersectionality in broader AI design and epistemology. Works that deeply engage with intersectionality exercise its tenets at every stage of the pipeline. Researchers can contrast modes of operationalizing intersectionality and in that tension, reimagine how they engage with the framework.

4.3.2 Source of bias. A paper may characterize bias as systemic, statistical, both systemic and statistical, or entirely fail to describe its source. Understanding sources of bias is pivotal to aligning AI fairness with intersectional praxis. Intersectionality posits that unequal outcomes reflect a systemic reproduction of existing power relations [28]. Systemic descriptions of bias concern structures and oppressive forces which subsequently permeate sociotechnical

Table 1: Critical review statistics ($N = 30$)

Characteristic	N	%
Intersectionality literature referenced	22	0.73

Empirical	23	0.77
Engineering	11	0.37
Other	6	0.2
Synergy across disciplines	16	0.53

systems. In contrast, statistical descriptions limit sources of bias to the model or data.

4.3.3 CS paper type. We study paper types considered valid in CS (as determined by those in positions of power), exposing tensions between intersectionality and visibility, and allowing us to interrogate assumptions about supposed barriers to knowledge due to disciplinary divides [79]. We classify papers as theoretical, engineering, empirical, or a combination of types based on Stent [86]. Papers that do not fit any of these types are tagged as "other." This information enables AI fairness researchers to interrogate possible interplays between intersectionality and their epistemology.

4.3.4 Synergy across disciplines. Papers are tagged for synergy if they incorporate literature beyond other AI papers and intersectionality scholarship (tagging process described in §A). By incorporating knowledge forms beyond CS, we make room for dialogue across "more than one way of knowing" [48, 83]. This is particularly important for sources of marginalized knowledge that may go unheard. Smith [83] asserts that knowledge is always situated; dominant academic AI epistemologies describe systems as "universal" or "neutral," when in fact these terms simply indicate that other ways of knowing have been subjugated. Engaging in participatory AI research is one way of "recovering [...] stories of the past" [90]. However, researchers can also embrace synergy across disciplines. This allows us to examine how AI epistemology's alignment with other works interacts with intersectionality to create new forms of knowledge production towards advancing AI fairness.

5 DEDUCTIVE ANALYSIS

Quantitative Summary. We report tenet distributions across all papers in Figure 1. Complexity (97% of all papers), inequality (83%), and justice (83%) appeared most often in works that engaged with at least 1 guiding question. In contrast, the tenets that appeared least often were power (53%), context (57%), and relationality (60%). Taking the number of questions answered as a proxy for depth of engagement with a tenet, we see drops in every tenet. The largest

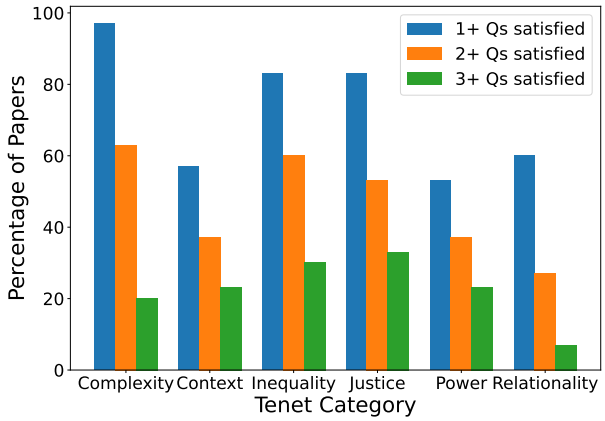

Figure 1: Distribution of intersectionality tenets split by depth of engagement with our guiding questions.

drop (20%) between answering 1+ questions versus 3+ questions is in complexity, despite high overall engagement. Relationality similarly drops from 60% to just 7%. These results are interrelated just as the tenets are; understanding power across structures requires understanding social context and the relations between social groups [30]. Therefore, it is suspect that a majority of papers purportedly center social justice and inequality with so few discussing power.

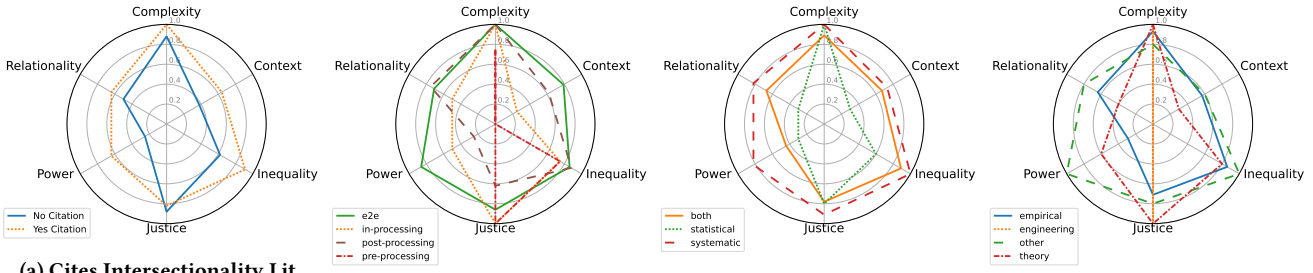
Cites Intersectionality Literature. Figure 2a shows that citation of intersectionality literature (see §A for more details) affects how papers engage with power, inequality, and context. It does not, however, seem to cause differential engagement with complexity and justice.

64% of papers that cite intersectionality literature engage with power, compared to 25% of papers that don't cite it. Engagement with the literature would explain this, as intersectionality is grounded in an analysis of power. However, the overall consideration of power is middling, echoing intersectionality theorists' observation that the "recasting of intersectionality as a theory primarily fascinated with the infinite combinations and implications of overlapping identities from an analytic initially concerned with structures of power and exclusion is curious given the explicit references to structures that appear in much of the early work" [22].

We see a similarly large gap in engagement with inequality. 91% of papers that cite intersectionality literature also discuss social inequality as a phenomenon with social and historical roots, or something their work impacts, compared to only 62% of papers that don't cite it. We see this difference as a reflection of intersectionality's motivation as a framework to examine inequalities.

Papers only seem to show consistent engagement with the tenets of complexity and justice, regardless of whether they cite intersectionality literature (above 80% of papers in each of these splits). This reflects the CS paradigm of understanding intersectionality as rejecting single axes of identity, and the ethos of AI fairness – one that seeks justice and a better future. Overall, citing intersectionality literature correlates with deeper tenet engagement.

Operationalization of Intersectionality. Figure 2b shows differences in how intersectionality is used across the AI pipeline. Papers



(a) Cites Intersectionality Lit.

(b) Operationalization

(c) Source of Bias

(d) CS Paper Type

Figure 2: Relative distributions of papers across intersetionality tenets if a paper engages with at least 1 question per tenet.

operationalizing intersectionality end-to-end had the largest coverage across intersectionality tenets, with each tenet appearing in 71-100% of these papers. Meanwhile, the lowest engagement across tenets came from papers focused on pre-processing, with *none* of them engaging with context, power and relationality.

The locus of operationalization seemed to make the biggest difference in how context and power were engaged with. Engagement with the social context tenet seemed to increase as papers went further down the AI pipeline; no pre-processing focused papers engaged with it compared to 25% of in-processing focused papers, 50% of post-processing focused papers, and 71% of end-to-end papers. This pattern mostly held for power as well, except that in-processing papers (50%) engaged with this tenet more than post-processing papers (25%). Overall, papers engage with more tenets when they operationalize intersectionality end-to-end and in processes.

Source of Bias. Differences in tenet engagement across the source of bias are shown in Figure 2c. Papers treating the source of bias as statistical had the lowest engagement across tenets, with only 30% of these papers engaging with context, relationality, and power. On the other hand, these papers have 100% coverage of the complexity tenet. This could be attributed to a common narrow reading of intersectionality as just multiplying identity categories rather than as a structural analysis or a political critique [51].

When considering bias to be systemic rather than statistical, tenet coverage increases noticeably; engagement with relationality jumps from 30% to 67% of papers in the category, context goes from 30% to 73%, and inequality goes from 60% to 100%. This aligns with existing literature in which discussing the social reality of a phenomenon allows one to more deeply assess the factors that contribute to it in the first place [5].

Papers that conceive of bias as *both* statistical and systemic have the best tenet coverage overall, with roughly 80-90% of papers discussing each of complexity, inequality, and justice. This dual conception of bias incorporates both the social and technical aspects of AI systems and how they may inform or magnify each other.

CS Paper Type. Figure 2d shows that papers across all CS paper types consistently engage with complexity and justice, with at least 70% of papers of each type covering these tenets. This consistency breaks down more dramatically across power, relationality, context, and inequality. *No* engineering papers engaged with these four tenets. At the other end of the spectrum, papers classified as other engaged with the largest array of tenets. 100% of these papers engaged with power, as opposed to 60% of theory papers and a quarter of empirical papers. Theoretical papers seemed to engage relatively less with context (32%) and relationality (41%). Overall, despite disciplinary divides, papers in CS are able to engage with intersectionality tenets. Supplementing these findings, our inductive analysis in section §6 indicates that many works use a heuristic definition of intersectionality that is easily operationalized across theoretical, engineering, and empirical papers, resulting in a narrow use of the framework. Engaging with literature outside the empirical and engineering papers that are de rigueur in CS can expand tenet coverage.

Synergy Across Disciplines. Figure 3 shows each tenet category split by whether or not they had a synergistic component. As it pertains to the source of bias, synergistic papers incorporate a wider range of tenets at higher rates than non-synergistic papers (Figure 3a). Even among papers that treat bias as systemic and thus engage with a social component of bias, tenet coverage benefits hugely from synergy, with 63-73% more papers discussing complexity and justice. Figure 3b shows that when papers that discuss intersectionality across the entire pipeline have a synergistic component, they have better tenet coverage. Synergy appears not to have a big effect on papers that focus on in-processing, pre-processing or post-processing, sometimes even appearing to decrease tenet coverage. With CS paper type (Figure 3c), papers that incorporated intersectionality in an empirical and theoretical paradigm had better tenet coverage when they had a synergistic component. We note that no engineering papers in our data have a synergistic component – an interesting finding in its own right. As before, this suggests that the biggest benefit to tenet coverage can come from first operationalizing intersectionality throughout the pipeline and attending to processes and norms, which arguably *necessitates* interdisciplinary synergy. Overall, disciplinary synergy correlates with higher intersectionality tenet coverage.

6 INDUCTIVE ANALYSIS

Intersectionality as intersectional subgroup fairness. Among papers which cite intersectionality literature, many conflate intersectionality with intersectional subgroup fairness. For example, Fitzsimons et al. [44] posit:

> *"... a model that satisfies conditional parity with respect to race and gender independently may fail to*

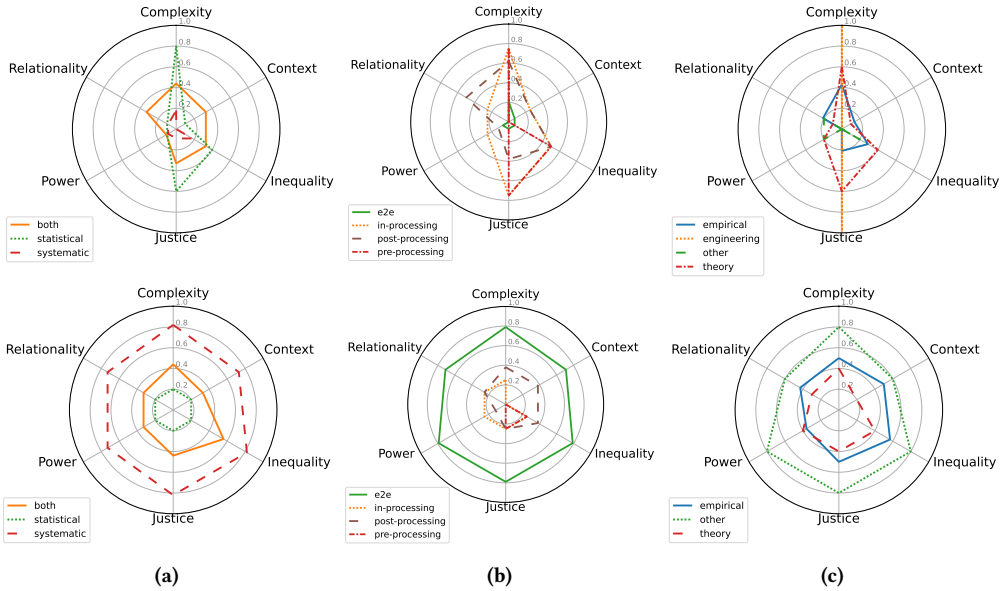


Figure 3: Papers with at least 1 tenet characteristic, split by presence of a synergistic literary component (top=no, bottom=yes).

> *satisfy conditional parity with respect to the conjunction of race and gender. In the social science literature concerns about, potentially discriminated against, subdemographics are referred to as intersectionality."*

Similarly, Mougán et al. [74] state, "For intersectional fairness, we created the variable EthnicMarital, engineered by concatenating Ethnic and Marital status." Indeed, we observe that many papers conceptualize intersectionality as identity-centric, and its ties to power and inequality are not explicitly named [73, 74, 95]. Our finding substantiates the concerns of intersectionality scholars that intersectionality is diluted to a "two-by-two analysis of gender by race" rather than "constituting a structural analysis or a political critique" [51], or contending with "overlapping systems of subordination" [30]. Notably, papers even discuss power and inequality in depth at first, but nevertheless operationalize intersectionality as subgroup fairness without engaging these points again [46].

Such additive frameworks are helpful insofar as they enable structural inquiry. However, per our annotations, despite overwhelming discourse on cross-sectional social categories, papers' discussions of subgroups often lack social or historical context [18, 44, 73]. Few works comment on the structural factors that cause certain groups to be underrepresented in datasets, critically engage with the colonial origins of protected attributes [41], or connect groups to social structures and inequality (c.f., the explicit recognition that Black communities are targeted at a higher rate by law enforcement using facial recognition in [17]).

The obfuscation of intersectionality as subgroup fairness reflects cultural denial, "the process that allows us to know about cruelty, discrimination, and repression, but never openly acknowledge it" [40]. We do not claim that the intentions of AI fairness researchers are malicious; rather, groups "los[ing] meaning as a descriptive, non-analytical category" prevents researchers from engaging in critical inquiry [28]. This disarms praxis: AI fairness can no longer contend with advancing justice for those at the margins if their experiences with AI-driven social inequalities are not centered. Therefore, we echo Collins' call for "intellectual vigilance" in analyzing and articulating intersecting power relations. Using an intersectional lens is crucial to refocusing on marginalized communities, and can inform social justice efforts across various fields by addressing the root causes of harm, regardless of one's training.

Recommendation. Researchers exercise intellectual vigilance when using additive frameworks by creating statistical methodologies that preserve unique social and historical characteristics of intersecting groups. [93] exemplifies this. Leadership incentivizes this inquiry. Researchers and leadership prioritize widening their conceptualization of intersectionality beyond the "subgroup fairness" interpretation, which is limited in its social justice praxis.

Anti-discrimination legislation informs design. Several papers draw from regulation (e.g., anti-discriminatory legislation) to define their fairness objective. For example, Molina and Loiseau [73] state:

> *"In many—if not most—real-world applications, there are multiple protected attributes (typically 10-20) along which discrimination is prohibited [1, 2]."*

Foulds and Pan [46] similarly motivate their fairness criteria from a legal perspective: "consider the 80% rule, established in the Code of Federal Regulation." Additionally, Foulds et al. [45] seek to "[determine] whether disparities in system behavior meet legal thresholds for discrimination." Furthermore, Ghosh et al. [49] remark, "there does not exist a single universally agreed upon definition of fairness," citing how different "anti-discrimination legislation exists in various jurisdictions around the world."

Motivating AI fairness from a strictly regulatory lens (e.g., the 80% rule, protected groups) does not fully embrace social and historical context. Several critical scholars argue that discrimination is often legitimized through anti-discrimination law [35, 38, 47, 84]. According to Freeman [47], these laws see racial discrimination "not as conditions, but as actions inflicted on the victim by the perpetrator." He adds that such laws reflect the idea that "only 'intentional'

discrimination violates anti-discrimination principles," creating "a class of the 'innocent' who need not feel any personal responsibility for the conditions associated with discrimination" [47]. Similarly, in AI fairness, researchers prioritize intersectional subgroup fairness over the structures that give rise to unfairness to begin with. Interestingly, AI fairness researchers who adopt a regulatory lens abundantly cite Crenshaw [36], although this work illuminates how anti-discrimination laws render Black women invisible:

> *"In a monumental paper published in 1989, Kimberlé Crenshaw [11] introduced Intersectionality by referencing a court case where black women were unfairly discriminated as a result of an activity to mitigate the race and gender discrimination independently" [65].*

AI fairness researchers must heed the warnings of critical legal studies: indifference to the social and historical context of groups and their intersections risks reproducing histories of discrimination. For example, an important step towards dismantling injustices is challenging social categories rooted in colonialism, as "this structure imports a descriptive and normative view of society that reinforces the status quo" [35]; hence, failing to investigate how the mechanisms responsible for the unjust social realities of oppressed groups are upheld by one's technology is fundamentally incompatible with reparation and advancing justice [32, 37]. Therefore, while social beneficence may motivate an AI fairness approach, its technical operationalization must consider the sociotechnical environment it operates within. In other words, if the goal of researchers is to leverage intersectionality towards the creation of just AI systems, these systems must be infused with social and historical literacy throughout their lifecycle to prevent indifferent engagement with the people they affect.

Recommendation. Researchers, including those in leadership, critically engage with and remain vigilant of how operationalizations of anti-discrimination laws in their AI systems do not automatically mean that their systems are fair to marginalized communities. They may do this by engaging with critical legal studies texts [35, 38, 47, 84] and marginalized communities to learn how they are unfairly impacted even by systems that pass legal audits. [59] does a good job of examining the tensions between prioritizing different forms of fairness.

Angles of power examined: technodeterminism rules. Collins describes intersectionality as examining the mutual influences which "intersect and interlock" across "structural, disciplinary, cultural, and interpersonal" [26] domains of power. However, among papers that cite intersectionality literature, power is the least engaged tenet, with "power" mentioned in only 53% of papers. Moreover, merely mentioning "power" does not entail engaging with it in depth, e.g., Foulds and Pan [46] write in their abstract that "intersectionality [...] analyzes how interlocking systems of power and oppression affect individuals along overlapping dimensions," but do not discuss power elsewhere in their paper. Similarly, Yang et al. [96] only mention power in their related works section.

Furthermore, across papers that do engage with power and power relations, engagement style varies. For example, we see power described as a distributable commodity; Suresh et al. [87] assert, "our work [...] stems from the acknowledgment that power is not equally distributed in the world." In contrast, Kirk et al. [62] note, without explicitly using the term "power," that "models can exacerbate existing biases in data and perpetuate stereotypical associations to the harm of marginalized communities."

One can argue that AI fairness researchers study mechanisms of inequality, namely the way inequalities emerge as "AI harms," so that we may reduce them. As such, the allocational and representational harms of our systems are the result of power enacted by our systems unto those at the margins. We do not reject these approaches to making sense of power discrepancies observed in AI-driven systems. However, many AI fairness researchers constrain their discussion of power to the AI system alone, removing themselves from the equation. The notion that a system itself exerts power is technodeterministic, i.e., it reifies the idea that systems, and not their creators, are responsible for reproducing inequalities. Only a few papers that we review escape technodeterminism, e.g., Kasy and Abebe [59] state, "The second alternative perspective focuses on the distribution of power and asks: who gets to pick the objective function of an algorithm? The choice of objective functions is intimately connected with the political economy question of who has ownership and control rights over data and algorithms." Engaging with intersectionality forces researchers to shed their technodeterminism and contend with the value-laden choices made by the humans that contribute to the lifecycle of AI systems. This is central to praxis that may effectively advance justice in AI fairness.

Recommendation. Researchers flex intellectual vigilance by being explicit about how their methodologies may contribute to perpetuating social inequalities. They state their full-pipeline design choices at the beginning of projects and iterate as designs are updated. Leadership gives researchers opportunities to engage in critical reflexivity. These issues are further discussed in [5, 39, 75].

Questionable citational praxis of intersectionality. Several papers reference literature incorrectly to justify their operationalization of intersectionality. For example, Ghosh et al. [49] assume that Buolamwini and Gebru [17] concerns intersectionality though it is actually a study of intersecting subgroups. We see this phenomenon again in Kang et al. [57], which cites only Buolamwini and Gebru [17] when describing intersectionality. In contrast, some papers, like Makhlouf et al. [69], discuss intersectionality, but only cite a paper on affirmative action [58]. Other papers, like Foulds and Pan [46] and Mougán et al. [74], mention intersectionality, yet do not reference any relevant literature at all; this is reflected in our deductive analysis, with 19% of papers that use the term "intersectionality" not citing any intersectionality literature.

These findings exemplify a weak spot in the citational praxis of AI fairness researchers. Alexander-Floyd [1] calls for us to cite intersectionality literature, showing that within social science literature, there has been an erasure of Black women and Black feminist knowledge in papers that discuss intersectionality. She describes the centering of positivist and empiricist methods of knowledge production as a force that (re-)subjugates Black feminist knowledge and contributes to maintaining the status quo of whose knowledge counts as "scientific" [1]. Bilge [7] identifies similar power structures in feminist studies and the broader neoliberal academy that contribute to "neutralizing the critical potential of intersectionality for social justice-oriented change."

We find this gentrification of intersectionality in our field too; AI research interprets intersectionality as a dimension of "solvability" and scale, "perpetuat[ing] the status quo injustice" [66]. Furthermore, potentially due to disciplinary barriers or gaps, papers use vague language when describing intersectionality. For instance, Kobayashi and Nakao [65] assert, "the concept of Intersectionality covers diverse discussions including the issue of the oppression that people feel due to the discrimination [15]." Camara et al. [19] mention "the complex and interconnected nature of social biases." Mitchell et al. [71] state, "an individual's identity and experiences are shaped [...] by a complex combination of many factors." Vague language prevents intersectionality from being appropriately situated in sociotechnical systems, and may convey an incomplete understanding of intersectionality, neutralizing both researchers' and readers' engagement with power structures and inequality.

Recommendation. Researchers explicitly share how their interpretation of intersectionality literature informs their methodology and assumptions. They read critical social justice literature outside of CS and cite it when incorporating it in AI design. Researchers, including those across leadership, expect and enforce intersectionality citational integrity when peer-reviewing.

Intersectional AI fairness lacks relationality. We find that AI fairness researchers have adopted intersectionality in a way that strips the relationship between structures from the complexity of intersectionality's arguments. This "misrepresents [the] initial intent" of intersectionality [27, 94], i.e., to question "how larger social structures influence supposed group level differences" [16]. For instance, some works that engage with intersectionality literature propose statistical solutions for inequality, e.g., Foulds et al. [45] tackle data sparsity by exploiting the structure of data distributions of data-dense subgroups (e.g., white women, Black men) to inform the data distribution of data-sparse subgroups (e.g., Black women). We do not reject statistical approaches to reducing AI harms; however, formulations that do not situate their statistical methods in a social context by, for instance, stating statistical *and* social assumptions those methods are based on, entirely miss the point of intersectionality as a critical framework.

Being intellectually vigilant about the relationship between statistics and the social sciences is crucial for their intersection. However, we observe different levels of contending with this intersection. Vigilance is missing entirely when the assumptions and reasoning behind the translation from social science knowledge to statistics is not explicit (e.g., [18, 44, 74]), with Fitzsimons et al. [44] describing: "In the social science literature concerns about, potentially discriminated against, sub-demographics are referred to as intersectionality [12]. More formally, this work proposes a simple approach to ensure group fairness in expectation across an arbitrary set of subgroups." Jin et al. [55] provides a more intentional socio-technical translation: "although all value combinations are assessed for intersectional fairness, some subgroups may be semantically meaningless and hence should not be returned as the output," though what is "meaningful" is not described. Other works go into more depth with their assumptions, (e.g., [93], [71]), with Mitchell et al. [71] stating with respect to subgroup formation that "collaboration with policy, privacy, and legal experts is necessary in order to ascertain which groups may be responsibly inferred, and how that information should be stored and accessed."

We caution against citing intersectionality literature while ignoring the relationships between the structures that create social categories. This fortifies the fallacy that we have engaged in intersectional praxis if we statistically supplement missing knowledge without examining the embedded assumptions and implications of doing so. It is through this neutralization of critical vigilance and reflexivity that AI fairness researchers are unable to identify where social inequalities may emerge through their own praxis. Invoking an intersectional lens enables this and is, therefore, pivotal to understanding the interlocking systems that produce AI injustices and doing AI justice work.

Recommendation. Researchers remain intellectually vigilant about how scholarship from the social sciences relates to and informs both statistical and wider research methodology. As a result, they preserve the social context of social groups when employing statistical methods, e.g., by transparently stating how they infuse statistical assumptions with context. Across points of power, researchers have "vigilance check-ins" to check translative assumptions during AI development milestones. [71] engages with transparency at the model level which complements these points.

AI social justice praxis varies. Some papers treat improved fairness as social justice praxis regardless of the task's context. For example, Foulds et al. [45] use recidivism prediction as a fairness benchmark task. As recidivism prediction is a "byproduct of ongoing regimes of selective policing and punishment" [5], the task only serves to uphold the carceral state [52]. Here, intersectionality posits sites of violence are saturated intersections of power [29].

Furthermore, many works are not grounded in social context, which ought to inform social justice praxis [61, 65, 81]. Some papers provide context (e.g., data collection is "biased toward non-minorities" [45]), but nevertheless prioritize generalization [45]. Some papers even give credence to inferring the social category of individuals; Fitzsimons et al. [44] state, "gender labels were inferred using the employees' first names, parsed through the gender-guesser python library." Furthermore, we identify works that highlight the oppressive nature of social categories though often defer contestations to future work. For example, Kirk et al. [62] advocate:

> *"Future research is recommended to make ground truth comparisons across a broader range of countries against the set of gender-intersections examined in this paper and to comment on a broader spectrum of gender identities."*

Moreover, few papers complement technical contributions with social action, and some even tout their "purely statistical approach" [73]; this neglects the complexity inherent to dismantling social injustices. Mathematical saviorism restricts the operationalization of critical praxis to the pre/in/post-processing stages. This encourages AI researchers to locate sources of unfairness situated only within the technical domain, ignoring the broader sociotechnical milieu linked to the power relations and inequalities upheld by AI [39]. Consequently, people already at the margins are erased, even in these contexts that ostensibly address fairness, oppression, and complexity. Thus, AI fairness researchers must engage in praxis that is informed by the experiences of those at the margins.

Some papers justify design choices that do not center care for those at the margins through utilitarian perspectives, e.g., Molina and Loiseau [73] reason, "an algorithm which discriminates 1 person among a 1000 can be described as fair to an extent." On the other hand, works like Suresh et al. [87] and Mitchell et al. [71] concretely advocate to dismantle injustice and shift power through participation in model development and transparency in deployment, respectively. The contrast in social justice praxis is notable; AI fairness researchers must consider how design choices situate AI systems within their sociotechnical context.

As Crenshaw [35] has said, "addressing the needs and problems of those who are most disadvantaged" means that "others who are singularly disadvantaged would also benefit." Centering these people and the contexts tied to their oppression deepens social justice engagement and creates equity. This way of engaging with intersectionality thus equips AI fairness researchers, regardless of training, to better address inequalities and injustices in AI.

Recommendation. Researchers bridge social justice inquiry and praxis by investing in and valuing the knowledge from communities that their AI systems harm. Researchers and leadership make sure that the AI design process prioritizes harm reduction to promote justice for marginalized communities. [87] does a good job at centering AI development through community engagement.

AI fairness misses critical reflexivity. Several papers neglect to state their social context and its implications for research methodology. This is reflected in our annotations, with 43% of papers—even critical ones, e.g., Kong [66]—not including their social context (often the US) [18, 68, 95]. Furthermore, when describing social context, some works only include the US as an important context, without commenting on the aspects of complexity and power inherent to doing so. This privileges western contexts as the "default" context, resulting in western prototypicality (c.f., white prototypicality [50]). For instance, Kirk et al. [62] argue:

> *"using US data may provide an appropriate baseline comparison: 50% of Reddit traffic comes from the US, and a further 7% from Canada and the UK each [34]. Given that US sources form a majority in GPT-2's training material [...], we consider the US dataset a satisfactory first benchmark."*

Moreover, when authors do name their social context, they often phrase it as a blanket limitation rather than a contextualization of their research choices; Yang et al. [96] share that "the social construction and definitions of sensitive attributes" are "outside the scope of the present work but which are important in any real application." Stating their context as a limitation—instead of a point which textures their work from the onset —situates their context as an afterthought, rather than something that undergirds the entire research process. On the other hand, Suresh et al. [87] center reflexivity throughout their work stating: "Throughout this process, we take an explicitly feminist approach, both in our overaching process—which we strive to make iterative, reflexive, contextual, and participatory—as well as the technology we build".

All in all, critical reflexivity is crucial to operationalizing intersectionality, both as inquiry and praxis. AI researchers are overwhelmingly located in the Global North [12], which makes many power relations and AI injustices invisible to us, especially when we lack the abilities to inquire upon it. Reflexivity requires that we observe the power relations we participate in or benefit from, dismantle these relations, and identify opportunities for social justice within AI fairness. Our advice aligns with conceptualizations of decolonization within the computational sciences; Birhane and Guest [11] comment that decolonizing "requires the beneficiaries of the current systems to acknowledge their privilege and actively challenge the system that benefits them."

Works that decouple social context and relationality from intersectionality may reflect academic incentives (e.g., conference acceptances, funding [13], citations) and infrastructural forces (e.g., conference paper formats, objectivity-washing). These push AI researchers to make "fairness" palatable by treating it as a complexity-free scientific quantity that can be optimized [10, 89]. Our paper is bound by similar constraints; we empirically validate our critical analyses in order to publish and our citation of the papers we review gives them "academic currency" even as we critique them.

Recommendation. Researchers across points of power iteratively dialogue on unlearning "universal" frameworks of knowledge and remain vigilant of *whose* knowledge is centered when developing AI. Leadership incentivizes and provides resources for their team to engage in critical reflexivity tools throughout development. [64] provides a good example of iterative reflexivity.

7 CONCLUSION

What we cannot name, we cannot see. What we cannot see, we cannot address. By examining AI fairness papers related to intersectionality, we identify several patterns in how the literature discusses intersectionality and how it impacts our ability to produce equitable tools. While our field has much energy to get this technology right, we caution the community against assuming that surmounting a "fairness issue" pre/in/post the AI pipeline means we have fixed the social reality driving the problem. This work does not seek to discard existing AI fairness work; instead, we invite a widening of AI fairness practice by centering marginalized people and valorizing critical knowledge production that makes room for their voices. We provide recommendations grounded in producing critical knowledge on how AI systems reproduce social inequalities. Our recommendations are not mutually exclusive with respect to AI fairness infrastructure. Rather, they empower researchers to flex the intellectual vigilance required to produce intersectional work, regardless of CS paradigm. Expanding both the conceptualization and operationalization of intersectionality will enable AI fairness researchers across points of power to engage in deeper social justice praxis for AI. To do this, we advocate for adopting intersectionality as an analytical sensibility rather than an axis of optimization.

> *"I lack imagination you say*
> *No. I lack language. The language to clarify*
> *my resistance to the literate."*
> *- Cherríe Moraga (1983)*

ACKNOWLEDGMENTS

We are immensely grateful for the work of intersectionality scholars, especially Black women scholars. We thank Dr. Lisa Bowleg and the anonymous reviewers for their feedback.

APPENDIX

A TAGGING FOR INTERSECTIONALITY LITERATURE

Initially, we only tagged works as incorporating intersectionality literature when they included Collins and Bilge [29], Crenshaw [35], Hancock [53], or Cho et al. [22]. However, during our weekly discussions, we noticed that papers cited a wider array of intersectionality works; either other works by these same authors, or other scholars who center intersectionality within critical disciplines. Because we want to gauge how AI fairness conceptualizes intersectionality, casting a wider net on tags is valuable in that we can include works that, while unaware of our initial list of texts, state intersectionality as a motivation in their work and cite other works about intersectionality like [26], [30], [27], or [36]. As a result, we tag the presence of intersectionality literature if any paper includes works that: 1) discuss intersectionality outside of CS and 2) frames intersectionality as a critical social inquiry and praxis framework.

B GUIDING QUESTIONS AND CONSIDERATIONS

We chose to create 3-4 guiding questions per tenet in order to balance in-depth coverage of each tenet with annotation feasibility. We share all our guiding questions in Table 2. While some guiding questions are straightforward (e.g., "Do the authors consider cross-sectional social categories?"), others are more up to our interpretation and experiences (e.g., "Are there any discussions on how spaces operate at different domains of power?"). Our interpretation of the intersectionality tenets for advancing justice in AI fairness is influenced by our social context and location, including our formal AI training, social identities, and experienced social inequalities (§1). For instance, we (the investigators) are all trans and people of color, and hence were likely more attuned to the discussion in Kong [66] of power differentials in "regular" experiences, e.g., going through airport security.

C ANNOTATION METHODOLOGY

We follow Lincoln and Guba's 1981 model of trustworthiness in our analysis [76], taking steps to maximize its credibility, dependability, confirmability, and transferability.

- **Credibility:** We are highly familiar with Collins and Bilge's tenets. We also engaged in in-depth intersectionality intensives hosted by Black feminist scholars. Furthermore, we all have done justice work in some capacity. The majority of authors on this paper are trans people of color operating in AI. One author is a social scientist who confronts social inequities in their scholarship through intersectional perspectives. We spent over 6 months developing the guiding questions.
- **Dependability:** 11 out of the 30 papers were evaluated by three annotators, and we present our tenet-level interannotater agreement for these papers in Table 3. The scores in Table 3 indicate moderate to high interannotator agreement. The remaining 19 papers were each evaluated by at least 1 annotator.
- **Confirmability:** During weekly investigator meetings, we discussed our guiding questions and identified major sources of disagreement in our annotations.
- **Transferability:** Our guiding questions can be operationalized across paper types and domains outside of academia.

D MEASURING INTERANNOTATOR AGREEMENT

We use Randolph's κ to estimate inter-annotator agreement, which is free-marginal rather than fixed-marginal; we choose this because κ is computed over six distinct items (i.e., tenets).

Table 2: Collins and Bilge's tenets of intersectionality and our corresponding guiding questions

Tenet	Guiding Questions
Social inequality	1) Do the authors ground their work in how specific social or historical contexts factor into social inequality? 2) Do the authors acknowledge the implications of their work with respect to social inequality? 3) Is there a discussion of how intersecting power relations produce social inequality?
Social power	1) Do the authors mention power? 2) Do the authors discuss any movement of power to the powerless? 3) Do the authors mention the mutual construction of power? 4) Is their own power in the work named or do the authors reflexively comment on the oppressive power relations within which their work participates?
Social Context	1) Do the authors name their social context or social location with respect to their work? 2) Do the authors discuss how their social context influences their ideas and work's design, decisions, and development? 3) Do they acknowledge the limitations of their contexts?
Relationality	1) Do the authors discuss the relationships between either social groups or structures? 2) Do the authors engage with how different social groups, typically treated as separate, face shared oppression? 3) Do the authors comment on how their identities shape their inquiry in relation to the people affected by their work?
Complexity	1) Do the authors consider cross-sectional social categories? 2) Do they involve those without power in the generation and social construction of new knowledge? 3) Do the authors comment on the interplay between technical interventions and social action, or critical inquiry and practice? 4) Are there any discussions on how spaces operate at different domains of power ?
Social justice	1) Do the authors state their commitment or motivation as social justice? 2) Do the authors discuss ways in which fair predictions or rules are not equally applied to everyone and can still produce unfair and unequal outcomes? 3) Do authors aim to dismantle a form of injustice, rather than solely documenting it in the form of a paper?

ABSTRACT

Calls for new metrics, technical standards and governance mechanisms to guide the adoption of Artificial Intelligence (AI) in institutions and public administration are now commonplace. Yet, most research and policy efforts aimed at understanding the implications of adopting AI tend to prioritize only a handful of ideas; they do not fully connect all the different perspectives and topics that are potentially relevant. In this position paper, we contend that this omission stems, in part, from what we call the 'relational problem' in socio-technical discourse: fundamental ontological issues have not yet been settled—including semantic ambiguity, a lack of clear relations between concepts and differing standard terminologies. This contributes to the persistence of disparate modes of reasoning to assess institutional AI systems, and the prevalence of conceptual isolation in the fields that study them including ML, human factors, social science and policy. After developing this critique, we offer a way forward by proposing a simple policy and research design tool in the form of a conceptual framework to organize terms across fields—consisting of three horizontal domains for grouping relevant concepts and related methods: Operational, Epistemic, and Normative. We first situate this framework against the backdrop of recent socio-technical discourse at two premier academic venues, AIES and FAccT, before illustrating how developing suitable metrics, standards, and mechanisms can be aided by operationalizing relevant concepts in each of these domains. Finally, we outline outstanding questions for developing this relational approach to institutional AI research and adoption.

1 INTRODUCTION

Public institutions, such as government ministries and executive agencies, are increasingly making use of artificial intelligence (AI), particularly machine learning-driven (ML) systems, with the aim of improving service delivery and informing policymaking [19]. The advanced capabilities of these tools have prompted the recognition that we need new metrics, technical standards and governance mechanisms to evaluate and guide their use. However, while research on institutional AI, research related to the technical as well as ethical, social, political and legal implications of algorithms and computing in public administration, is now commonplace, most work arguably still fails to account for the diverse potential advantages and consequences of adopting AI in a public sector context. Instead, reflecting trends in socio-technical discourse more broadly, many contributions at premier conferences arguably tend to foreground only a handful of topics, perspectives, concepts and methods [2, 5, 9, 14, 34], such as mathematical formulations of outcome fairness in ML applications [17], at the expense of others. How then do we ensure that future research on new metrics, technical standards and governance mechanisms better accounts for all the topics, concepts and methods potentially relevant to the institutional adoption of AI?

In this position paper, we focus on one theoretical issue, which we call the 'relational problem', that has arguably hindered scholarly efforts at the two premier conference venues for socio-technical issues, AIES and FAccT, to comprehensively study AI systems in an institutional context: fundamental ontological issues within the field have not yet been settled—including semantic ambiguity and, more significantly, a lack of clear relations between different topics, perspectives, concepts and methods (henceforth also abbreviated to 'terms and approaches'), leading to differing standard terminologies

across subcommunities. We contend that this failure exasperates the prevalence of disparate modes of reasoning to assess institutional AI systems—such as "formalist algorithmic thinking" in computer science [14]—and contributes to the prevalence of conceptual isolation in the fields that study them including ML, human factors, social science and policy. After developing our argument, we propose a simple research and policy design tool in the form of a conceptual framework to organize terms and approaches across disciplines—consisting of three horizontal domains for grouping relevant concepts and related methods: Operational, Epistemic, and Normative.

Within the context of AIES and FAccT, the utility of our framework derives from the fact that it seeks to be discipline-agnostic; it aims to be instructive for individual policymakers and researchers studying institutional AI systems from a range of disciplines, both in helping with organizing concepts and methods and, more importantly, by drawing attention to whether all potential topics and concepts—by virtue of being relevant to one or more of the three proposed domains—have been accounted for. Our framework therefore aims to achieve two key aims: (1) disciplinary reach, i.e., bridge different subcommunities at AIES, FAccT and elswhere (ML, human factors, social science, policy etc.), and (2) provide impetus for an intellectual shift that reframes how researchers and key stakeholders (decision-makers, policy creators, advocates, etc.) think about and ultimately regulate institutional AI applications.

The rest of the paper is structured as follows. In Section 2, we motivate our argument and situate it against the backdrop of recent socio-technical discourse at AIES and FAccT. We then introduce our framework in Section 3 and illustrate how developing suitable metrics, standards and mechanisms can be aided by identifying and operationalizing relevant concepts across each of the proposed domains. Finally, in Section 4 we conclude by outlining key questions needed to develop a research agenda for advancing a relational approach to institutional AI research and adoption.

2 THE STATE OF SOCIO-TECHNICAL DISCOURSE

In this section we consider why certain topics, concepts and methods have been disproportionately studied in socio-technical discourse studied and consider the role played by unresolved ontological issues. Importantly, throughout this paper, the word 'method' is taken to mean the different technical or policy measures that may be used to evaluate and guide the use of AI systems (i.e., metrics, mechanisms, standards etc.), either by operationalizing a specific concept (e.g., classification accuracy in the case of performance) or combining a number of concepts into a qualitative framework (e.g., algorithmic impact assessment). Concepts are meanwhile understood both as an abstract idea that offer a point of view for understanding some aspect of experience (e.g., bias), and, relatedly, a mental image that can be operationalized (e.g., measurement bias). As such, a loose parallel can be drawn between our use of the terms concepts and methods, and the terms 'principles and practices' in AI Ethics discourse [22].

2.1 The Double-Edged Sword of AIES and FAccT

As more institutions move to employ AI systems in high stakes decision-making contexts like criminal sentencing, heightened attention has been drawn to the detrimental effects this can have—especially for marginalized and traditionally under-served groups—ranging from simple inefficiencies to major injustices [32]. Biased performance, inscrutable design and the uncritical implementation of complex AI applications have subsequently been identified, among others, as the main causes of these undesirable consequences [6, 10, 29]. More recently, the structural, historical and power disparities that permeate society and necessarily affect the design or adoption of technical systems have also received more attention [4, 5, 40]. Over the last five years, this discourse has matured, and a number of academic venues have become established platforms for computer scientists and scholars from other disciplines to raise awareness of these topics. Yet, this development has arguably been a double-edged sword. On the one side, it has put a bright and much-needed spotlight on socio-technical issues in AI. On the other, it has resulted in certain topics and methods receiving considerable attention, at the expense of other ideas and challenges. This unequal emphasis on particular topics has also characterized the growth of the two premier conferences, AIES and FAccT, which we focus on herein.

Officially, AIES and FAccT seek to consider the ethical ramifications of AI systems (including those used in public administration and social service provision) and their impact on human societies, address general questions that consider perverse implications, distribution of power, and redistribution of welfare and ground research in existing legal requirements. In practice, however, there has been a disproportionate focus on a handful of narrow topics and methods. [17] diagnose this troubling trend most clearly in their four-year analysis of FAccT, finding that there has been an out-sized focus on, among other topics, "quantitative work on fairness, displacing discussions about broader AI policy and governance, both within and across years". This is in spite of the more general way that FAccT defines its aims. Similarly, [5] find that while the goals of the majority of contributions to AIES are often commendable, "their consideration of the negative impacts of AI on traditionally marginalized groups remained shallow", leading them to conclude that there is an overall inadequacy of scholarship in engaging with perspectives that are "not a part of the standard".

To be clear, it is to be expected that different subcommunities and disciplines study and thereby value different topics, concepts and issues. This is, after all, the point of specialization. A problem occurs, however, when fields are meant to be united in studying the same topic (i.e, socio-technical issues in AI systems) but do not acknowledge these differences and fail to integrate ideas from their peers. The result is the use of divergent terminologies and the exasperation of knowledge silos, meaning terms like 'fairness' and 'discrimination' are understood differently by ML researchers than by HCI or AI Ethics scholars [40]. In some cases, this even means that certain highly valued topics and approaches may become embedded in supposedly value-neutral and universally beneficial research, e.g., generalization, quantitative evidence, and efficiency in the case of

ML [4]. This situation threatens to create great challenges for effective understanding, dialogue, and integration between disciplines and academic subcommunities.

2.2 Ontological Issues and The Relational Problem

We are by no means the first to consider whether certain terms and approaches have dominated socio-technical discourse at AIES and FAccT. In fact, there have been a growing number of calls from within the scholarly community to diversify the number of topics studied within recent years. In prior work examining trends in recent proceedings, scholars have offered in-depth analyses of why and how certain topics, such as fairness [2, 7, 15, 23, 30], have been researched more than others [3, 5, 17, 40]. For instance, [40] argue that, because of corporate capture, i.e., conflicts of interest, conference contributions "frequently limit their gaze to the 'technical' part of 'sociotechnical'—the level of data, metadata, or models" and reduce complex concepts like fairness to "dimensions of arbitrary narrowing that both obscure and reproduce structures of social injustice". Similarly,[35] contend that, by abstracting away the social context in which these systems will be deployed, "fair-ML researchers miss the broader context, including information necessary to create fairer outcomes, or even to understand fairness as a concept". [5] meanwhile offer a more sociological explanation, arguing that existing scholarship has been influenced by the centralization of power between highly cited researchers, tech companies, and elite universities, resulting in topics and concepts related to oppressive social structures, the distribution of power, and harm receiving less attention.

Yet, while it is important to acknowledge that sociological factors and economic incentive structures (i.e., scientific funding) clearly influence *what* different topics researchers study [39], here we wish to focus on an altogether more theoretical factor relevant for understanding differences in *how* researchers study the same topic. Specifically, our main contention is that discrepancies and inequalities in the terms and concepts that researchers employ to study institutional AI are, in part, connected to the fact that fundamental ontological issues within socio-technical discourse have not yet been settled. That is, there are semantic ambiguity problems, specifically, a lack of agreed upon definitions for key terms, a lack of clear and consistent relations between topics, concepts and related methods, and differing standard terminologies across subcommunities. [17] draw attention to this problem in passing, noting, for instance, that universally agreed upon definitions are even lacking for foundational terms like 'AI'.

Although the lack of commonly agreed upon definitions within fields is an ongoing problem, we contend that the most troubling development is the failure of research efforts to establish clear relations and make connections between different topics and concepts—especially between those that are easily quantifiable and those that are not. One recent survey of ML research, for instance, found that terms related to user rights and ethical principles, like interpretability, privacy and non-maleficence, "appeared very rarely if at all" compared to performance or efficiency, and "none of the papers mentioned autonomy, justice or respect for persons" [4]. This is despite the fact that these represent topics that are clearly also important when considering the application of ML, as scholars in AI Ethics have long shown. In the case of technical work on measures and methods to improve fairness in AI systems [2], for instance, [23] contend that most so-called 'fairML' efforts happen in isolation and lack "serious engagement with philosophical, political, legal and economic theories of equality". Instead, researchers oversimplify or 'level down' the broader topic of distributive justice into a single evaluation metric that attempts to operationalize fairness, while other topics and approaches (e.g., algorithmic impact assessments that also consider priority and welfare) are minimally discussed or ignored altogether. This results in semantic ambiguity, as concepts like fairness can have multiple definitions and can mean very different things depending who you ask [25].

It is important to re-emphasize that certain concepts and methods have necessarily received disproportionate attention given they currently exert an out-sized influence on scientific progress, public institutions or society more broadly. To stay with the obvious example, ML is actively being used or trialed in myriad different applications and public administration contexts [11], including in healthcare, policing, criminal justice and other so-called high stakes domains [33]—where fairness is inherently important. As such, it is to be expected that ML, fairness and consideration of these high stakes domains has been a considerable focus of proceedings at AIES, FAccT and broader societal discourse at large. The issue we wish to stress is that most work on these topics does not effectively relate the terms and approaches used to other, perhaps less well-studied but potentially equally relevant and important terms and approaches. This results in rich-get-richer and echo-chamber system dynamics in institutional AI research as whole, whereby certain perspectives of important topics (i.g., mathematical definitions of outcome fairness) dominate discussion. Alongside fairML and other related topics (e.g., Explainable AI [20]), some scholars have started to draw attention to this issue in the context of specific subfields or disciplines. [14], for instance, argue that computer scientists, as a result of adopting a formalist mode of reasoning, often do not fully engage with other disciplines when considering the social and political contexts of AI systems. Drawing on studies of sociotechnical systems in Science and Technology Studies, [35] similarly argue that when researchers treat fairness and justice as terms that have meaningful application to technology separate from a social context, they make a category error, or as they posit, an 'abstraction error'. This is because fairness is a property of social and legal systems like employment justice, not a property of the technical tools within a system.

Overall, this ontological failure to explicitly connect terms and approaches, which may be called the 'relational problem'—as it mirrors debates in AI Ethics on how to reframe concepts in relation to those affected [3]—will, if left unaddressed, arguably only worsen the existence of conceptual isolation in the fields that study institutional AI adoption including ML, human factors, social science and policy. In the context of AIES and FAccT, this will in turn likely make it easy for certain concepts (e.g., fairness) and methodological formulations (e.g., mathematical) favored by popular subfields (e.g., ML) to continue dominating discussion. As a result, other topics and perspectives may be pushed further to the margins of discourse

[5] and any definitional consensus may be better described as manufactured rather than genuine [40]. Most importantly, it ultimately means that the development of new metrics, technical standards and governance mechanisms to guide the adoption of AI in public administration ends up reflecting only a small subset of perspectives and concepts pertinent to the complex reality of institutional AI. As a consequence, we are left with, at best, a distorted view of the implications of adopting AI systems and, at worst, the neglect and perpetuation of real-world algorithmic harms and injustice that affect historically disadvantaged or marginalized groups the hardest.

3 A RELATIONAL MULTIDOMAIN FRAMEWORK FOR INSTITUTIONAL AI

How then do we address these ontological issues and ensure that future socio-technical research on new metrics, technical standards and governance mechanisms better reflects all the terms and approaches potentially relevant to the institutional adoption of AI? What is arguably needed is a change in how researchers and policymakers conceptualize the application of AI in institutional contexts to begin with. That is, to move beyond current disparate modes of reasoning, which each do not fully account for the realities of algorithmic impacts, requires a fundamental shift—from a single lens to multiple perspectives—in how to think about all relevant topics, concepts and methods—be it outcome fairness, welfare, performance or accuracy metrics—and how to link them to each other. Given that many concepts employed to discuss socio-technical issues at conferences like AIES and FAccT are fundamentally multi-faceted or discipline-specific, we do not wish to propose new definitions or prescribe which specific terminologies or modes of reasoning should be used. Rather, we use the rest of the paper to propose, as a starting point, a simple policy and research design tool in the form of a conceptual framework to organize terms and approaches across fields.

Our framework consists of three discipline-agnostic domains for grouping relevant concepts and related methods that each have a distinct thematic and semantic scope. We label these: Operational, Epistemic, and Normative. The main aim of our framework is to achieve two specific aims: (1) disciplinary reach, i.e., bridge different perspectives (CS, human factors, social science etc.), and (2) provide impetus for an intellectual shift that encourages researchers and key stakeholders (decision-makers, policy creators, advocates, etc.) to think about institutional AI systems more holistically. Our overarching goal is to offer a way to organize disparate socio-technical research outputs into general thematic categories, making it easier to align and integrate efforts from different scholarly subcommunities. Below we first introduce and define the domains before discussing how they can be integrated and unified into a single framework.

3.1 Grouping Socio-Technical Topics into Three Domains

Our framework is ontological in the sense that is it composed of three domains or meta-concepts that aim to act, both individually and collectively, as guides for researchers to relate and connect different terms and approaches within socio-technical discourse to each other. Importantly, the concepts and terms that can be grouped into one of the three domains are not synonymous but we assume that they are all used to discuss institutional AI systems in a similar way. As such, each domain can loosely be said to function as a semantic field, a set of words related in meaning (i.e., terms used to study institutional AI systems), and are defined by their unique thematic focus, or what we label as 'scope'.

To theorize and define the scope of the three domains we took inspiration from three strands of work. Firstly, social science and human factors research that emphasizes the behavior and beliefs of human agents in influencing the performance of technical systems including AI applications (e.g., [31]). Secondly, computer science work on reasoning about the knowledge-related properties of a technological system [8]. And thirdly, the insight of moral philosophers that questions about the social implications of socio-technical systems including AI applications depends on political decisions about normative issues [12].

3.1.1 Operational Domain. The operational domain aims to represent the terms and approaches related to the routine activities and functionality of institutional AI systems [29]. Its scope is meant to capture concepts that are mainly but not exclusively defined, operationalized and studied in a technical, applied context. More specifically, it is meant to enable researchers to categorize into a single category all relevant concepts that can be employed both as an abstract idea (e.g., 'accuracy') and easily operationalized to quantitatively measure a specific performance attribute of a particular institutional AI system (i.e., 'percentage of correct predictions'). As such, the common characteristic of all the concepts and related methods in this domain, regardless of how they are operationalized, is an emphasis on describing specific functional requirements or attributes of institutional AI systems. This reflects what is arguably unique about the operational domain, namely, it aims to draw attention to concepts that can be conveniently specified in a common technical (mathematical) language or easily quantified, allowing for the succinct description and comparison of specific models or applications.

3.1.2 Epistemic Domain. The scope of the epistemic domain aims to capture knowledge-related terms and approaches connected to a particular AI system or institutional AI in general. That is, the epistemic domain is meant to help researchers and policy-makers group together concepts that seek to describe properties which pertain to the interface between AI applications and human actors. Both in terms of the knowledge, beliefs, and intentions of those using AI applications (e.g., a desire for transparency), and the internal properties of the system itself (e.g., its interpretability). Given that AI systems represent a step-change from earlier ICTs due to their increased technical complexity, among other factors, epistemic domains concepts are likely also useful in delineating different types of AI systems. Relatedly, while the domain seeks to capture terms that are often employed analytically to highlight epistemic issues about institutional AI systems (a lack of reproducibility, openness etc.), it is also meant to account for and help organize methods and concepts operationalized in a technical manner to improve human knowledge of a system (e.g., explainability, interpretability).

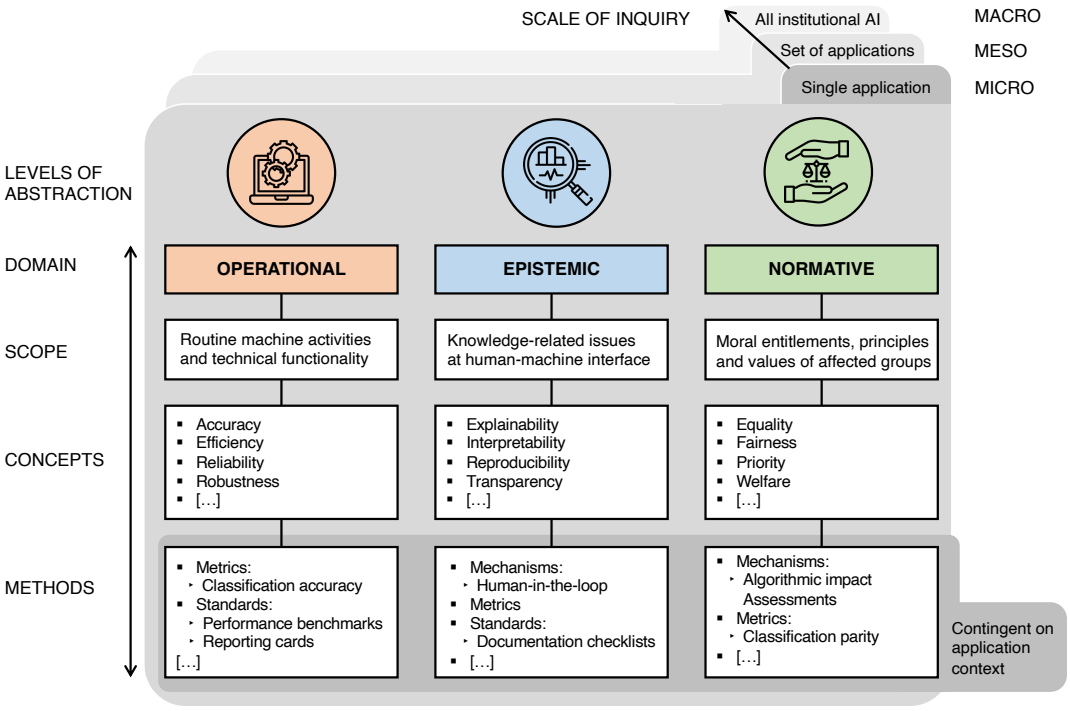

Figure 1: Graphic representation of our framework for grouping relevant concepts and related methods relevant to institutional AI adoption. The framework consists of three domains that each have a distinct thematic and semantic scope: Operational, Epistemic, and Normative. These domains can be used to consider AI at all three scales of analytical inquiry: a single AI application (micro), sets of similar applications (meso) and all institutional AI applications considered as a single class (macro). Listed concepts and methods are for illustrative purposes and not exhaustive; example methods (e.g., the metric of classification accuracy) are taken to be contingent on the local application context.

3.1.3 Normative Domain. The meaning and uses of concepts in the normative domain, the final domain we propose, collectively relate to the entitlements, values and principles of political morality that stakeholders and affected groups hold towards a particular AI application or institutional AI in general. The term 'political morality' is used here to refer to normative principles and ideals regulating and structuring the political domain. In the context of institutions, stakeholders may be said to include system developers (e.g., designers, engineers, and domain experts), those who manage and operate them within the public sector (e.g., decision-makers, policy creators, advocates), and end-users affected by the AI system (i.e., individual citizens or specific groups). In some cases, this may include large parts of society [28], as AI systems can increasingly result in individual and collective harms [38]. We anticipate that the normative domain primarily covers concepts that can be understood in two ways. Firstly, those used in a practical ethics sense, such as in bioethics, to stress the values that underlie the safeguarding of individuals (e.g., 'non-maleficence'). Secondly, those used in a legal framing, as in human rights discourse, to discuss the set of entitlements due to all human beings under the rule of law for a particular jurisdiction [18] (e.g., justice). Importantly, while this means concepts and topics in the normative domain may appear to only be relevant to particular disciplines (i.e. AI Ethics), this is by no means the case as normative domain concepts also need to be operationalized by computer science researchers if we are to move from principles to practices [22].

3.2 Integrating the Dimensions

The operational, epistemic and normative domain are each meant to act as independent analytical categories that can be used to help researchers focus on a particular aspect of institutional AI (e.g., knowledge-related issues) and make connections between related concepts (e.g., explainability, transparency, etc.). However, the real utility of this relational approach comes to the fore when each of the three domains are integrated and unified into a unified framework. Figure 1 provides a graphic representation of this. When each domain is considered together in this polycentric manner, the emphasis is on the conceptual need to always think horizontally when proposing new methods or discussing socio-technical issues in AI systems including institutional AI applications. That is, rather than expecting scholars to employ every single concept in a particular domain when discussing how to evaluate an AI system, the framework aims to encourage researchers to connect concepts and methods across the three domains. In practice, this means that ML researchers currently working on fairML, for instance, are reminded to consider how fairness relates to other normative domain concepts like welfare and take into account the need to consider

epistemic domain concepts like interpretability and reproducibility, alongside accuracy, efficiency and other operational domain concepts. Similarly, the framework reminds AI Ethics and policy scholars working on transparency to link their work laterally to other epistemic domain concepts and not ignore operational domain concepts like robustness and reliability.

Crucially, the framework does not seek to prescribe which specific concepts in each domain are most important or which related methods are most useful and relevant. As such, each of the example concepts and methods discussed herein and listed in Figure 1 are cited primarily for illustrative purposes. Different disciplines and academic subcommunities will, as already discussed, rightly study and value particular topics, and certain terms and approaches necessarily receive more scholarly attention. In light of this, the framework aims to act primarily as a discipline-agnostic design tool that can help researchers and policymakers organize diverse concepts across fields and motivate them to adopt a more relational, holisitic approach. Hence, we do not attempt to list all of the concepts and methods that fall into each domain. Rather, by outlining and specifying the scope of each domain, we encourage researchers that study institutional AI including scholars in ML, human factors, social science, policy and AI ethics, to start identifying and connecting additional concepts themselves. While we have tried to define the scope of each of the domains in a narrow enough way so that any socio-technical concept falls into a single domain, certain complex concepts may naturally span more than one domain. 'Accountability', for example, is often defined too imprecisely and can pertain to a variety of values, practices, and measures. It is considered by some scholars as a necessary feature of a trustworthy AI system, while others argue that only humans can be accountable [26]; depending on whether they are defined in function-based terms or not, concepts like accountability or trustworthiness [37] may thus be considered to be an operational and or normative domain concept.

A further important clarification pertains to how various methods may relate to particular concepts. More specifically, while foundational concepts like accuracy are more or less taken to have universal relevance when it comes to the institutional adoption of AI systems, differences in moral values [1], including with regards to the AI use case [27], and practical contextual factors (i.e., the type and number of systems that are institutionally adopted) additionally means that certain concepts may in practice be more important than others. As such, the exact concepts and related methods which are most relevant to each domain are necessarily contingent on the application context. That is, while we envisage that our framework can be used to study and evaluate AI systems at different scales of analytical inquiry, when the object of study is a specific AI system designed for a local institutional application context, we nevertheless anticipate that the most relevant methods to operationalize particular concepts may change. For instance, data documentation checklists and model reporting cards [21] may be considered sufficient when seeking to apply operational and epistemic domain concepts like reliability and interpretability, respectively, to understand the adoption of a recommender system to provide suggested links on a local government domain. However, if a similar system is used by a national healthcare provider to recommend medication, additional methods may be necessary (e.g. mechanisms like human-in-the-loop operating protocols).

3.3 Applying the framework in practice

Overall, our framework is intended to help researchers and policymakers within various fields engaged in studying and regulating institutional AI systems, such as AI-assisted decision support systems or criminal justice tools. Specifically, it is meant to act as a starting point for conceptualizing the desired attributes of AI systems, and thus purposely aims to foreground the need to integrate ideas, alongside being applicable to various real-world examples of AI systems, and remaining stable and useful over time as a conceptual model [24]. In context of AIES and FAccT, the framework's utility therefore derives from the fact that it seeks to be discipline-agnostic; it aims to be instructive for individual researchers studying institutional AI systems from a range of disciplines, both in helping with organizing terms and approaches, and, perhaps more importantly, by drawing attention to whether all potential intellectual and moral perspectives—by virtue of being relevant to one or more of the three proposed domains—have been accounted for.

Despite the theoretical nature of our framework, we anticipate that it can practically help address some of the ontological issues we outline, such as as the need to bridge quantifiable and non-quantifiable terms and concepts, when it is viewed as a simple policy or research design tool. That is, we contend that the framework can be used as a strategy to help researchers go about deciding which terms and approaches are relevant for studying a single or set of AI systems and ensuring they assess these from multiple perspectives. This can be achieved by relying on the four levels of abstraction (see Figure 1) to deductively guide the process of conceptualization. In other words, after first relying on the three meta-concepts (domain) to ensure all types of concepts covering different thematic areas (scope) are accounted for, researchers can then choose particular terms (concepts) that are most appropriate to the system under consideration, before finally operationalizing these (methods), depending on the application context.

As an example, consider the use of a recommendation system, special-purpose software designed to suggest content to a user of an online service, in an institutional context, such as for suggesting links to citizens on a pubic domain government website. Although recommendation systems like Google Search's autocomplete function and Amazon's recommendations for related products are well-known examples of AI systems, they carry a number of ethical implications and the use of similar systems within public institutions adds another layer of ethical complexity [16], as is the case for the UK's GOV.UK, which uses machine learning to guide guide users through complex service journeys [36]. To understand and regulate such public service recommender systems, the framework encourages authors to consider operational as well as epistemic and normative topics, ensuring they are situated within the fairness, accountability, and transparency discourse [13]. Specifically, it reminds authors to consider how epistemic topics like explainability, interpretability and reproducibility may be important for ensuring a system is democratic. Similarly, it reminds authors to also consider how fairness, equality, and welfare may need to be considered to ensure the system meets legal accessibility requirements (e.g.,

can be accessed on legacy devices) and does not infringe privacy concerns by relying on user data or provide biased outputs. Measuring and evaluating each of these criteria may in turn involve multiple methods (i.e., metrics, standards, and mechanisms) that will be contingent on the application context. For instance, for operationalizing normative concepts like equality, justice and fairness, researchers and policymakers will need to rely on the fundamental rights enshrined in law for the particular jurisdiction where a system is being implemented; in some cases these may be more or less universal (e.g., the prohibition of discrimination).

4 MAPPING A RESEARCH AGENDA FOR A MULTIDOMAIN APPROACH TO INSTITUTIONAL AI

Our conceptual study has primarily aimed to shed light on theoretical, specifically, ontological issues in socio-technical discourse, focusing in particular on contributions to AIES and FAccT, and considered how we might begin to resolve them. While these conferences continue to be dominated by a subset of topics and methods, there are signs of a shift, evidenced, for instance, by the gradual but significant increase in legal, social science, and ethics papers over the years, alongside ML papers about fairness [17]. Yet, the fundamental relational problem we described in Section 2 will arguably remain until scholars start actively integrating more perspectives, concepts and methods from their peers.

While we hope our framework can enable all researchers at AIES, FAccT and elsewhere to adopt a more holisitic approach to conceptualizing and evaluating institutional AI systems, we wish to stress that it is only a first step. We must not only consider the use of multiple domains to assess and evaluate institutional AI systems but also understand how each works together. As such, we have identified 10 key outstanding questions that we anticipate will be key for developing this multidomain relational approach to institutional AI research and adoption:

(1) Do we need to further delineate and operationalize the operational, epistemic, and normative domains as tangible concepts, or is it enough for these to act as abstract categories of analysis?
(2) To what extent does there need to be scholarly consensus on how we decide whether concepts fall into a particular domain and not into a different one?
(3) Should the importance of different concepts and metrics in a particular domain be considered? And if so, how?
(4) How much attention and focus on one domain at the expense of the other domains is acceptable?
(5) Is it of value to consider how we can move to unite each of the domains into a single category?
(6) How can lessons across domains be captured to develop their definitions?
(7) Which methods in each domain are least contingent on the application context?
(8) How can we decide which methods are most appropriate for operationalizing a particular concept?
(9) What other unique domains may exist that capture enough additional concepts to be worthy of inclusion as new domains?
(10) How can be empirically quantify the strength of relations between different concepts and methods?

5 CONCLUSION

This position paper has considered why most research and policy efforts aimed at understanding the implications of institutional AI tend to prioritize only a handful of ideas, and how this relates to the state of socio-technical discourse more broadly. Specifically, we have sought to highlight one fundamental theoretical issue, which we call the relational problem, that has arguably hindered scholarly efforts at two premier socio-technical conference venues, AIES and FAccT, to comprehensively study AI systems: fundamental ontological issues within the field have not yet been settled—including semantic ambiguity and, more significantly, a lack of clear relations between different topics, perspectives, concepts and methods, leading to differing standard terminologies across subcommunities. We contend that this failure has contributed to the prevalence of conceptual isolation in the fields that study them including ML, human factors, social science and policy, among others. In response, we have offered a way forward by proposing a simple policy and research design tool in the form of a conceptual framework to organize terms across fields—consisting of three horizontal domains for grouping relevant concepts and related methods: Operational, Epistemic, and Normative.

The main contribution of our research is providing a first step for those studying institutional AI to connect topics and consider whether all relevant topics and concepts have been accounted for. Future work will benefit from further considering the ontological ontological and epistemological underpinnings of the relational problem. While we have focused on understanding how the existence of ontological issues in socio-technical discourse ensures research remains fragmented, several factors may explain how this arises to begin with, relating to the relative newness of the field, the transdisciplinary nature of the work, the sociopolitical dynamics of academic research, the influence of industry, to name a few. A fruitful avenue of inquiry will be to consider each of these interact, what other plausible contributors are, and what the implications are for applying the framework we put forth.

In closing, we hope our contribution benefits the AIES and FAccT community by facilitating a constructive dialog around the challenges we face as a diverse, interdisciplinary field aiming to address sensitive, high-stakes socio-technical issues that will only grow in magnitude and significance in the years to come. In these hotly contested spaces with no clear answers, by analyzing these problems across three domains, we contend that we are able to more clearly see the many interacting parts at play, in order to create more functional, ethically sound institutional AI systems.

ABSTRACT

Biases in large-scale image datasets are known to influence the performance of computer vision models as a function of geographic context. To investigate the limitations of standard Internet data collection methods in low- and middle-income countries, we analyze human-centric image geo-diversity on a massive scale using geotagged Flickr images associated with each nation in Africa. We report the quantity and content of available data with comparisons to population-matched nations in Europe as well as the distribution of data according to fine-grained intra-national wealth estimates. Temporal analyses are performed at two-year intervals to expose emerging data trends. Furthermore, we present findings for an "othering" phenomenon as evidenced by a substantial number of images from Africa being taken by non-local photographers. The results of our study suggest that further work is required to capture image data representative of African people and their environments and, ultimately, to improve the applicability of computer vision models in a global context.

1 INTRODUCTION

Data collection and processing are crucial to the machine learning (ML) pipeline and are the source of many biases in AI systems, which have been shown to largely stem from a lack of diverse representation in training datasets [7]. Currently, most large-scale computer vision datasets are collected via webscraping and subsequent data cleaning. For example, the ImageNet database ([12]; 42607 citations per Google Scholar, accessed Sept. 14, 2022) is comprised of images sourced from search engines like Google and Flickr, while the COCO dataset ([20]; 26751 citations per Google Scholar, accessed Sept. 14, 2022) is comprised of images sourced entirely from Flickr. Thus, biases inherent to Flickr influence the performance of models for visual tasks as diverse as object classification, pose estimation, instance segmentation, image captioning, and beyond. Some of these dataset biases have been explored in detail: for ImageNet and the Flickr-sourced Open Images dataset [19] it has been shown that data from India, China, and African and South-East Asian countries is vastly underrepresented despite their large populations [14]; while for COCO, data has been shown to be heavily skewed towards lighter-skinned and male individuals [37]. In particular, such biases impact the applicability of models in a global context. For instance, DeVries et al. [14] manually sourced image data from 264 globally-distributed households and demonstrated how object recognition model performance drops when applied in lower-income nations. Motivated by the popularity of datasets sourced using Flickr data, we here analyze **1.5 million** geotagged images in the Flickr database to deeply explore its representation of African people and settings (see Figure 1).

In this paper, we aim to highlight the limitations of webscraping generic and human-centric[1] image data from Africa for ML training purposes. We analyze image data for every African nation with direct comparisons to population-matched higher-GDP European nations and show that there is far less data available from Africa. We report the distribution of African geotagged image data as a function of fine-grained, intra-national wealth estimates [8] and assess data with respect to license restrictions, population size, nominal GDP, Internet usage, and official languages. Additionally, we collect crowdsourced annotations to explore image content, and provide evidence for an "othering" phenomenon as the majority of African geotagged images we analyzed were taken by foreigners, while the opposite trend is shown for select European nations. Such results highlight the importance of considering geodiversity metrics beyond ancestry/ethnicity of individuals within images and, moreover, how the mechanisms by which images are obtained can quantitatively and qualitatively affect how the image corpus represents the world (*e.g.* imposing a "Western gaze"). Overall, we find that Flickr provides a very limited and skewed representation of African countries which likely contributes to many of the biases in models trained on popular, large-scale image datasets.

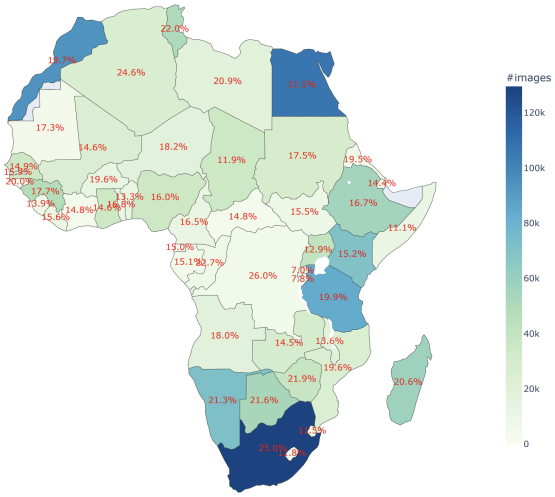
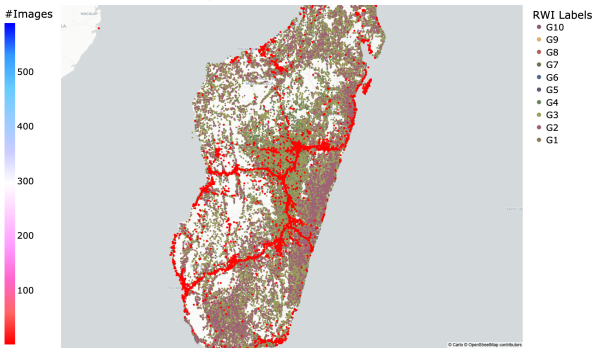
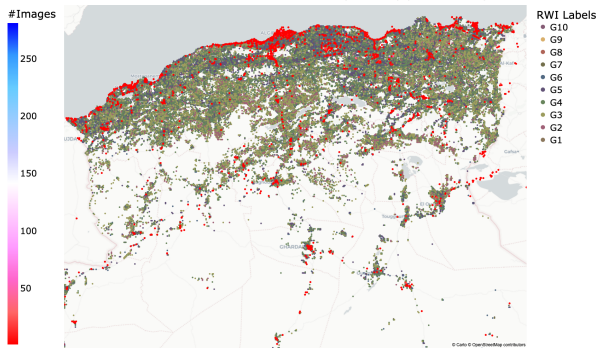
(a) Africa: Image data distribution colored by RWI.



(b) Africa: Total number of geotagged images.



(c) Madagascar: RWI group overlaid with image count per region.



(d) Algeria: RWI group overlaid with image count per region.

Figure 1: A collection of maps displaying relative wealth index (RWI) and geolocation of Flickr Africa images via country name query. Tolerance distances from geotag to nearest RWI-labeled point are: ((a, b) dist: $\leq 300km$; (c, d) $\leq 10km$). (b) Nations are colored according to total number of geotagged images and the percentages (rounded to one decimal place) indicate the percentage of geotagged images out of the total image count per nation. South Africa had the highest number of geotagged images and Sao Tome and Principe had the smallest number of geotagged images while Cape Verde had the highest percentage of geotagged images and Rwanda had the lowest percentage of geotagged images.

1.1 Related work

While prior works have explored diversity beyond Western nations [24, 28], studies of access to, and applicability of, AI systems in Africa remain limited [1, 2]. Scholars such as Abebe et al. [1] highlight the challenges of data sharing practices in Africa, such as those concerning trust, awareness, and infrastructure, and note that "The continent's plural and at times divergent norms, practices, and traditions furthermore complicate the African data access and sharing ecosystem." Computer vision researchers have produced diverse datasets in an effort to reduce model biases and assess fairness outcomes (*e.g.* [16]), with some centered specifically on geographic and contextual diversity [3, 5, 9, 10, 14, 36]. Such data collection involves trade-offs, however [35]; while manual data collection enables desired contextual diversity specifications to be met, it is expensive and frequently limits access to low-income regions (see *e.g.* [14]). Thus, researchers have explored more automated methods of scraping diverse data from web platforms and public media, producing datasets such as the Geo-Diverse Visual Commonsense Reasoning dataset (GD-VCR) [36], GeoImageNet [5] , Functional Map of the World (fMoW) [10], YFCC100M [26], and Open Images Extended [18], among others. Wang et al. [27] construct an ImageNet-style image data hierarchy across languages and cultures beyond English for visually grounded reasoning. While valuable, these initiatives have not deeply explored intra-national diversity, such as according to regional wealth estimates. Likewise, those datasets which utilize geolocation alone may result in a stereotypical portrayal of people in developing nations.

Geodiversity has been studied from various angles beyond dataset production. Scholars have proposed methods for measuring geodiversity in image datasets [25, 29] or performing geography-aware learning [4]. Zhao et al. [37] expose the propogation of racial and

cultural biases into model predictions, while Mandal et al. [21] study geographical bias in image search and retrieval. Denton et al. [13] highlight the importance of annotators' lived experiences on their annotation results.

Additionally, Crandall et al. [11] and Johnson et al. [15], among other researchers, have studied volunteered-geographic information (VGI) and its relation to localness in Flickr user-generated content. At metropolitan-area and individual landmark spatial scales, Crandall et al. [11] use textual and visual image data to develop a classification technique which automatically exposes the relation between location and content in six months of Flickr-scraped images. Johnson et al. [15] define four localness metrics: n-days, plurality, and location-field, to investigate the localness of user-generated content on Flickr, Twitter, and Swarm. In particular, their work assessed the Flickr-scraped YFCC100M dataset, containing images from thousands of users in the contiguous United States, whereas we focus on Africa and a few population-matched European countries. Notably, the authors found that with 31.1% recall accuracy, only 40.7% of Flickr images inspected with the "location field" localness metric (photographer self-reported location information) were local.

2 METHODOLOGY

2.1 Data Collection

2.1.1 Flickr Africa. For each nation in Africa, we utilized Flickr queries to construct a dataset of images and associated metadata. Using the FlickrAPI, we scraped images and associated metadata from Flickr between dates 2004-02-10 and 2022-02-10 (18 years) by querying by country name (*e.g.* "*Togo*") and the country name + people (*e.g.* "*Togo people*"), with the latter querying choice motivated by construction methods of related large image datasets (*e.g.* COCO, which utilizes the Flickr query "person"). We scraped Flickr data for 54 African countries: {*Algeria, Angola, Benin, Botswana, Burkina Faso, Burundi, Cameroon, Cape Verde, Central African Republic (CAF), Chad, Comoros, Ivory Coast, The Democratic Republic of the Congo (DRC), Djibouti, Egypt, Equatorial Guinea, Ethiopia, Eritrea, Gabon, Gambia, Ghana, Guinea, Guinea Bissau, Kenya, Lesotho, Liberia, Libya, Madagascar, Malawi, Mali, Mauritania, Mauritius, Morocco, Mozambique, Namibia, Niger, Nigeria, Republic of Congo, Rwanda, Sao Tome and Principe, Senegal, Seychelles, Sierra Leone, Somalia, South Africa, South Sudan, Sudan, Swaziland, Tanzania, Togo, Tunisia, Uganda, Zambia,* and *Zimbabwe*}. Utilizing Flickr metadata associated with each image, we generated 108 *csv* images data files (2 per country, associated with each query) with values for the following variables: {*"license", "title", "datetaken", "image_url", "country", "city", "tags", "latitude", "longitude", "rwi of nearest point", "distance to nearest rwi labelled point (km)", "latitude of nearest point",* and *"longitude of nearest point"*}. City and country information were determined by reverse geo-locating the longitude-latitude values provided in the image metadata using open-source reverse geocode ([23]; accuracy analyses in [17]). All data is available at https://doi.org/10.5281/zenodo.7133542. The RWI data is described below. Total image counts were recorded and images without valid geotags were excluded.

2.1.2 Population-matched European countries. The data collection process was repeated for four European nations. In the interest of comparing data availability and content to higher-GDP European nations, we chose the following countries as a function of similar population size ([30, 31, 33]): Switzerland and Sierra Leone (GDP: 841.97k vs. 4.27k); Cyprus and Djibouti (GDP: 27.73k vs. 3.84k); Finland and Central African Republic (CAF) (GDP: 297.62k vs. 2.65k); and Slovenia and Lesotho (GDP: 63.65k vs. 2.56k). For all 58 countries we collected data pertaining to percentage of internet users [32], nominal GDP [31], population size [30, 33] and official languages [34].

2.1.3 Relative Wealth Estimates. Fine-grained relative wealth estimates were associated with each geotagged image. To assess the image distribution according to local wealth estimates, we utilize the relative wealth index (RWI) data collected from Low and Middle-Income Countries (LMICs) by Facebook's Data for Good project [8]. RWI scores are normalized by nation, so the data should only be utilized for intra-national wealth analyses. The RWI dataset contains relative wealth distribution for 49 African countries, such that the following countries are excluded from our original list of nations: {*Somalia, Seychelles, Sao Tome and Principe, Sudan,* and *South Sudan*}. Therefore, when analyzing the relationship of RWI to geotagged images, these four countries are excluded. RWI data is provided in the form of 3-lettered iso-codes and the following variables are provided: *"quadkey", "latitude", "longitude", "rwi", and "error"*; Nominatim API [22] was utilized to assign and add variables *"country", "city"* to the data files. Using k-nearest neighbour, we computed the nearest RWI-labeled geographic location of each image. Figure1a shows the distribution of RWI-labeled geotagged images with a 300km maximum tolerance limit between the image geotag and the nearest RWI-labeled location.

2.1.4 Manual Content Annotation. Crowdsourced annotations were collected for six additional image features.

We used Amazon Mechanical Turk (AMT) to collect annotations describing image contents. Each Human Intelligence Task (HIT) involved 21 images, with six binary questions per image as shown in Figure 2. The binary questions required the annotator label the image according to: indoor vs. outdoor setting, public vs. private setting, nature vs. manmade setting, the presence of people, real vs. synthetic image type, and offensive vs. inoffensive content. Below were our definitions of the terms or labels;

- An indoor image is typically within the confines of a building or transportation means, e.g., inside a house, restaurant, or car.
- A private image is taken from a household or residential setting, e.g., kitchen or bathroom.
- A nature image predominantly contains nature or contents within a natural environment, e.g., images of a sky, ocean, water, people and animals outside of towns and cities.
- A real image is not a painting, an image of another image, or an otherwise synthetically generated image.
- An offensive image contains abuse/violence, nudity/suggestive content, hate symbols/writings, and or rude gestures.

We compensated workers at a rate of $15 USD/hour. We sourced each annotation from three different annotators and chose the

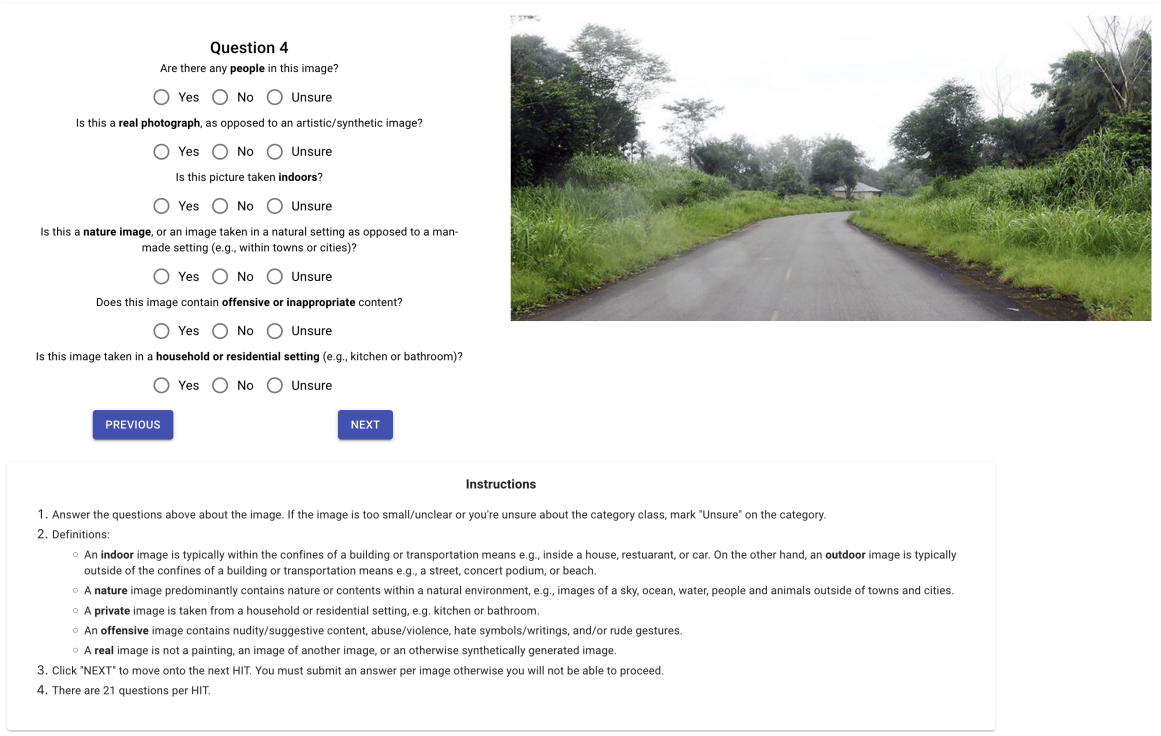


Figure 2: Sample AMT task page which annotators utilized to label binary attributes pertaining to image content. Each HIT involved interaction with an introductory instructional page followed by 21 task pages similar to the one shown above.

majority consensus value, excluding those images marked "Unsure". To ensure high annotation quality, we recruited workers with at least 95% acceptance rating and completion of 1000+ prior tasks. We randomly inserted a gold standard image within each set of 20 standard images to assess annotator performance; if the worker failed on this test image, we discarded the annotations but still paid the worker for their contribution.

2.2 Limitations of Our Approach

We acknowledge four notable limitations of our method. First, we recognize that geolocation data (longitude, latitude) is inherently unreliable. Values may be modified or removed by the Flickr user or otherwise not reflect the location of capture, while reverse geolocation methods are computationally expensive and often fail, particularly with geographic locations close to region borders. This motivates our use of both geotags and country name tags for cross-validation of location, though this restricts us to fewer data samples overall. Secondly, to determine location of photographers to assess localness, we relied on photographers volunteered information of their location from their profile metadata. This doesn't take into account confounding factors like an immigrant visiting their home nation. Additionally, some forms of geodiversity are difficult or impossible to determine from visual inspection alone, such as an individual's gender, ethnicity, or religion. Finally, we were limited to obtaining data using only two queries, namely, by country name or country name + "people". We anticipate future work exploring a wider variety of query terms, both in English and local languages; here, no correlation was determined between dominant national languages and geotagged image availability.

2.3 Ethical Considerations

We note that although the Flickr images analyzed here are all publicly viewable, we show that most have the Flickr default license of "All Rights Reserved". Thus, we have opted to provide image URLs in lieu of images for direct download to avoid duplication of protected content, particularly in the event that a Flickr user chooses to remove or modify the permissions of an image. We acknowledge the weaknesses of this method in terms of consent, as public Flickr images are typically not taken by those in the images (as pointed out by Birhane and Prabhu [6]); likewise, Flickr users may wish to avoid the utilization of their images for research purposes. Given that our objective is to critique large-scale image dataset curation strategies which do not respect image licenses (*e.g.* the methodology for generating the COCO dataset), we deemed it justifiable to perform basic analyses on protected images and to build awareness regarding widespread license violations in standard AI training pipelines.

3 RESULTS AND DISCUSSION

3.1 Data Availability and Geographic Distribution

There were very few geotagged images from Africa, as shown in Figures 3a and 3b. In terms of total geotagged image counts with

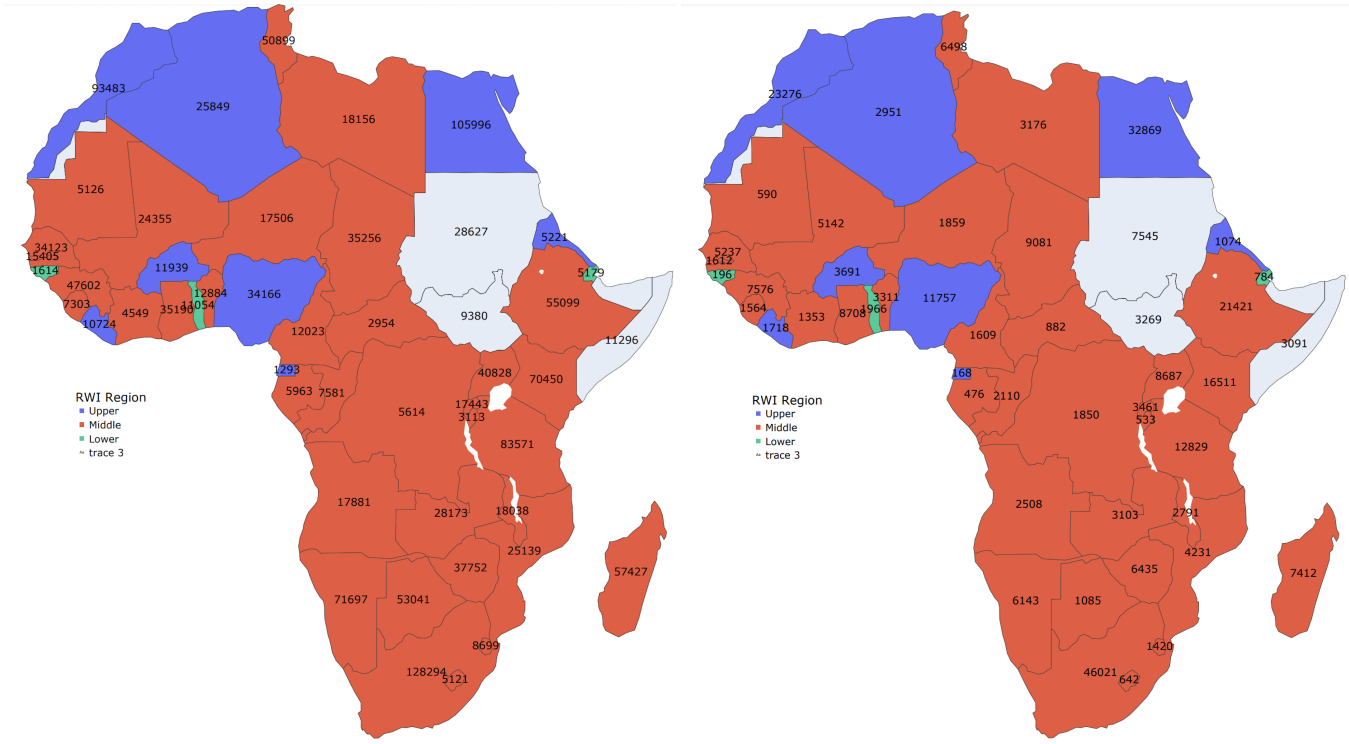

Figure 3: Geotagged image counts by nation and respective RWI regions for (a) "query-by-country name" and (b) "query-by-country name+people". Nations are colored according to dominant RWI group (upper, middle, or lower wealth group) from which most images were sourced. Images mainly came from middle RWI groups ($G4$, $G5$, $G6$ and $G7$). The numbers denote the number of geotagged images. Countries that didn't have RWI data are in grey.

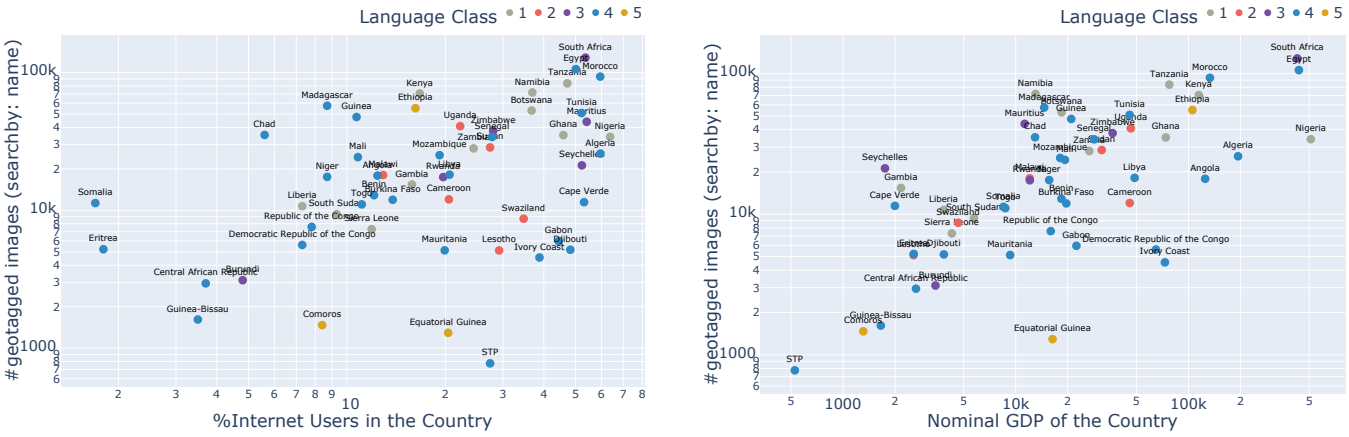

Figure 4: Plots showing the number of geotagged images as a function of (a) the percentage of Internet users in the country, and (b) the nominal GDP of the country. Data points are colored according to national dominant language class (see Section 3.1). In general, the number of geotagged images increased with increase internet usage and GDP, with no observable trend in language class; "STP" denotes the country Sao Tome and Principe.

Table 1: Number of geotagged and total images, and percentage (rounded to 2 decimal places) of geotagged images for the five countries with the highest percentage of geotagged images according to query type.

	query-by-name		
Country	#geotagged	#all images	%geotagged
Cape Verde	11,465	43,283	26.49
DRC	5,614	21,560	26.04
South Africa	128,294	513,082	25.00
Algeria	25,849	105,254	24.56
Republic of Congo	7,581	33,438	22.67

	query-by-name+people		
Country	#geotagged	#all images	%geotagged
Burkina Faso	3,691	12,990	28.41
DRC	1,850	7,028	26.32
Republic of Congo	2,110	8,249	25.58
Cape Verde	1,333	5,390	24.73
Botswana	1,085	4,664	23.26

Table 2: Number of geotagged and total images, and percentage (rounded to 2 decimal places) of geotagged images for the five countries with the lowest percentage of geotagged images according to query type.

	query-by-name		
Country	#geotagged	#all images	%geotagged
Lesotho	5,121	43,282	11.83
Swaziland	8,699	75,631	11.50
Somalia	11,296	101,989	11.08
Burundi	3,113	39,888	7.80
Rwanda	17,443	250,469	6.96

	query-by-name+people		
Country	#geotagged	#all images	%geotagged
Zambia	3,103	33,063	9.39
Equatorial Guinea	168	2,081	8.07
Gabon	476	7,286	6.53
Burundi	533	9,862	5.40
Rwanda	3,461	76,521	4.52

query-by-name and query-by-name+people from African nations, South Africa (128, 294 & 46, 021) and Egypt (105, 996 & 32, 869) had the highest counts, and Equatorial Guinea (1, 293 & 168) and Sao Tome and Principe (776 & 116) had the lowest counts. Cape Verde had the highest percentage of geotagged images (26.49%) from query-by-name and Burkina Faso (28.41%) had the highest from query-by-name+people. By contrast, Rwanda had the lowest percentage of geotagged images (6.96%, 4.52%) from both query-by-name and query-by-name+people. African nations with the highest and lowest percentages of geotagged images are summarized in Table 1 and Table 2.

Thus, the low number of African geotagged images indicates the ineffectiveness of Flickr scraping as a data collection methodology in this region and, therefore, a need to explore alternative geodiverse data collection methods, *e.g.* utilizing manual data collection.

The population-matched European countries had higher numbers and percentages of geotagged images than the corresponding African countries, as is further emphasized in Table 3. For example, with query-by-name, despite relatively similar population sizes, the percentage change of the number of geotagged images from Sierra Leone to Switzerland is 1673.48%, that is, 18× as many total geotagged images as Sierra Leone as shown in Table 3.

Thus, African countries had far fewer images (both geotagged and non-geotagged) than the corresponding European countries of similar population size. We recommend that computer vision experts be cognizant of this discrepancy in Flickr scraped datasets and to consider the corresponding potential for bias when training computer vision models.

We analyzed the statistical effect of factors that might potentially affect taking, uploading and tagging images on Flickr; population-size, internet usage, official language, and countries' GDP.

In general, the number of geotagged images increased with population size (correlation: 0.412 & 0.538, query-by-name and query-by-name+people respectively), internet usage (0.474 & 0.385), and GDP (0.599 & 0.748); the latter two are shown in Figure 4. An investigation of the effect of these variables on the number of geotagged images was found to be statistically significant: (population size: $p\text{-value} = 0.0019$ & $p\text{-value} = 0.000119$, query-by-name and query-by-name+people respectively), (internet usage: $p\text{-value} = 0.00029$ & $p\text{-value} = 0.003999$), and (GDP: $p\text{-value} = 0.160$ & $p\text{-value} = 0.059$). By contrast, official language was not found to have a meaningful correlation to the number of geotagged images ($p\text{-value} = 0.2021$ & $p\text{-value} = 0.846$). Because image dataset queries are typically done in English, to assess the impact of dominant national languages relative to English on geotagged data availability, we coded each of the countries' official languages ([34]) according to five categories for analysis: 1- (English is the only official language), 2- (English is among the two official languages), 3- (English among atleast three official languages), 4- (English not among atmost three official languages), and 5- (English not among atleast three official languages). No correlation was determined for any language category.

Thus, when data collection is required in regions with lower population size, internet usage, and/or GDP, we recommend the use of local, manual data collection techniques in lieu of webscraping whenever feasible. Additionally, RWI information may be useful when assessing diverse areas for data collection.

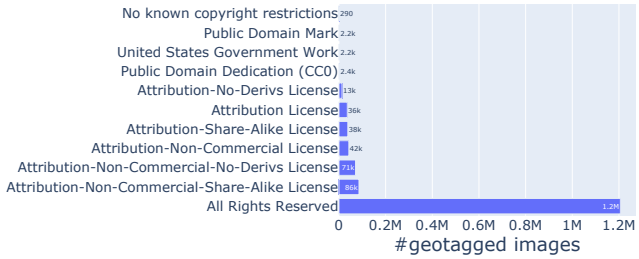
3.2 Tags and Licenses: Query-Based and Applicability Limitations

The use of both country name tags and geotags (latitude/longitude) was found to be necessary to ensure data was accurately sourced from the country of interest. The naïve country name querying method is particularly limiting when applied to certain nations, such as *Chad*, *Guinea*, and *Republic of Congo*. Images from query by *Chad* were predominantly geotagged from *United States* (54.63%), *United Kingdom* (16.58%), and *Canada* (9.30%), with only 5.14% of the images coming from *Chad* according to geotag location results. In total images from query by *Chad* were geotagged from 129 countries. Likewise, images from query by *Guinea* predominantly came from *Papua New Guinea* (29.97%) and *United States* (10.84%), with geotags from 190 countries. Finally, image geotags from query by *Republic of Congo* mainly reflected the following countries; *Congo, The Democratic Republic of the* (42.14%), *United Kingdom* (11.34%),

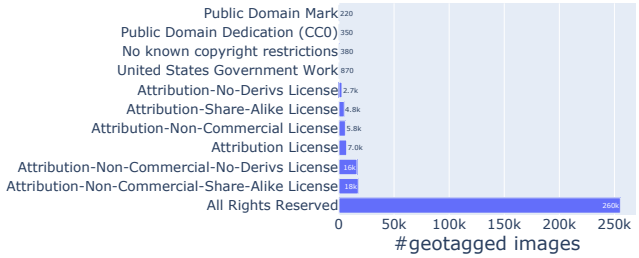
Table 3: Number of geotagged and total images, and percentage (rounded to 2 decimal places) of geotagged images for population-matched African and European nations (query-by-name) side-by side, e.g Switzerland and Sierra Leone on line 1.

European Countries				
Country	population	#geotagged	#all images	%geotagged
Switzerland	8.75M	129,518	535,843	24.17
Finland	5.55M	119,901	522,637	22.94
Slovenia	2.11M	86,630	371,584	23.31
Cyprus	918.10k	77,826	371,504	20.95

African Countries				
Country	population	#geotagged	#all images	%geotagged
Sierra Leone	8.30M	7,303	52,530	13.90
CAF	5.60M	2,954	19,901	14.84
Lesotho	2.10M	5,121	43,282	11.83
Djibouti	976.11k	5,179	36,029	14.37



(a) License information for query-by-name



(b) License information for query-by-name+people

Figure 5: Bar charts showing the total count of each Flickr license type for the entire image datasets as a function of (a) "query-by-name" and (b) "query-by-name+people". The most restrictive license type is by far the most common, "All Rights Reserved", likely because it is the Flickr default option.

.

and *United States* (7.55%).
Thus, we conclude that reliance upon country name queries is insufficient for constructing a geodiverse dataset in the absence of more robust geolocation data. We recommend that data collectors consider using RWI data to source more geographically diverse visual data.

We furthermore report the most frequent tags as the name of the place where the image was taken, for example "Africa" and the country name, in addition to image contents. The least frequent tags were usually those in foreign languages and whose meanings were hard to decipher because of multiple concatenated words.
Thus, in an African context, the utilization of image tags alone to generate datasets with specific image content may be less reliable due to the variable nature of selected tags; we believe this warrants future exploration.

Additionally, the vast majority of images with query-by-name and query-by-name+people respectively are licensed as "All Rights Reserved" (80.46%, 81.99%), indicating the Flickr default setting when images are uploaded to the platform (see Figure 5).
Thus, those constructing datasets using Flickr Africa data must be aware that most images are unavailable for model training and evaluation without copyright violations, thereby further limiting ethical access to geographically diverse data.

3.3 Geodiversity by RWI

To assess the impact of wealth on the availability of geotagged image data, we examine image counts by RWI values binned into 10 percentile groups, $G1$-$G10$. For most nations, the majority of image data comes from the middle RWI regions ($G4$, $G5$, $G6$ and $G7$) and the least from low RWI regions ($G1$, $G2$ and $G3$). However, this is not always the case, *e.g.* Madagascar and Algeria from which data is sourced from low-income areas (along main roads close to national parks) or high-income areas (in major cities), respectively.
Thus, RWI has potential as a mechanism for constructing geo-diverse datasets in future work.

3.4 Image Content

By utilizing crowdsourced annotations, we examine 16,000 images' content data across 2,000 images from each population-matched African and European nation pair (identical to the image subset in Section 3.5). Sample images by attribute and results for matched African/European nation pairs are shown in Figure 6a for each binary attribute with the exception of "offensive" vs. "inoffensive" content and with manually obscured human faces. We collected information about these six attributes to gauge the applicability of African-sourced image datasets for various computer vision tasks: *e.g.* the presence of people for human-centric tasks such as pose estimation, body part segmentation or face detection; the prevalence of indoor/private settings for specific object recognition tasks; or real/appropriate image content for training dataset viability. Likewise, we originally hypothesized that African images were more likely to be taken by foreigners (which was found to be supported by the data; see Section 3.5); this motivated the count of nature-centric images.

The AMT results revealed that query-by-name images from both African and European countries were predominantly "real" (93.47% and 91.94%), "inoffensive" (88.51% and 89.41%), "outdoor" (77.89% and 79.28%), "public" (90.27% and 90.19%), and "nature" (63.68% and 62.96%) images. There were negligible variations across nations for the percentage of "real', "outdoor", "public", and "nature" images. However, as shown in Figure 6b, nations varied in percentage of people in images, and in general most nations' images did not contain people. For example, 69% of Sierra Leone's 2000 sampled geotagged images contained people, while only 33% of Djibouti's

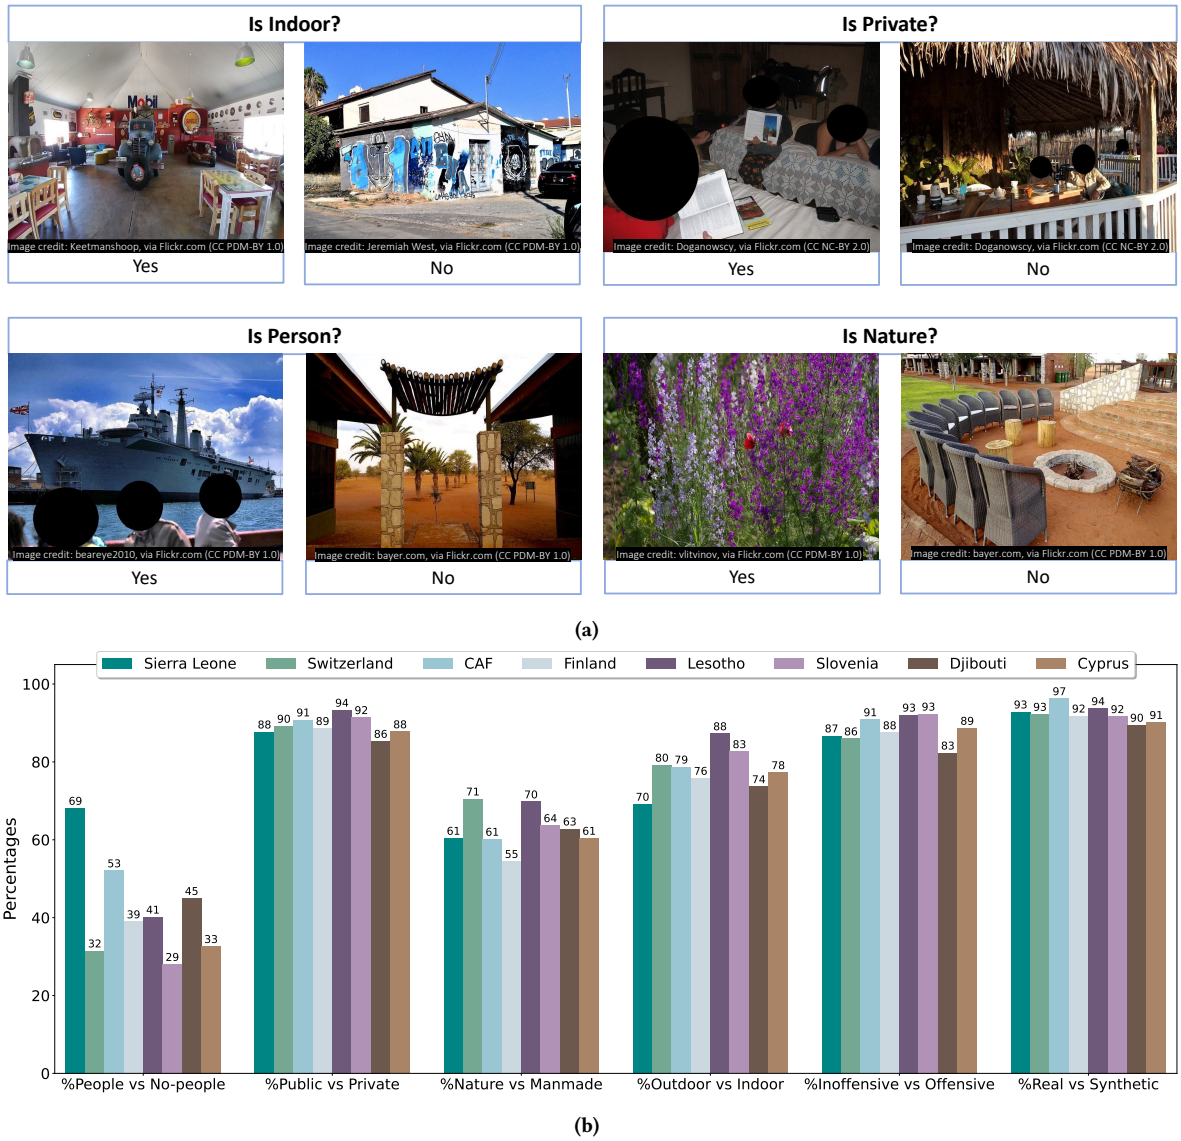


Figure 6: (a) Sample images sourced from African nations, and (b) image content percentages for select African and European nations, according to AMT workers reporting across six binary attributes. Workers were asked to report if the images contained people, public settings, nature content, outdoor settings, and inoffensive content, and if they appeared to be real images. Image content was found to be similar percentage-wise across different nations, although far fewer images overall were captured in the population-matched African nations in comparison to corresponding European nations. Images displayed here were selected among those with permissible licenses with face obfuscation for display purposes only.

2000 sampled geotagged images contained people.

Thus, although no major differences between African and European image content were observed according to the six attributes considered, we believe these findings are important in the context of data regarding data quantity. Given that image content was fairly similar across most attributes annotated, and there exist far fewer geotagged images from Africa (see Table 3), we anticipate insufficient African data availability for certain computer vision tasks. For example, the lower prevalence of images captured in "private" and "indoor" settings indicates *e.g.* household object image data inaccessibility, which thereby impacts downstream object recognition system models consistent with the findings of DeVries et al. [14].

3.5 Local vs. Non-Local Representation

Beyond analyzing the image content of the 2, 000 randomly-sampled images from each of the 8 nations, we examined the local vs. non-local status of those Flickr users who captured and uploaded the

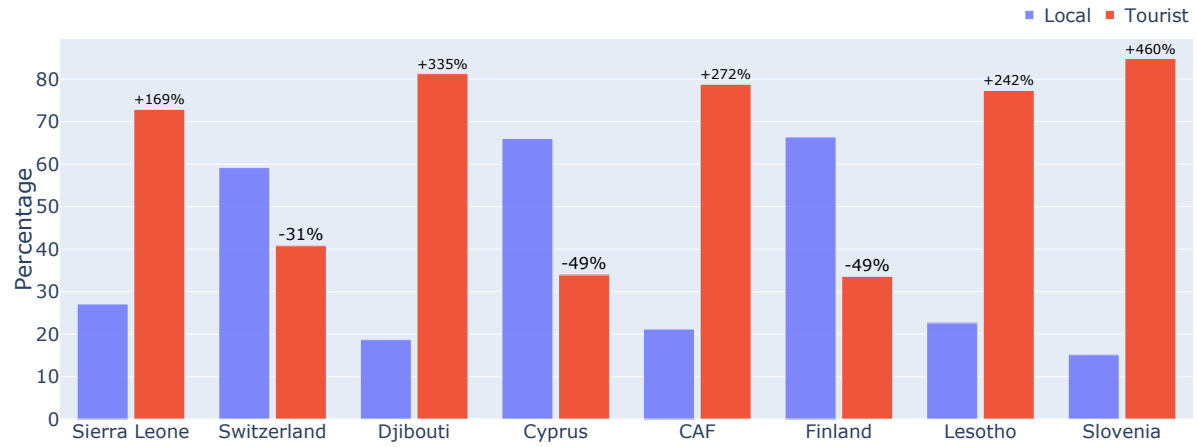

Figure 7: Bar chart showing the percentage out of 2,000 images from each population-matched African/European nation pair via query-by-name as taken by locals (blue) and tourists (red), according to Flickr users' reported locations. The percent change from local to tourist percentage value is additionally indicated for each nation. Images from African countries were predominantly taken by foreigners whereas those from higher nominal GDP European countries were predominantly taken by locals. "CAF" indicates the country Central African Republic.

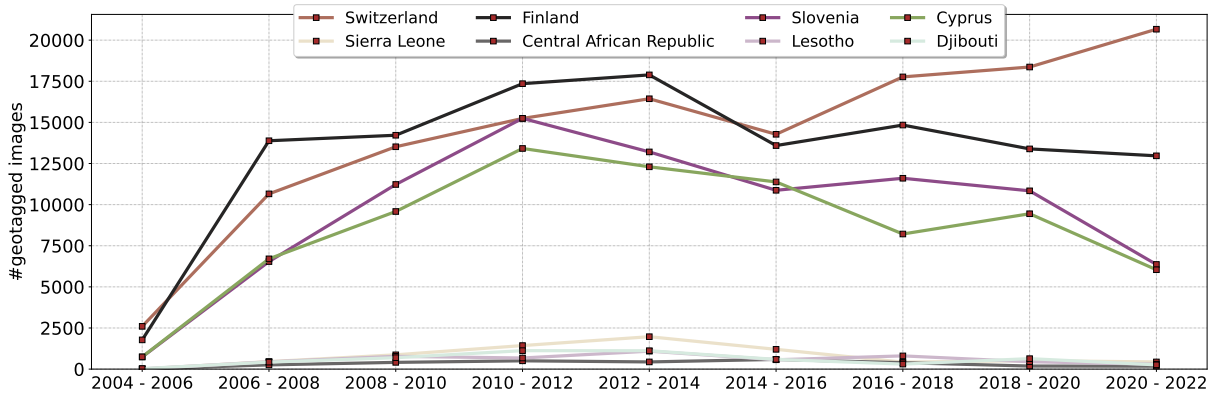

Figure 8: A comparison of the number of geotagged images from select African and European nations in approximately 2-year time ranges, as queried by country name. In general, a high number of images were uploaded in the dates in range 2012-2014, with the exception of Switzerland which had high upload volume in 2020-2022.

geotagged images. An assessment of the residence or origin of the Flickr users revealed that for the African geotagged nations, images were far more likely to be taken by foreigners than locals whereas the opposite trend was observed for higher-GDP European nations, according to comparisons between geotags and Flickr users' reported locations. For Sierra Leone, +169% of images were captured by foreigners compared to locals, while for Switzerland it was -31%. The same trend applies to Djibouti and Cyprus (+335% and -49%) and CAF and Finland (+272% and -49%); results are reported in Figure 7. A random inspection of the Flickr map[2] also further shows that images geotagged in Africa are less likely to be taken by the locals.

Thus, the prevalence of non-local representation may explain the image content results described in the previous section, as Flickr users from similar backgrounds may contribute image data from both Africa and Europe. AI practitioners should be wary of stereotyped representations of African life within such datasets given that these images are typically taken by foreigners in public, outdoor locations. Additionally, current methodologies for image dataset collection are unlikely to capture visual data pertaining to the private, daily life of African people nor visual information the locals of each country consider to be important, resulting in biases propagated by AI systems trained on such data.

3.6 Temporal Analysis

We performed a temporal analysis to investigate and contextualize the data in time according to data quantity, relative wealth index

[2]When we inspected the map (https://www.flickr.com/map/) on 06-16-2023, 2/2 of the geotagged images were taken by France and Spanish photographers

(RWI) at location of capture, license type and Flickr user origin. We studied the geotagged images distribution in the in approximately 2-year spans time ranges.

Number of geotagged images. In general, there were relatively fewer geotagged images in the years 2004-2006 and 2020-2022, as shown in Figure 8 for population-matched African/European nations. The image distribution could be the result of factors including less internet penetration and popularity of Flickr from 2004-2006 reducing image uploads, and the COVID-19 pandemic limiting outdoor activities from 2020-2022. This trend held in all analyzed countries with the exception of Switzerland; there, the highest number of images was uploaded in the date range 2020-2022, as shown in Figure 8. The highest number of uploaded and subsequently downloaded geotagged images for most nations came from 2010-2014, potentially explained by the growth of internet usage and exposure to Flickr in different countries within this time span.

RWI regions of image uploads. We explored trends in dominant RWI groups per nation over time, in order to determine if there were observable shifts towards images sourced from higher or lower RWI regions. Over the time range of 2004 to 2022, query-by-name images from Botswana, Libya, Namibia, South Africa, Tunisia, Swaziland, Uganda, Zambia, and Zimbabwe all came from the middle RWI regions. Images from Morocco consistently came from the upper RWI regions. On the other hand, query-by-name+people images from Rwanda and Swaziland all came from the middle RWI regions and those from Morocco all came from upper RWI regions. Lower and middle RWI regions countries had their data distributions varying between lower and middle RWI regions over the years. Countries whose images were from predominantly upper RWI regions had their data distributions varying between middle and upper RWI regions over the years.

Licenses of the uploaded images. We analyzed the quantity of images with various Flickr license options. Images were found to have predominantly the "All Rights Reserved" license type across all time ranges analyzed; as noted in Section 3.2, this substantially limits data usage. There were almost no images licensed under the "Public Domain Dedication (CC0) CC" and "Public Domain Mark CC" among those uploaded to Flickr from 2004 to 2022.

Local vs. non-local representation. We performed a temporal analysis of the geotagged images to investigate the local vs. non-local status of Flickr users. For the 2,000 randomly sampled images from the 8 countries analyzed for image content, we observed differences in sampling dates: that is, Cyprus, Slovenia, and Finland images were mainly sampled from 2004 to 2008; Switzerland images were mainly sampled from 2004 to 2006; and the African nation images were were mainly sampled from 2004 to 2012. Following these results, we repeated the temporal analysis across all images sourced from each of the 8 nations. In general, more images across all nations were taken by non-locals compared to the smaller 2,000-image datasets. However, the prior trends held in the sense that when African countries were considered, far more geotagged images were taken by non-locals than in comparable European nations, e.g., +329% for Sierra Leone versus +39% for Switzerland. Section 3.5 describes implications of non-local representation in image data from Africa; namely, the risk of an "othering" phenomenon and its impact on downstream bias in AI systems.

4 CONCLUSION AND FUTURE WORK

Geographical context shapes data, and data shapes the performance of models trained using such data. The key findings from our Flickr Africa data analysis (1) expose the limitations of current large-scale image data collection methodologies, and (2) expose unique data challenges to Africa, including the lack of data crucial to specific domains (*e.g.* a researcher cannot source sufficient, representative household object data if very few images are taken within indoor/private scenes). Notably, we reported on the extreme lack of data availability when compared to wealthy European nations; for instance when querying by country name, Switzerland had 18x the geotagged image data as Sierra Leone, an African nation of similar population size (8.75M vs. 8.30M, respectively), while Sao Tome and Principle only had (776, 116) geotagged images in total (depending on query). Moreover, data may be even less accessible according to use case, given that most of the Flickr Africa data has a restrictive use license, and certain image content attributes were found to appear less frequently (*e.g.* private and indoor settings). Nationally, higher quantities of geotagged image data was found to positively correlate with population size, GDP, and Internet usage, but no significant correlation was discovered based on dominant national languages. Additionally, we interrogate where African image data comes from: generally from middle-wealth regions as measured intra-nationally by RWI, though this differs by nation; and with images mainly taken by foreigners, though the opposite trend is identified in wealthier European nations. We discussed how AI systems may propagate biases in accordance with the stereotyped representation of African life by outsiders. Temporal analyses were performed and demonstrated that certain trends, such as dominant RWI region, prevalence of restrictive license type, and non-local representation of African nations in geotagged images held over time.

Looking forward, we encourage new scholarship centering novel methods for sourcing geodiverse datasets and measuring new forms of geodiversity specific to Africa, such as analyses of tribal diversity as opposed to the more commonly studied diversity by race/ethnicity. We openly provide our large-scale dataset to enable future researchers to utilize and augment Flickr Africa for model evaluations across a wide domain of computer vision tasks; likewise, more rigorous bias identification methods (*e.g.* [27]) may uncover still more limitations. Finally, we would be interested to explore the extent to which privacy and consent are respected in Africa.

ACKNOWLEDGMENTS

We wish to thank Jerone Andrews and Dora Zhao in particular for their expertise and assistance with our work pertaining to crowdsourcing. We also express gratitude to the whole SONY AI Ethics team, especially William Thong for great discussions and informative feedback on this research. Lastly, we would like to thank the anonymous reviewers for the insightful feedback that helped improve our paper.

ABSTRACT

Algorithmic audits of industry face recognition models have recently incentivized companies to diversify their data collection methods, which in turn has reduced error disparities along demographic lines, such as gender or race. We argue that it is important to understand exactly how various forms of targeted data collection mitigate performance disparities in these updated face recognition models. We propose an empirical framework to assess the impact of additional dataset collection targeted towards various racial groups. We apply our framework to three racially-annotated benchmark datasets using three standard face recognition models. Our findings empirically validate the notion that the introduction of data from the demographic group with the initially-lowest performance improves performance on that group significantly more than adding from other groups. We also observe that in all settings, the introduction of data from a previously omitted group does not harm the performance of other groups. Furthermore, investigation of feature embeddings reveals that performance increases are associated with a larger separation among images of different identities. Despite the commonalities we observe across datasets, we also find key differences: for example, in one dataset, training on one racial group generalizes well across all groups. These differences speak to the criticality of re-applying empirical evaluation methods, such as the methods in this work, when introducing new datasets or models.

1 INTRODUCTION

In the last decade, extensive research studies have demonstrated the prevalence of demographic biases in machine learning systems, due to a lack of representation in training datasets [29]. Most notably, in the domain of face analysis, standard face datasets include very few images of individuals with darker skin types, and researchers have determined that commercial gender classification models have much higher error rates for women with darker skin types [8]. However, facial recognition continues to be used widely: from identity verification in mobile devices to public surveillance in certain countries, many people interact with these systems in their day-to-day lives [22]. While some argue for the complete removal of facial recognition techologies [7], the use of these technologies may not disappear. As such, opponents of face recognition along with the developers of these systems may both benefit from a careful analysis of how the demographic makeup of training datasets may impact a model's performance on various demographic groups.

In order to remedy past data representation bias, researchers have developed several new benchmark face recognition datasets that are more balanced along demographic attributes such as gender or race [38, 44]. While these balanced datasets have improved model performance, accuracy disparities still persist [45]. For example, the optimal allocation of training data by demographic group is not always the equally-balanced allocation: Gwilliam et al. [19] find that a balanced training set (with equal number of samples per racial group) obtains a higher accuracy variance across groups but the same overall accuracy compared to another training data allocation.

Additionally, curating new datasets requires time and resources, and can intrude upon the subpopulation being studied [33]. It is also incredibly time-consuming to train models on all possible allocations of demographic groups in order to find some "optimal" allocation. Rather than searching for the best subgroup allocation for a training set of a fixed size, companies may prefer a greedy solution — a solution in which new data is added in an add-only manner. Hence, we focus on the following goal: to examine *additional data collection* and its impacts on the performance of various racial groups.

Consider the following scenario: an entity (e.g., a company or a group of researchers) trains a face recognition model using some initial training dataset which lacks data from some particular racial group. Upon evaluation on held-out test data or due to an external bias audit, the company realizes their performance lags on that group, and now wishes to collect more data from the omitted group. They have the budget to collect only a fixed number of samples and have limited resources to train additional models (and, perhaps, can only train one other model). This process closely follows several

corporations' past responses detailed in Raji and Buolamwini [35] and allows us to pose these research questions:

(1) How does additional data from the underrepresented group change the test performance for that particular group, as well as the test performance for other groups?
(2) How does data collection targeted towards the group with the initially-lowest performance impact that group's test performance and overall group differences, in comparison to introducing data from other groups?
(3) Are our results consistent across racial groups, datasets, and models?

To answer these questions, we develop an empirical framework to evaluate the performance impact of data augmentation by demographic subgroup. For our framework and analyses, we focus on *one-to-one facial recognition*: given two images of faces, a one-to-one facial recognition system is designed to determine whether or not those two images are of the same person. We implement this framework for three racially-annotated datasets (BFW [38], BUPT [43, 44], and VMER [16]) and three state-of-the-art face recognition models (SE ResNet [9], CenterLoss [46], and SphereFace [27]). We summarize our main empirical findings below:

(1) The introduction of samples from any racial group X improves the performance for every group that we tested. (Different datasets use different terms. Using the terms in the source datasets, e.g., for BUPT [43, 44], we considered images labeled as *African, Asian, Caucasian, or Indian.*)
(2) The addition of data from the lowest-performing group improves that group's performance the most and closes performance gaps across racial groups.
(3) Increasing data from the highest-performing group X widens performance disparities, regardless of whether the initial training dataset contained images from group X, a specific counter to the notion that more data or more representation reduces discrimination.
(4) The above findings are *consistent* across all datasets and models we examined, while some findings are *different* across different datasets.

That some findings are *not* generalizable from the analysis of only a single dataset — speaks to the criticality of assessing various datasets. While the academic benchmark datasets we examine do not reach the commercial scale, such as Clearview AI's training data of 30 billion images [26], we find that our framework is still useful to understand how various datasets behave and how pre-conceived assumptions of additional representation do not always hold.

Thus, based on our findings, we encourage future work that introduces new datasets to re-apply our methodology (and others) as benchmarks to evaluate those datasets with known face recognition models. To facilitate this process, we publish our source code online at https://github.com/hongrachel/representation-disparities.

2 BACKGROUND AND RELATED WORK

In computer vision, researchers have extensively examined data representation biases and how models trained on datasets unrepresentative of the general population perform poorly on underrepresented groups.

For example, Pahl et al. [32] annotate several facial expression datasets and observe that these datasets skew heavily towards younger Euro-American subjects. In addition, Wilson et al. [47] find that a standard pedestrian detection dataset contains more data from individuals with lighter skin tones, and resulting models obtain higher accuracy for detecting individuals with lighter skin tones. Albiero et al. [2] investigate the source of gender bias in standard face recognition systems and determine that the test accuracy gap is attributed to models mapping images of women closer together.

Shortly after the publication of Buolamwini and Gebru [8], which demonstrated how several commercial face recognition systems discriminate by skin tone, these corporations updated their face recognition APIs to mitigate performance disparities. In their released statements, they explicitly cited new dataset collection efforts in order to ensure diverse representation in their training sets [35]. These newly updated models significantly decreased (previously high) error rates for individuals with darker skin and attributed their improvement to the targeted collection of additonal data along the lines of skin tone, gender, and age [37]. Diverse data collection is a promising method to address bias [23], but there has been little work investigating cases when the new data is composed of some explicitly-chosen demographic group that was previously underrepresented or omitted in the initial training set.

As a result, the lack of diverse data has spurred the creation of balanced training datasets, which have shown marked improvements in classification accuracy rates for previously underrepresented groups, even when trained with the same model architecture. Specifically, much recent work has focused on the collection of diverse face image datasets, along dimensions such as race, gender, age, lighting, pose, and expression, in order to allow models to generalize well on real-world variations [9, 24, 28]. These datasets have also been used to evaluate proposed face recognition models that reduce bias, which incorporate novel loss functions or model architectures. For instance, Serna et al. [41] show that a sensitive triplet loss function improves both accuracy and fairness across racial groups.

Recently, several studies examine how demographic subgroup distribution in training plays a role in accuracy disparities. In the case of gender bias in face recognition, Albiero et al. [3] observe that training datasets equally-balanced by gender lowers the prediction accuracy gap between groups, but the equally-balanced allocation does not minimize the accuracy gap. Similarly, Gwilliam et al. [19] vary the racial group makeup of the training set and also observe that the equally-balanced allocation is not the most optimal or fair one. Our work builds off their research and extends this investigation by analyzing the impact of *adding data* from different racial group distributions, rather than holding the training size fixed.

There are also several recent works in fairness literature that formally explore data collection processes. Most notably, Rolf et al. [39] form a theoretical framework to model subgroup allocations in training for a fixed training set size. They find that dataset composition impacts performance more than upweighting samples from minority groups. Chen et al. [10] provide a procedure to estimate the value of collecting additional samples and empirically validate the notion that additional data collection can mitigate discrimination without an accuracy tradeoff. Their work focuses on introducing data drawn from the same sampling distribution rather than data

collection targeted by demographic group. Abernethy et al. [1] propose several adaptive sampling algorithms for achieving min-max fairness, which minimizes the loss of the group that is worst off, to update the model over a series of iterations. Finally, Gong et al. [15] survey several definitions of input diversity in training data, through various sampling processes that upweight diverse batches in training. Our focus complements these works by assessing the empirical impact of targeted data collection on performance inequities.

3 METHODOLOGY

3.1 Problem setup

We now describe our task setting; we focus on *face verification*, or 1-to-1 face-matching, due to its ability to handle identities outside of the training distribution. We follow the standard face recognition training process in deep learning literature [42]: given a dataset $\mathcal{D}$ with face images $\{x\}$ and identity labels $\{y\}$, we train a model that takes an image as input and outputs a vector corresponding to the image's predicted identity. This training minimizes the empirical risk with respect to a particular loss function. The model is then used to perform inference (or prediction) by removing the final output layer. The result is a model that takes an image as input and produces a feature embedding with some fixed size established during training. This output feature embedding can be thought of as a lower-dimensional representation of an individual face image.

We evaluate the performance of a given model on the task of face verification: given two images (x, x'), $x \neq x'$, do the two images belong to the same identity or not? This evaluation is performed on *pairs* of images from a held-out test set, where the images and identities beloging to the test set are disjoint from those in the training set.

To convert the model from one which produces embeddings to one which predicts whether pairs of images are of the same identity, we do the following. For a particularly fixed threshold t, the face verification system predicts that the test pair are of the same individual if the cosine similarity score of the two images' feature embeddings is at least t. As such, ground truth labels of a pair are separated into a *genuine* pair (label 1) or an *impostor* pair (label 0), following the terminology in existing literature on face verification [11]. In this manner, the verification process evaluates the differences between the genuine and impostor score distributions. This methodology does not explicitly assume that the test and training data collection processes are the same or even similar, though conceptual frameworks often assume the two are the same.

3.2 Experiment design

Given a model trained on a dataset $\mathcal{D}$, we study a method of data collection motivated by our scenario of interest, where a face recognition system developer might respond to bias audits by collecting more training data from some target demographic group. As such, we focus on benchmark datasets with each image belonging to some racial group.

We define our method, *single-group augmentation*, as the incremental addition of samples from a fixed racial group to some initial training set consisting of a single racial group. This enables us to compare the performance of re-trained models by adding data from various groups, in order to determine whether the model improves more by training on an unseen group versus the initial group. We give the formal definition of single-group augmentation below.

We stress that we are *not* arguing that this data augmentation method should be used in practice, nor does this precisely say that a facial recognition system might only train on a single demographic group in practice. Rather, our experimental methodology distills the core essence of a targeted data collection approach, such that the impacts of data augmentation can be isolated and empirically analyzed.

3.2.1 Procedure for single-group augmentation. We train our models across a variety of training set configurations to understand how the group-specific performance of a model changes with the introduction of data targeted towards a specific demographic group. We follow a very similar setup and build off of the codebase from Gwilliam et al. [19]. Unlike their work, however, we do not maintain a fixed size training set and change proportions, but instead augment the dataset with additional data, and we empirically analyze three datasets rather than one. The training configurations are defined as follows:

For each group A, the *initial training configuration* consists of images from N randomly-chosen identities from group A, where N is fixed dependent on the size of the benchmark dataset $\mathcal{D}$. Here we refer to group A as the *initial group*. To obtain subsequent training configurations, we iteratively augment the initial training configuration with n randomly-sampled identities from another group B, where n is also decided based on $\mathcal{D}$. We refer to group B as the *target group*. As an example, an initial training configuration may consist of images from 200 identities from the *African-American* group, and we incrementally add images from 50 identities from the *East-Asian* group to obtain the rest of the training configurations.

Note that in some settings, the initial group A may be equivalent to the target group B. This enables our empirical analysis to compare continually adding data from the same group to continually adding the same amount of data from a previously unrepresented group. In other words, we can assess the impact of increasing demographic representation in the training data.

The design of these training sets replicates the motivating scenario of training data collection targeted on a particular demographic group in a simple setting of moving from one group in training to two. This empirical framework therefore simulates an existing face recognition system's possible response to bias audits.

3.3 Datasets

We conduct experiments on three existing racially-annotated datasets that we present in order of dataset size: BUPT [43, 44] (the largest dataset), VMER [16], and BFW [38], all of which have been used in face recognition model evaluations of racial bias [14, 19]. Other datasets we considered lacked sufficient images per subject to adequately train a model [34, 40], or were designed for other face-related analysis tasks [24]. Table 1 gives a breakdown of the groups in each dataset we examine. We observe that each dataset names racial categories differently from each other, and some refer to ethnicity rather than race [25]. In our results, we refer to the terminology used in the evaluated dataset in italics, but also recognize

Dataset	Categories	Subjects per category	Images per subject	Test subjects per category
BFW [38]	*Asian, Black, Indian, White*	180	25	20
BUPT / RFW [43, 44]	*African, Asian, Caucasian, Indian*	5000	18	3000
VMER [16]	*African American, East Asian, Caucasian Latin, Asian Indian*	400	108	24

Table 1: A summary composition of datasets in training and test folds, subsampled to ensure equal number of images per subject. Here, a subject refers to an identity, of which there are some number of images. It is assumed each subject belongs to exactly one category.

there are both overlaps and key distinctions between each dataset's group definitions, which is discussed further in Section 5.3.

To form the test image pairs from a given test set, we follow standard methodology as Wang et al. [44]. In every dataset, we generate all possible pairs of distinct test images (x, x'), $x \neq x'$ from the same group, assigning label 1 if the images share the same identity and 0 otherwise.

BUPT-BalancedFace (BUPT) contains a total of 1.3 million images from 28,000 individuals and is equally broken down into 4 demographic groups: *African*, *Asian*, *Caucasian*, and *Indian* [43]. Images are collected from the benchmark MS-Celeb-1M dataset [18] and augmented via Google search for additional celebrities in particular categories. The subjects are categorized by racial group using their nationality as a proxy, as well as via the Face++ API. Using nationality and race prediction are not robust methods for race categorization [25]; however, this is one of the only large-scale face datasets to consist of at least 7 thousand subjects per group. To ensure at least 18 images per subject, we constrict to 5 thousand subjects per group, which matches the setup in Gwilliam et al. [19].

The accompanying test dataset Racial Faces in the Wild (RFW) consists of fifty million test pairs and uses the same racial annotation method as BUPT. RFW is also from MS-Celeb-1M [18], but does not have any overlap with any subject from BUPT. For simplicity, we refer to the BUPT training and RFW test dataset as "BUPT."

VGGFace2 Mivia Ethnicity Recognition (VMER) dataset adds group annotations (*African American*, *Asian Indian*, *Caucasian Latin*, and *East Asian*) to the entire VGGFace2 training and test sets, which is one of the largest academic face recognition datasets [16]. VMER uses manual annotations across three million images to categorize subjects into four racial groups. Greco et al. [16] intentionally choose this annotation procedure rather than pre-trained models, in response to critiques that ethnicity classifiers fail to generalize well on racially-diverse datasets [24]. This dataset also consists of many more images per subject. To conduct our experiments with equal training set size per group, we randomly sample 440 individuals per group with 108 images per individual, which allows us to evaluate models trained on significantly more images for a given subject.

Balanced Faces in the Wild (BFW) is another dataset with an equal number of images and subjects from each racial category, but is also balanced by subgroups *Male* and *Female* within each racial group [38]. Each category consists of five thousand images from two hundred subjects with an equal number of faces per subject. BFW also samples from VGGFace2 [9], but instead uses pre-trained ethnicity classifiers to categorize subjects into the following groups: *Asian*, *Black*, *Indian*, and *White*. As with BUPT, pre-trained ethnicity classifiers, even if well-designed, may have inaccuracies [25]. To form the test set, we randomly select a hold-out fold of twenty individuals per group. Since the test sets for BUPT and VMER are fixed, for consistency of analysis, we similarly create a static test set for BFW as well.

3.4 Models

We perform these experiments on three state-of-the-art face verification architectures defined below. In each experiment, we train a model from scratch on the training configurations defined in Section 3.2.1. The models each use cross-entropy loss as the base classification loss function, stochastic gradient descent as the optimization function, and train for 50 epochs. We define the explicit hyperparameters used for each model in Appendix A.5.

The **SE-ResNet** model uses ResNet-50, a standard convolutional neural network with 50 layers [20], as a backbone and attaches Squeeze-and-Excitation blocks, which dynamically recalibrate channel wise feature responses [21]. Cao et al. [9] implement SE-ResNet to train on their proposed VGGFace2 dataset to demonstrate their improved performance in comparison to prior benchmarks. The **CenterLoss** model learns a center vector for each identity, in order to incorporate a loss penalty between feature embeddings and the identity's center, along with the base cross entropy loss function [46]. This minimizes the within-identity feature embedding distance and separates identities within the feature space. The **SphereFace** model introduces a multiplicative angular margin to the model's output, which maximizes the variance between feature embeddings of different identities.

3.5 Evaluation

To empirically measure model performance, we consider several evaluation metrics and in this section briefly describe the tradeoffs between them.

3.5.1 Global threshold. In face verification tasks, the model once trained depends on some chosen threshold to form binary predictions. We find, however, that the model evaluation of a global threshold does not sufficiently capture a model's behavior. Robinson et al. [38] demonstrate that using a singular threshold across demographic groups results in accuracy gaps, and that group-specific thresholds can strictly improve test accuracy across groups. In addition, many commercial face recognition systems, such as Amazon's Rekognition, allow users to set thresholds according to some application objective, i.e., to maintain a certain false positive rate [5]. Therefore, it is important to examine the model performance across a range of thresholds, rather than evaluation of a single one.

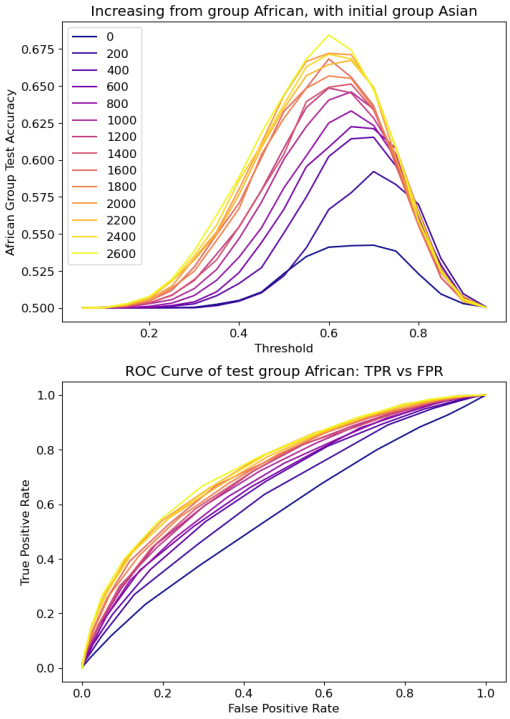

Figure 1: Initial exploration of impact of threshold on test accuracy, for an example initial group, target group pair on the BUPT dataset and SE-ResNet model. Color denotes size of target group, while initial group stays fixed at 2000.

Previous work on demographic group allocation in training have studied the accuracy rates obtained from a particular threshold [3, 19]. In our initial exploration of single-group augmentation, for every test group we plot test accuracy against threshold values across each training configuration, as shown in Figure 1. While we find trends in increasing the size of the target group, it is difficult to capture how test accuracy increases, given that the optimal threshold changes at each line. If we hope to understand the different forms of single-group augmentation, we find that distilling the ROC curve to a single metric enables comparisons among many training configurations.

3.5.2 Overall accuracy. Regardless of the threshold selection problem, we also find that studying overall accuracy has its limitations: there are many cases when equalization of accuracy rates by group still allows for disparate treatment [13]. For example, a face verification system may obtain a high false positive rate and a low false negative rate for one group, but still maintain equal accuracy across all groups. If this system is used for biometric authentication, this disparity in false positive rates could result in disproportionate security vulnerabilities for one demographic group. As a result, in our evaluation, we avoid studying accuracy as a comparison metric. Moreover, this prompts us to also examine the impact of targeted data collection on the group with the lowest performance, instead of using equal performance as the primary objective.

3.5.3 Area under the curve. As a consequence of the above disadvantages, we shift our attention to the *area under the curve* (AUC) calculated by the receiver operating characteristic curve (ROC) curve, an evaluation metric that has been used in prior face recognition literature [6]. The AUC is the probability that a positive test pair has a higher similarity score than a negative test pair, which enables our analysis to capture the distance distributions of feature embeddings, rather than merely considering the accuracy (or false positive or negative rates) of a binary classification task for a fixed threshold.

We note that AUC is a single numerical value which describes the functional relationship between true positives and false positives of a classification model derived from thresholding a regression model. It therefore is an incomplete description of the ROC curve, and two regression models might have equal AUC values but very different behavior in terms of this tradeoff.

3.6 Broader contexts and limitations

In addition to the previously-mentioned assumptions of demographic group fairness, we find certain limitations to the ability to generalize beyond our datasets, which are clarified below (in Section 5.2 we discuss how the limited ability to generalize from our results to other datasets is a strength for some of our other conclusions). In this section, we also situate our methodology in relation to the broader context of machine learning research.

3.6.1 Group fairness. In our work, we examine the task of face verification from a group fairness lens because we find that the main demographic information attached to standard face benchmarks is group membership. The datasets we study partition identities into only four racial groups, which excludes and merges many racial categories. Moreover, each dataset implicitly assumes that each individual belongs to a single category. This inherently ignores individuals with multi-racial identities, and the lack of additional demographic information may prevent analysis of intersectional differences along other dimensions, such as gender or age. We believe that this is an important topic for future study, especially as adding a single training sample can often increase representation across multiple demographic groups. At the same time, it is still beneficial to understand existing differences in performance among these groups, given the limitations of real-world data containing demographic information in the first place. In Section 5.3, we elaborate upon the implications of group-level annotations based on our results.

3.6.2 Image variations by racial group. Specific to the BUPT dataset, prior research has shown that the average face-to-image ratio is much lower for images from the *Caucasian* and *African* groups [19]. We obtain similar findings even when we control for face-to-image ratios, but this discrepancy indicates that other image variations by racial group, such as lighting or pose, may factor into our results. Previous work on performance gaps in group-balanced datasets has extrapolated that learning for a particular demographic is inherently more difficult [44]. We caution against making the broad claim that performance is capped for a certain sociodemographic group, as image quality and inter-group image variations can often also explain these gaps. For instance, many face image datasets are scraped

from celebrity photographs online; as a result, researchers have pointed out distinct differences of celebrity photography by race or gender, such as higher proportions of women wearing makeup than men, which may in turn affect performance disparities by demographic group [2, 4].

3.6.3 Underrepresented versus unrepresented groups. We also highlight that the single-group augmentation framework narrows the problem space we consider: from our motivation of racial groups that are *underrepresented* in training, to our experiments on racial groups completely *unrepresented* in training. We make this simplification intentionally to isolate the impact of augmenting one group with another group — underrepresentation on the extreme end.

The specific task of evaluating a model on an unseen group relates to domain generalization, a well-studied subfield of machine learning. While domain generalization techniques can be applied to this problem, Gulrajani and Lopez-Paz [17] show that model selection may not be straightforward when evaluated on a variety of datasets; this is an important area for further study. As a result, we recognize that our study examines only one piece of the puzzle: dataset representation bias does not encapsulate demographic bias across the entire face recognition system. Due to the variations in image quality by demographic group as described above, model interventions may be needed to ensure some chosen fairness criteria or generalization property. In this work though, we center our focus on the racial composition of training datasets, instead of a specific machine learning algorithm.

3.6.4 Generalizability of datasets. Finally, the dataset-specific artifacts highlight the difficulty of making generalizations of our observed trends to apply to all future forms of data collection. We limit our study to face recognition models and benchmark datasets available for academic study. If we hope to understand how corporations should best respond to bias audits, it is unclear whether our findings extend to systems training on datasets with sizes at a much larger magnitude. Moreover, we recognize that commercial face recognition systems may rely on vast pre-trained models that are not publicly available. We therefore acknowledge that our work may not align with the training procedures and large-scale datasets that industry face recognition systems may follow — this prompts the need for the release of commercial datasets and practices to the research community.

However, the fact that differences between datasets exist is itself an important contribution, especially as BUPT, BFW, and VMER continue to be used as benchmarks in face recognition literature to evaluate racial bias [14, 19]. In Section 5.2, we explore how our methodology may inform how future work can use these benchmark datasets, in addition to new ones.

4 RESULTS

We now present some representative findings in the figures below. For brevity, we show results for the SE-ResNet model, though the relative comparisons and general trends are consistent for CenterLoss and SphereFace. In general, we focus on the BUPT dataset to demonstrate key results due to its large size, but clarify otherwise when there are distinct dataset differences. For more details and accompanying results, please refer to Appendix A.

4.1 Differences among datasets

First, we observe in Figure 2 that the group-specific performance impact of single-group augmentation differs across datasets. Training on data from some racial group may not impact performance in the same manner across various datasets. As such, evaluation of a single benchmark dataset may not be sufficient; we elaborate on this further in Section 5.2.

4.1.1 VMER: Increasing representation improves AUC of unrepresented group more than addition from other groups. In Figure 2a, we show the impact of single-group augmentation on the AUC of each test group. We find that setting the target group as the test group results in the highest growth in AUC for the ranges in training size that we examine. In other words, if we were to update a face verification model by introducing samples from a single racial group, in VMER, the best choice to improve group X's performance is to add more data from group X.

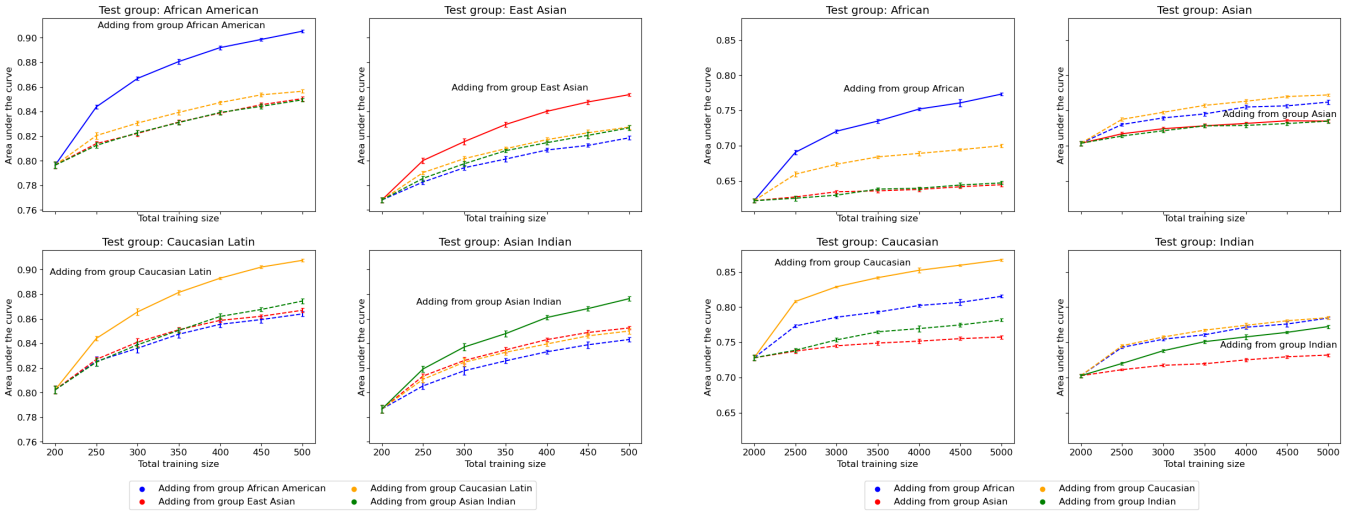
The same relative comparisons can be made when broken down by initial training configuration (see Appendix A.1 for details). Given an initial training set without group X, in the VMER dataset, the re-trained model's performance on unrepresented group X increases the most when increasing representation from group X in training. Even if the model initially trains on X, we find that continuing to augment the training set with samples from group X outperforms augmentation from any other group.

This case illustrates an example where out of all forms of single-group augmentation, improving demographic representation in training datasets increases the unrepresented group's performance the most. This matches existing intuition behind the development of training datasets that are balanced along demographics or more diverse in face composition, in response to prior face datasets that lacked representation along these dimensions [9, 24, 28].

4.1.2 BUPT: Training on some racial groups generalizes across all groups more than the addition of unrepresented groups. Figure 2b demonstrates the change in AUC for each group in the BUPT dataset. We observe that introducing data from the *African* and *Caucasian* groups improves the AUC for all groups regardless of the initial training configuration (Appendix A.1). Introducing data from the *Asian* and *Indian* groups does improve group-specific performance, but not as much as adding from the other groups, even when evaluated on the *Asian* and *Indian* test groups.

Compared to VMER, this result demonstrates that in the BUPT dataset, data from *African* and *Caucasian* groups generalizes strongly across all four groups. Gwilliam et al. [19] also confirm this trend since they find that when training on data from a single group, training on data from the *African* and *Caucasian* groups obtains the highest test accuracy for each group. A potential explanation may be that a significant proportion of images from *Asian* and *Indian* groups in training have much larger face-to-image ratios than in test [19]. We show that the same relative comparisons hold even when controlling for face-to-image ratios in Appendix A.1.1, but note that the shift from training to test sets might look different between demographic groups along other relevant dimensions.

Figure 2b shows that the addition of data from an unrepresented group is not always the best way to improve the performance for that same unrepresented group, unlike our findings in Figure 2a.



(a) VMER dataset **(b) BUPT dataset**

Figure 2: AUC for each test group under single-group augmentation averaged across all initial training configurations for both VMER and BUPT datasets. The solid line continually adds data matching the test group, and the dashed line continually adds data from a different group. Evaluated on SE-ResNet model across 5 trials with consistent results across models (per dataset).

These findings complicate the idea that the most data-efficient way to improve performance for a population X (excluded in training) is to increase representation of population X in the training set.

4.2 Similarities across datasets

In addition to the differences in results across datasets we described above, our analysis methodology revealed several trends which hold across the three datasets and three models. We highlight these trends and assess whether our analyses confirm the intuitions and findings in prior literature.

4.2.1 AUC on all test groups increases with additional training data, regardless of the group being introduced. In Figures 2a and 2b, we observe that with any form of data addition, the AUC values across all test groups increase regardless of the group being introduced and the initial training group. We find the same trend for every dataset-model pair single-group augmentation experiment we perform. Particularly, in our experiments, a model that retrains on additional training data from some target group does not sacrifice performance on the initial group in order to account for the target group. This demonstrates the notion that large neural networks have extensive capacity to capture arbitrarily complex functions [48], which also applies to new samples from distinct demographic groups.

4.2.2 No performance tradeoff among groups: Introducing data from racial groups distinct from the initial group does not harm the initial group. In various studied settings with group fairness objectives, researchers have demonstrated the existence of fairness-accuracy tradeoffs, especially in low-parametrized models, such as linear regression [12]. In our face verification experiments, we find that the introduction of data from groups distinct from the initial group does not harm the initial group; instead, the retrained model strictly increases performance across all groups.

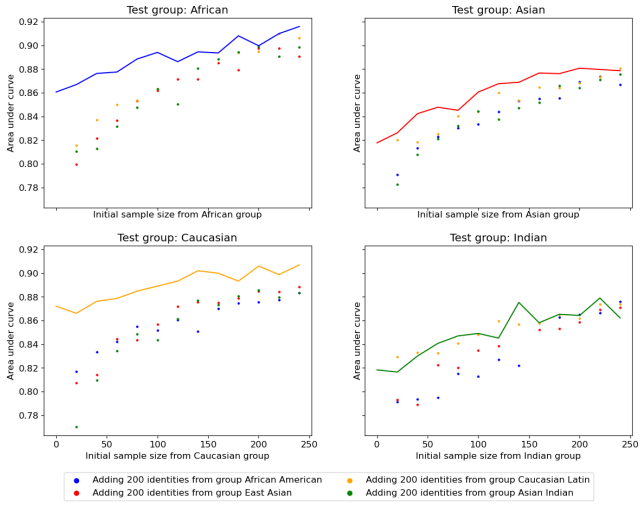


Figure 3: AUC of each test group under fixed-size data additions versus the size of the initial training set, composed of samples matching the test group. The solid line represents adding 200 identities from the test group, and the points represent adding 200 identities from a different group. Note that AUC increases as the initial training set size increases along the x-axis. Evaluated on VMER dataset with SE-ResNet model with consistent results across models.

4.2.3 Marginal performance of fixed-size data additions from the test group versus data additions from other groups shrinks as initial

training set grows. In Figure 3, we focus on the addition of a fixed number of samples from any group, instead of the continual introduction of samples from a single group as illustrated in prior figures. This form of analysis thus answers the following question: given an initial training set on group X, how does performance on group X differ between adding N samples from group X versus from another group?

In the VMER dataset, Figure 2a shows that adding data from the same group as test improves the test group's performance the most, in comparison to other forms of single-group augmentation. As such, the AUC value from adding from the test group (solid line) is higher than adding from another group, across most initial training set sizes. However, we observe that as the initial training set size gets large, the marginal benefit of introducing data from the test group compared to another group shrinks. We find this phenomenon across other models and in the BFW dataset as well. Due to the size limitations of the benchmark datasets we examined, it is unclear if adding data from a non-test group will ever obtain a higher performance than adding from the test group and requires further study.

4.3 Performance disparities for single-group augmentation

In Figure 4, we study different measures of performance disparity among racial groups with single-group augmentation.

4.3.1 Examination of group AUC disparities reveals examples that additional data can widen performance gaps. Figure 4a uses widest AUC disparity as a metric for unfairness via single-group augmentation. While equalizing performance across groups is not always desirable due to cases of sacrificing performance to satisfy parity, we have observed no decrease in performance with any form of additional data. As such, we still find it valuable to understand how performance gaps may change as a result of incorporating data from some racial group.

In Figure 4a, introducing data from the *African* group lowers the AUC disparity. This is driven by an increase in the *African* group's performance, which was originally the lowest. On the other hand, introducing data from the *Caucasian* group increases the test performance gap. This is driven by an increase in the *Caucasian* group's performance, which was originally the highest, even without inclusion of the *Caucasian* group in the initial training configuration.

4.3.2 Results contradict principle that more data reduces demographic bias. Figure 4a thus illustrates how data collection can generate various outcomes in performance disparities, and we find similar examples in other datasets (Appendix A.2). Moreover, the finding that adding data from an unrepresented group, such as the *Caucasian* group, widens performance gaps is a clear counter to the idea that more data mitigates discrimination as discussed in Chen et al. [10]. Their work proves that collecting more data from the population distribution decreases the population loss gap between groups. In our work, we consider data collection methods that may not match the test distribution, which may be realistic in cases when the test distribution is unknown. As a result, we demonstrate how the introduction of data from a group unrepresented in training may worsen performance disparities.

4.3.3 Adding data from the group with the initially-lowest AUC increases the AUC for that group significantly more than adding data from other groups. Figure 4b distinguishes different forms of single-group augmentation based on whether the target data is from the group that originally obtained the lowest AUC value. Across all models, datasets, and when separated by initial training configurations (Appendix A.3), we find that if the objective is to most improve the test performance for the group with the lowest AUC in the initial training set, adding data from that group increases performance significantly more than adding data from any other group.

4.3.4 Results connect to prior theoretical work on sampling from group with lowest performance. This validates prior theoretical analysis on active learning in group fairness. Abernethy et al. [1] find that updating the model with the samples from the current worst-off group converges to a min-max fairness solution, or minimizes the maximum classification loss across groups. In this manner, suppose a developer wishes to update their face recognition system to address concerns about a demographic group on which the model classifies poorly. Then targeted data collection on that group may improve the retrained model's performance, even if that group was already included in the initial training set.

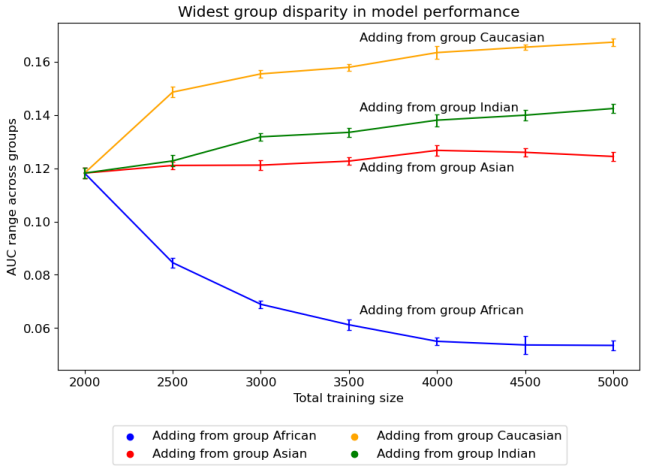
4.3.5 Lowest-performing group does not equal the least-represented group. Note the distinction between a group with the lowest performance and a group that is unrepresented in training. Although Figure 2b shows that data augmentation from some omitted group X may not significantly improve that group's AUC, this is still consistent with Figure 4b since group X did not have the lowest test performance in the initial training configuration.

4.4 Feature embedding similarity score distribution

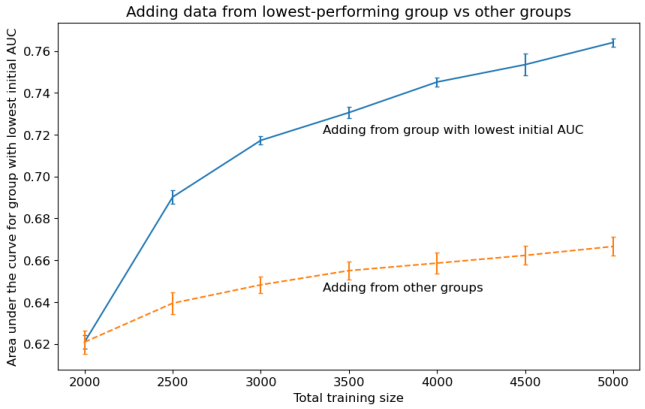
In order to explain the increase in AUC values from single-group augmentation, we investigate a model's feature embeddings from test images. Figure 5 plots the difference in average cosine similarity scores between genuine (label 1) and impostor (label 0) test pairs against the overall AUC of the test group. Each point represents a training configuration where the target group matches the test group, over all initial groups of the same size, and the color encodes the target group size at every point.

First, we find a clear positive relationship between distance and performance. This is consistent across datasets with more details in Appendix A.4. This observation indicates that higher AUC values for some test group are associated with genuine pairs having much higher cosine similarity scores on average than those of impostor pairs. This relationship follows from the model test pair procedure because models that further separate similarity scores between genuine and impostor pairs will obtain a higher AUC value by definition. This result matches findings in Albiero et al. [2], which examine test pair similarity distributions along gender and race.

Second, we notice that for every test group, the upwards trajectory is driven by adding samples matching the test group, regardless of the initial training configuration. This observation indicates that



(a) Widest disparity in AUC among groups when introduced with more data from each group.



(b) AUC of group with lowest performance in initial training configuration.

Figure 4: Performance disparity measures of single-group augmentation. Evaluated on BUPT dataset with SE-ResNet model across 5 trials with consistent results across models (per dataset).

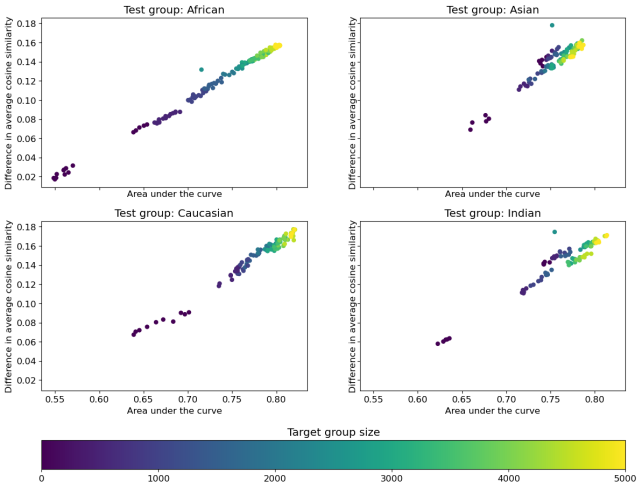


Figure 5: Difference in average cosine similarity scores between genuine (label 1) and impostor (label 0) test pairs for each training configuration run, plotted against area under curve. Color denotes the number of identities in training from the group that matches the test group, with the initial group held constant at 2000 identities. Evaluated on BUPT dataset for SE-ResNet, with consistent results for other models and datasets.

the introduction of some group X to any initial training set allows the model to better distinguish between genuine and imposter pairs from group X, which in turn, results in a higher AUC.

5 DISCUSSION

We now turn to a discussion of the broader implications of our results to (1) the addition of new training data in Section 5.1, (2) the general use of benchmark datasets in Section 5.2, and (3) the difficulty of group-level annotations in Section 5.3.

5.1 Broader implications of additional training data collection

From our analysis, we form several takeaways about the conditions and factors associated with data collection. Through simulating model retraining on the addition of new samples from a specific target group, we emphasize that we *do not* claim that this is the best method to add data, nor that data collection is the most effective way to improve a model. Instead, we aim to understand the impact of introducing data from various groups to some initial training set.

5.1.1 Results summary. Our empirical results illustrate an example in the BUPT dataset, where increasing representation from a group X initially omitted in training is not the best form of single-group augmentation to improve X's performance the most. However, across all datasets, we find that introducing data from the group that was originally worst-off obtains significant performance gains for that group. We make these performance comparisons by measuring AUC, but also recognize that AUC is an imperfect metric for capturing model behavior.

5.1.2 Importance of group annotations of both new and old data. Our results convey several implications about additional data collection. First, when augmenting training data, if we do not know the demographic group annotations of the additional samples, it is unclear how this new data will impact group-specific performance or group disparities. In other words, it is necessary to have knowledge of the demographic makeup of any additional data in

order to improve any group-specific fairness objectives. Second, our experimental analysis requires knowledge of initial performance across demographic groups. This underscores the importance of bias audits in the first place.

5.1.3 Data collection costs. At the same time, we recognize that data collection comes with various costs: Raji et al. [36] examine the ethical considerations when collecting diverse data collections, especially violations of the privacy and consent of the population being studied. As a result, targeted data collection can harm and unfairly monitor marginalized populations, as face recognition becomes used as a form of surveillance [30]. Therefore we qualify our recommendations to researchers and developers and encourage them to first assess the harms before choosing to engage in additional data collection.

5.2 Broader implications of the use of benchmark datasets

Given the limited number of publicly-available, large datasets with racial group annotations for face verification, our and other empirical findings may well be artifacts specific to particular datasets or models. For example, in Figure 2b, we observe that training on data from only the *African* or *Caucasian* group generalizes across all racial groups in the BUPT dataset, which is not replicated in the BFW and VMER datasets. The reason for this key difference between datasets is unclear and warrants further exploration. Yet because these datasets are used as benchmarks for racial bias evaluation in face recognition [14, 19], our findings are still valuable for models trained and evaluated on these same datasets.

5.2.1 Recommendations for future research on datasets and models. While the individual properties of our datasets, as discussed in Section 3.6, limits the full generalizability of our results, the unique characteristics of the datasets also leads to a strength of our study: recommendations for future research. As context for these recommendations, we observe that prior analyses on racially-balanced datasets examine one dataset instead of many. This is perhaps not surprising — and is not a criticism of past works — because these datasets are relatively new.

By studying three different datasets (across three models), we demonstrably find that there *are* important differences between datasets. Our findings here thus speak to the criticality of future work repeating evaluations like ours. For example, we recommend that future research that introduces new face recognition models to address racial bias should evaluate their models with several datasets. Similarly, we recommend that future research that introduces new datasets re-apply our methods and share the results of their analyses.

5.3 Annotations of demographic groups

For both data collection and dataset curation methods, we recognize the importance of demographic group-level annotations of data points, but also are aware of its limitations. Recent work, for instance, demonstrates that curators in each dataset follow different racial group annotation methods. Khan and Fu [25] point out that racially-annotated face recognition datasets define racial categories inconsistently, in spite of similarly named categories, and also encode stereotypes by excluding minority ethnic groups. From their evaluated datasets, the authors note that BUPT and BFW are the most consistent, due to having more images per individual.

Even simple investigation of the racial group annotation techniques reveals that some of these datasets conflate race, nationality, and ethnicity [43, 44]. Given that racial groups are socially constructed and dependent on cultural contexts [31], it is difficult to form concrete recommendations when training machine learning models that are equitable along the lines of race. However, since face recognition models have historically underperformed for people from certain racial groups [8], it is necessary to be aware of disparate treatment across groups, in spite of these groups not being well-formed. We find that our methodology still adds value and can still be performed for future datasets with differently-defined demographic groups even outside of the face recognition task.

6 CONCLUSION

In this work, we examine the group-specific performance impact of introducing additional training data from a particular racial group, if, for instance, a developer discovers that their face recognition model underperforms for some group unrepresented in its initial training set. By studying facial recognition, we acknowledge that some of its applications may create societal harm or invasions of privacy [7]. This work does not make a normative claim on the use of face recognition technologies; instead, we focus on the role that data collection plays on the model performance across groups, if these systems were to be used.

By proposing and evaluating an empirical framework that models targeted data collection, we find differences and general trends across 3 benchmark datasets and 3 standard face verification models. Some findings confirm previous intuitions about the relationship between a model's performance and the importance of data representation, while other findings reveal exceptions to these intuitions. In addition, significant differences in datasets reveal shortcomings in racial bias evaluation that use only one benchmark. We hope that our experimental results inform future instances of targeted data collection and racial bias evaluation on existing or new datasets.

ABSTRACT

Language models are trained on large-scale corpora that embed implicit biases documented in psychology. Valence associations (pleasantness/unpleasantness) of social groups determine the biased attitudes towards groups and concepts in social cognition. Building on this established literature, we quantify how social groups are valenced in English language models using a sentence template that provides an intersectional context. We study biases related to age, education, gender, height, intelligence, literacy, race, religion, sex, sexual orientation, social class, and weight. We present a concept projection approach to capture the valence subspace through contextualized word embeddings of language models. Adapting the projection-based approach to embedding association tests that quantify bias, we find that language models exhibit the most biased attitudes against gender identity, social class, and sexual orientation signals in language. We find that the largest and better-performing model that we study is also more biased as it effectively captures bias embedded in sociocultural data. We validate the bias evaluation method by overperforming on an intrinsic valence evaluation task. The approach enables us to measure complex intersectional biases as they are known to manifest in the outputs and applications of language models that perpetuate historical biases. Moreover, our approach contributes to design justice as it studies the associations of groups underrepresented in language such as transgender and homosexual individuals.

1 INTRODUCTION

Static word embeddings [6, 56] are known to reflect the semantics and biases of the populations that produce the data on which they are trained [12, 13, 69]. While problematic for their use in machine learning applications which are affected by these biased features [38, 82], static word embeddings have also allowed for the development of new social scientific approaches to studying societal norms and biases [24, 30, 35, 39]. However, static word embeddings have been replaced as the dominant representational paradigm in natural language processing (NLP) by language models [9, 17, 57, 59, 60], which form contextualized word embeddings, dynamic representations of words that undergo change over the course of the neural network based on the words which occur around them. Prior work suggests that, as this process of "contextualization" occurs, a contextualized representation becomes more semantically similar to the words which occur in context around it [79].

How can a principled and generalizable test for social bias, including intersectional bias, be designed for such dynamic representations? The present research proposes that, rather than studying changes in the representation of a certain word being evaluated for bias, one might instead look to the effects that a biased word has on its surrounding context. That is, instead of finding ways to compensate for the effects of contextualization when assessing bias, one can use the dynamic properties of language models to design a generalizable bias assessment method specifically suited to the paradigm of contextualization.

The first challenge in designing a bias test for contextualized word embeddings, however, is that they are not easy to analyze using common mathematical methods for measuring similarity between word embeddings, such as cosine similarity. While prior work has used principal component analysis (PCA) of subtracted vectors to find the dimension that maximizes the variance between biased representations [7], contextualized word embeddings are known to contain high-magnitude neurons which are often not semantic in nature [68, 79], preventing the development of a generalizable method for assessing semantic biases based on PCA.

The present research addresses this problem by using a maximum margin support vector classifier to learn a semantic property of the contextualized word embedding space: namely, the valence

(pleasantness vs. unpleasantness) subspace [53], onto which embeddings can be projected to measure their semantic properties. In social psychology, valence associations determine the biased attitudes towards social groups [28]. For example, are European American men or African American women perceived more positively valenced? Our method for isolating semantics in contextual spaces also allows for the introduction of a generalizable statistical test to quantify bias in language models by measuring the effects of contextualization. This work applies these methods to five language models (GPT-Neo, XLNet, ALBERT, RoBERTa, and T5) of varying architectures and demonstrates the ability to measure both contextualized word embedding semantics and bias in language models.

Code and data are made public at https://github.com/shivaomrani/LLM-Bias. The contributions of this research are outlined below:

(1) A method based on learning a maximum margin subspace to learn the valence subspace of an embedding space is introduced for isolating semantics in the highly contextual and anisotropic upper layers of contextualizing language models. Across five evaluated language models and without resort to pooling methods or postprocessing the contextualized embedding space, the approach is demonstrated to be robust to the geometry of contextualized embedding spaces, and outperforms a cosine similarity based method in the upper layers of every model. In GPT-Neo [23], scores on the ValNorm intrinsic evaluation task [69], which measures the correlation (Pearson's ρ) of human-rated valence with valence associations in models, fall to 0.56 in the top layer of the model when using cosine similarity; with the maximum margin method, the score remains high, at 0.81. A similar result is obtained for the four other language models studied, indicating the utility of the method for studying semantics in highly contextual and anisotropic embedding spaces.
(2) A statistical bias measurement based on the Word Embedding Association Test (WEAT) [12] is introduced to study differential biases arising from the process of contextualization in language models. The word "person" is placed into generated intersectional contexts with a wide variety of words reflecting social groups. "Person" is contextualized by these contexts, and its embedded representation is obtained from the top layer of a language model. The differential bias between two words is obtained by measuring their effect on the contextualized representation of the word "person" when placed in otherwise identical contexts, as measured based on the projection product with valence (pleasantness vs. unpleasantness) subspace. The method captures a wide variety of biases in language models related to age, education, gender, height, intelligence, literacy, race, religion, sex, sexual orientation, social class, and weight. The results reveal pronounced biases across five language models associated with gender identity (average effect size $d = 0.60$ - "cisgender" and "transgender"), social class (average effect size $d = 0.48$ - "affluent" and "destitute"), and sexual orientation (average effect size $d = 0.42$ - "heterosexual" and "homosexual").
(3) A method is introduced for studying biases without need for a binary, differential test. A permutation is used to generate a large sample of sentences that include social group signals in an intersectional context, each ending with the word "person." The embedded representation of person is computed from each sentence, and the projection product is obtained with the maximum margin subspace. The top 10% most pleasant sentences are returned, and the top 10% most unpleasant sentences are returned. In GPT-Neo, more than 90% of the most pleasant sentences contain the word "heterosexual," while more than 99% of the most unpleasant phrases contain the word "homosexual," again reflecting significant biases related to sexual orientation. Similar biases exist for gender identity in GPT-Neo, with more than 70% of the most pleasant phrases including the word "cisgender," and more than 93% of the most unpleasant phrases including the word "transgender."

The results of this research have implications both for the study of bias in AI, where researchers might employ the bias evaluation method to analyze language models for a wide range of intersectional biases by learning subspaces separating conceptual categories or evaluate the effectiveness of bias mitigation approaches, and for the social sciences, which might employ this approach to study the human biases encoded into machines.

2 RELATED WORK

The present research contributes new methods for measuring semantic norms and bias in contextualized word embeddings. This section reviews related work on the measurement of semantics and bias in static and contextualized word embeddings.

2.1 Static and Contextualized Word Embeddings

Word embeddings are dense, continuous-valued vector representations of words used to encode a statistical model of human language [3]. Static word embeddings such as those formed using the GloVe [56] and fastText [47] algorithms are trained on the co-occurrence statistics of words in a language corpus, and encode the semantic properties of language [48], such that algebraic operations on embedded representations can be used to solve analogical tasks [49]. Static word embeddings are known to encode societal attitudes and implicit and explicit biases of the population which produced the linguistic data on which they are trained [24, 43, 65]. While identifying and mitigating bias in word embeddings is a noteworthy area of study due to the propagation of these biases in downstream natural language processing (NLP) applications [11, 16, 38, 46, 82], the encoding of population-level human attitudes in word embeddings also allows them to be used as a statistical tool for studying bias, languages, societies, and historical events [15, 24, 30, 35, 39, 52, 70, 77].

Despite their widespread usefulness for both computer science and the social sciences, static word embeddings have a central limitation, in that they collapse all of the senses of a word into a single vector representation. Contextualizing language models such as ELMo [58], BERT [17], and the GPT family of models [9, 23, 59, 60] overcome this limitation by forming contextualized word embeddings, which incorporate information from surrounding words, such that the representation of a word depends on the context

in which it appears. Therefore, while polysemes and homographs (words with the same spelling but different meaning) share the same representation in static word embeddings, contextualized word embeddings capture semantic differences based on context and alter a word's representation to reflect the sense in which it is used [64]. However, polysemes and homographs are not the only words which change representation as they are processed in a contextualizing language model. Ethayarajh [22] shows that stopwords and articles are some of the most context-sensitive words in models like GPT-2, while Wolfe and Caliskan [79] demonstrate that contextualized word embeddings from seven language models become more semantically similar to the words that occur around them as they are processed in the model.

This suggests that a test of social attitudes and biases encoded in language models might be designed based on the effect a word has on the embedded representations of the words which occur around it. However, contextualized word embeddings have their own limitation: anisotropy, or directional uniformity [22]. Because language models are trained on a wide variety of objectives such as next-word prediction [59] and masked-word prediction [17], the geometric structure of contextualized word embeddings may reflect properties useful to performing a model's pretraining task, but detrimental for assessing embedding semantics using methods such as cosine similarity [79]. Recent research proposes methods such as the removal of non-semantic high-magnitude directions or the z-scaling of embeddings to expose semantic information in contextualized word embeddings [68, 79]; however, such methods necessitate the loss of information, even if that information is syntactic or otherwise non-semantic in nature. The present research introduces a method for assessing both semantic properties and bias in contextualized word embeddings with no postprocessing or loss of information.

2.2 Bias in Word Embeddings

Principled and generalizable evaluation of bias in word embeddings is grounded in cognitive psychology literature [12, 28]. These foundations, and the word embedding bias tests arising from them, are reviewed below.

2.2.1 Psychological Foundations for Measuring Machine Bias. Psychologists quantify the emotional association of a visual or linguistic stimulus using three primary dimensions of affect [32]: valence (pleasantness vs. unpleasantness), arousal (excitement vs. calm), and dominance (control vs. subordination) [45, 54, 67]. Social psychologists have compiled large lexica of affective norms, which reflect widely shared attitudes of human subjects who rate words based on valence, arousal, and dominance [2, 8, 50, 73]. A concrete example of a valence norm is that the word "vomit" triggers an unpleasant feeling for most English language speakers, while the word "love" triggers a pleasant feeling.

Valence is the principal dimension of affect that exhibits the strongest affective signal in language [69]. Psychologists use valence associations to evaluate biased attitudes towards social groups and concepts. Greenwald et al. [28] introduce the Implicit Association Test (IAT), which demonstrated the presence of implicit racial bias favoring European Americans over African Americans by showing that human subjects more readily paired European American names with pleasant words than they did African American names. The IAT inspired the design of the Word Embedding Association Test (WEAT) of Caliskan et al. [12], which demonstrated that a similar phenomenon occurs in static word embeddings, wherein names of European Americans are more similar to pleasant words based on measurements of cosine similarity than are names of African Americans.

In addition to its empirical grounding in social psychology, the WEAT offers theoretical benefits arising from its design as a statistical test: first, the WEAT returns an effect size, Cohen's d [12]. Cohen's d is defined such that 0.20 is small, 0.50 is medium, and 0.80 is large, and in most cases d ranges between -2 and 2; second, the WEAT returns a p-value based on a permutation test [12]. These qualities make the WEAT a useful method for interpreting the magnitude and statistical significance of bias in embedded representations. While Caliskan et al. [12] define the WEAT using cosine similarity, there is no inherent reason that cosine similarity should be the only measurement available for assessing the association of an embedding with some target. For example, Kurita et al. [36] develop a version of the WEAT which uses the masked word prediction objective of BERT to measure differential biases in masked language models.

The WEAT has been adapted previously to study biases in contextualized word embeddings and sentence embeddings formed by language models. May et al. [44] apply the WEAT to measure sentence-level biases in language models such as ELMo and BERT, while Tan and Celis [66] use a combination of the WEAT as well as method of May et al. [44] to measure biases in a variety of language models such as BERT and GPT-2 [60]. Guo and Caliskan [29] model contextualization as a random effect to measure the overall magnitude of bias across contexts in contextualizing language models. Wolfe and Caliskan [79] show that biases exist in the contextualized word embeddings formed by GPT-2 after non-semantic principal components are removed from the embeddings.

2.2.2 Valence-Based Intrinsic Evaluation of Word Embeddings. Prior work shows that the correspondence between the human-rated valence of a word and the valence association of its static [69] or contextualized [75] word embedding can be used to evaluate the intrinsic quality of embedding spaces, and to identify when the geometry of an embedding space interferes with the measurement of semantics using techniques based on cosine similarity [79]. Wolfe and Caliskan [79] find that contextualized word embeddings produced by language models most strongly encode the valence dimension of affect, and that human ratings of dominance also correlate moderately with dominance associations in the contextualized embedding space; arousal, on the other hand, correlates only weakly, with correlations $\rho < 0.30$. This research measures bias in language models using the valence dimension of affect, which corresponds to evaluating biased attitudes towards concepts and social groups.

2.3 Subspace Projection for Bias Detection and Mitigation

Another strand of prior work measures bias in word embeddings by identifying a bias subspace. Using 10 pairs of female-male difference vectors such as "woman" - "man" and "girl" - "boy," Bolukbasi et al.

[7] capture a "gender dimension" in static word embeddings by applying PCA to the vector differences and finding the component that best accounts for the variance [34]. Obtaining the projection of other embedded representations of words with this bias subspace yields a metric for quantifying gender bias. Bolukbasi et al. [7] demonstrate that traditionally masculine occupations such as doctor and pilot project towards masculinity, while traditionally feminine occupations such as nurse and librarian project towards femininity on the gender subspace. Similarly, using difference vectors such as "rich"- "poor," Kozlowski et al. [35] find the "affluence dimension" in a study of social class in diachronic (chronologically ordered) static word embeddings.

Subspace projection methods have also been adapted to contextualized word embeddings. Zhao et al. [81] measure and mitigate biases in ELMo's contextualized word embeddings, and show that a coreference resolution system in ELMo inherits its gender bias. Liang et al. [40] use a variation of a subspace projection method to measure and mitigate biases in ELMo and BERT's sentence representations. Ravfogel et al. [62] use an iterative variation of a subspace projection method to mitigate biases in contextualized word embeddings, and Basta et al. [1] apply the subspace projection as well as the method of Gonen and Goldberg [27] to measure gender bias in ELMo embeddings. When subspace projection approaches are used to develop techniques for bias mitigation, the success of these interventions is sometimes evaluated using the WEAT [62]. The present research builds upon prior work by introducing a machine learning method to learn a semantic subspace in the highly contextual and anisotropic upper layers of language models, and introducing a principled statistical test for measuring biases, in an intersectional setting, arising from contextualization in language models.

3 DATA

The present research examines semantics and bias in five language models based on the transformer architecture of Vaswani et al. [72], which employs a self-attention mechanism to allow word representations to draw information from the representations in the context around them. Models are selected to represent the state-of-the-art for three widely used transformer architectures: decoder-only causal language models; autoencoders; and encoder-decoder models.

3.1 Language Models

GPT-Neo is an open source replication of GPT-3 [9], trained on the next-word prediction objective and employ masked self-attention such that the current token only has access to information from words which precede it in a sentence. GPT-Neo is trained on the Pile, an 825 GB dataset of English text composed of 22 diverse and high quality sub-datasets [23]. Models trained on the Pile have been shown to outperform models trained on both raw and filtered versions of the Common Crawl on many benchmarks and downstream evaluations [23]. Prior work finds that GPT-Neo most strongly encodes human judgments of valence compared to six other language models, including GPT-2 [60], T5, and BERT [79]. This research studies the contextualized word embeddings generated by the 24-layer, 1.3 billion parameter version of GPT-Neo [5]. While GPT-Neo is one of the largest and empirically best-performing language models available open source [23], it is still much smaller than the largest version of GPT-3, which has 175 billion parameters [9].
XLNet is a causal language model that learns bidirectional contexts by permuting the factorization order of text input [80]. XLNet is trained on five corpora: English Wikipedia, BookCorpus [83], Giga5 [55], filtered versions of ClueWeb 2012-B [14], and the Common Crawl corpus [10]. The 12-layer base-cased version is used in this research.
RoBERTa is an optimized version of the bidirectional "BERT" autoencoder architecture of Devlin et al. [17], trained on masked language modeling (prediction of a hidden word) with dynamic masking to prevent memorization of the training data [42]. RoBERTa is trained on five corpora: English Wikipedia, BookCorpus [83], a curated subset of CommonCrawl News [42], OpenWebText [26], and Stories [71]. The 12-layer base version is studied in the present research.
ALBERT is a parameter-reduced version of the BERT architecture which introduces factorized embedding parameterization, cross-layer parameter sharing, and inter-sentence coherence loss, and outperforms BERT and RoBERTa on a variety of NLP benchmark evaluations [37]. ALBERT trains on English Wikipedia and the BookCorpus [83]. This research uses the 12-layer V-2 base version of ALBERT, which is also trained on additional corpora used to train RoBERTa and XLNet [37].
T5 is an encoder-decoder transformer model that takes text as input and produces text as output, and is trained on a variety of supervised and unsupervised NLP objectives [61]. T5 is trained on the Colossal Cleaned Common Crawl (C4), a large filtered version of the Common Crawl [61]. The present research uses the 12 encoder layers of the base version of T5.

All models used are the PyTorch implementations available via the Transformers library of Wolf et al. [74].

3.2 Valence Stimuli

As detailed in section 4.1, the present research learns a valence dimension by training a support vector classifier (SVC) to form a maximum margin subspace between groups of pleasant and unpleasant words. In keeping with prior research in contextualized word embeddings [29, 75, 79], the groups of pleasant and unpleasant words used to measure valence are the stimuli used to measure social biases in the IAT [28] and the WEAT [12].

Pleasant vs. Unpleasant stimuli obtained from Caliskan et al. [12] to learn an affective valence dimension are included below.
Pleasant: caress, freedom, health, love, peace, cheer, friend, heaven, loyal, pleasure, diamond, gentle, honest, lucky, rainbow, diploma, gift, honor, miracle, sunrise, family, happy, laughter, paradise, vacation
Unpleasant: abuse, crash, filth, murder, sickness, accident, death, grief, poison, stink, assault, disaster, hatred, pollute, tragedy, divorce, jail, poverty, ugly, cancer, kill, rotten, vomit, agony, prison

3.3 Social Biases and Categories

The present research designs a method for language models to study the effects of multiple biases interacting in a single string input in an intersectional setting. This requires the identification of a variety of societal biases which may overlap and compound

Table 1: Category terms chosen from related work in AI bias and social psychology to represent human social biases. The term r denotes the frequency ratio of the first category to the second according to Google ngrams corpus of English books [41].

Social Bias	Categories	r	Social Bias	Categories	r
age	young, old	0.59	social class	affluent, destitute	0.55
weight	thin, fat	1.40	race	white, black	1.30
height	tall, short	0.12	sexual orientation	heterosexual, homosexual	0.64
intelligence	smart, stupid	0.98	religion	christian, muslim	14.36
education	educated, ignorant	1.70	gender	cisgender, transgender	0.05
literacy	literate, illiterate	0.85	sex	male, female	0.98

each other in contextualizing language models, as they are known to human society. Drawing on prior work in psychology and AI bias [33, 35], 12 western societal biases are identified for study in this work. These include biases based on age, weight, height, intelligence, education, literacy, social class, race, sexual orientation, religion, gender, and sex.

For each of these 12 social biases, two categories are selected such that bias arising from the difference in these categories can be measured. For example, the categories "tall" and "short" are selected to measure bias based on height. Because word frequency can affect the representational quality of a word in a contextualizing language model [75], categories are selected such that they have relatively balanced frequency based on human usage as measured using Google ngrams [41]. For example, though "educated" and "uneducated" could be used to quantify biases based on educational attainment, "uneducated" is used roughly 10 times less frequently than "educated" in ngrams [41]. To balance the frequency of the words, "ignorant" is selected as the second category in the pair with "educated."

Table 1 shows the social biases evaluated and their corresponding categories. Column r describes the term frequency ratio of the first category to the second category. Although the intention is to represent each bias with category terms that have similar rates of frequency, the categories for gender bias are highly imbalanced. For the lack of a more suitable alternative, "cisgender" remains one of the gender categories, despite its imbalance with the more commonly used term "transgender."

Many of the biases examined in this research could be represented with more than two categories. There are, for example, more religions, sexual orientations, and genders than those captured here. This research introduces a new method and demonstrates that it captures these well-studied social biases. The method generalizes beyond the categories defined herein.

4 APPROACH

The present research describes a new method for measuring biases based on valence in contextualized word embeddings. This involves first learning an affective dimension in the contextualized embedding space, and then measuring bias based on the projection product of a contextualized word embedding with the learned dimension. Figure 1 summarizes the approach.

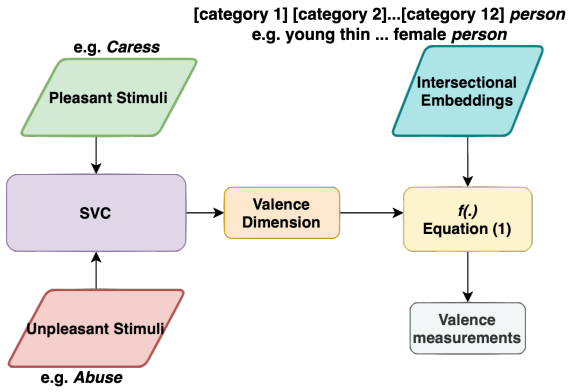

Figure 1: A support vector classifier is used to learn the valence dimension in the upper layers of contextualizing language models. Biases related to pleasantness are evaluated by taking projection product of the contextualized representation of "person" at the end of a context with the learned valence dimension.

4.1 Learning an Affective Dimension

While recent work shows that the semantic properties of contextualized word embeddings, including valence [79], can be isolated by removing top principal components, these methods have the significant drawback of postprocessing the embeddings, and removing information from the model's representations. To mitigate this constraint, the present research proposes a method which requires no postprocessing of the embedding space, but instead learns a property of the space against which contextualized representations can be measured.

The valence direction is learned in the contextualized embedding space by training an SVC with a linear kernel given the high dimensionality of the space. For valence, the SVC is trained to classify contextualized representations of 25 pleasant words and 25 unpleasant words such that the separating subspace between the pleasant words and the unpleasant words maximizes the distance between them. The coefficients of the separating subspace are extracted, and used as a valence dimension of the contextualized embedding space, respectively. The words used to learn a separating subspace are input to the model in the decontextualized setting, *i.e.,* with no surrounding context. Each decontextualized word is preceded

by the <BOS> (Beginning of Sequence) token, extracted from the model tokenizer.

4.2 Contextualizations of "Person"

While prior work evaluates word embedding bias on the word level [12, 79] or the sentence level [44], this research measures biases resulting from the contextualization of the word "person," such that it is altered along the valence dimension. More concretely, the question under consideration is whether the word person becomes more pleasant or unpleasant when it occurs in a sentence with a word like "transgender" or "cisgender" (*e.g.,* "a transgender person"). Because causal language models employ masked self-attention such that the current word only has access to the information of the words which precede it, this research positions the word person at the end of the sentence, such that information can be drawn from all other words in the sentence. Models such as BERT and T5, which employ bidirectional self-attention, are also able to retrieve information from any word in a context given this format.

4.3 Measuring Valence Associations

The valence association of a word's embedded representation is measured by its orthogonal scalar projection onto the learned affective dimension. For a vector v, and subspace U defined by n orthogonal vectors $u_1, u_2, \ldots, u_n$, the scalar projection of v onto U is computed as follows:

$$\mathrm{S}(v, U) = \sum_{i=1}^{n} \frac{(v.u_i)}{(u_i.u_i)} \tag{1}$$

where $(a.b)$ refers to the dot product of a and b. The valence dimension is learned such that positive values of s correspond to greater association with pleasantness (*i.e.,* high-valence words will project onto the positive side of the valence dimension), while negative values of s correspond to greater association with unpleasantness (projection onto the negative side of the valence dimension).

4.4 Quantifying Differential Bias Using the SC-WEAT

The WEAT and the SC-WEAT measure biased associations and return two values: an effect size, Cohen's d, and a p-value based on a permutation test [12]. Caliskan et al. [12] define the WEAT as using cosine similarity as a means of assessing the similarity between two embedded representations, as this distance metric reflects a widespread paradigm for measuring similarity in static word embeddings [12, 49]. However, the WEAT is a statistical method for assessing differential similarity of two sets of targets (*e.g.,* two social groups) with two sets of attributes (*e.g.,* pleasantness and unpleasantness), and is not necessarily dependent upon cosine similarity as a distance metric when a more appropriate measure is validated for an embedding space. For the present research, a WEAT is defined to capture the differential bias of two words in contextualizing language models, based on their projection product with the valence dimension. The formula of the SC-WEAT is readily adaptable for this purpose, as it measures the differential similarity of a single target vector with two attribute groups:

$$\frac{\mathrm{mean}_{a \in A}\mathrm{S}(a, U) - \mathrm{mean}_{b \in B}\mathrm{S}(b, U)}{\mathrm{std\_dev}_{x \in A \cup B}\mathrm{S}(x, U)} \tag{2}$$

In this case, the learned affective dimension U (*i.e.,* valence) is used as the target. To measure the differential bias for two words across contexts, the A attribute group is defined to include the embedded representations a of the word "person" in all of the sentences which include a certain attribute word, such as "transgender," and a B attribute group is defined to include a set of sentences which are identical to the A group, but with the target word replaced with an opposing category word, such as "cisgender," for which the differential bias effect size will be obtained. The bias measurement is defined as the difference in the mean projection product of the A group with the valence dimension and the B group with the valence dimension, divided by the joint standard deviation of projection products, commensurate with Cohen's d. A p-value is obtained using the same permutation test as employed in the SC-WEAT [12].

5 EXPERIMENTS

In this section, details are provided for three different experiments and their results. Experiment 1 examines the utility of the learned valence dimension for capturing semantics in language models. Experiment 2 studies differential biases based on valence in language models. Experiment 3 examines the words most biased based on association with valence.

5.1 Evaluating Learned Affective Dimensions Against Human Judgments of Semantics

The utility of the learned dimension for representing valence in the contextualized word embedding space is assessed using the ValNorm method of Toney and Caliskan [69]. ValNorm is an intrinsic evaluation task that obtains the correlation (Pearson's ρ) of a word's human valence rating in a valence lexicon with the SC-WEAT valence association of its embedded representation. Toney and Caliskan [69] employ three valence lexica in evaluating ValNorm, of which we select Bellezza's lexicon [2], a set of 399 words rated by human subjects based on pleasantness, which Wolfe and Caliskan [79] show is sensitive to the presence of non-semantic high-magnitude directions in language models. To show that the method is effective in the highly contextual upper layers of language models [22], a ValNorm score (Pearson's ρ) is obtained at every layer of the language model using the projection product with the valence subspace as a word's valence association in the model.

5.2 Bias Evaluation Using SC-WEAT

The categories derived from the 12 social biases considered in this research are placed into a sentence in the order shown in Table 1, *i.e.,* "a young thin [...] female person." While maintaining the order of the biases, the context is altered such that every category occurs in a sentence with every other combination of categories, except for its own opposing category. This leads to a total of 2^{12}, or $4,096$ contexts. Each category occurs in exactly half of these contexts, or $2,048$ occurrences.

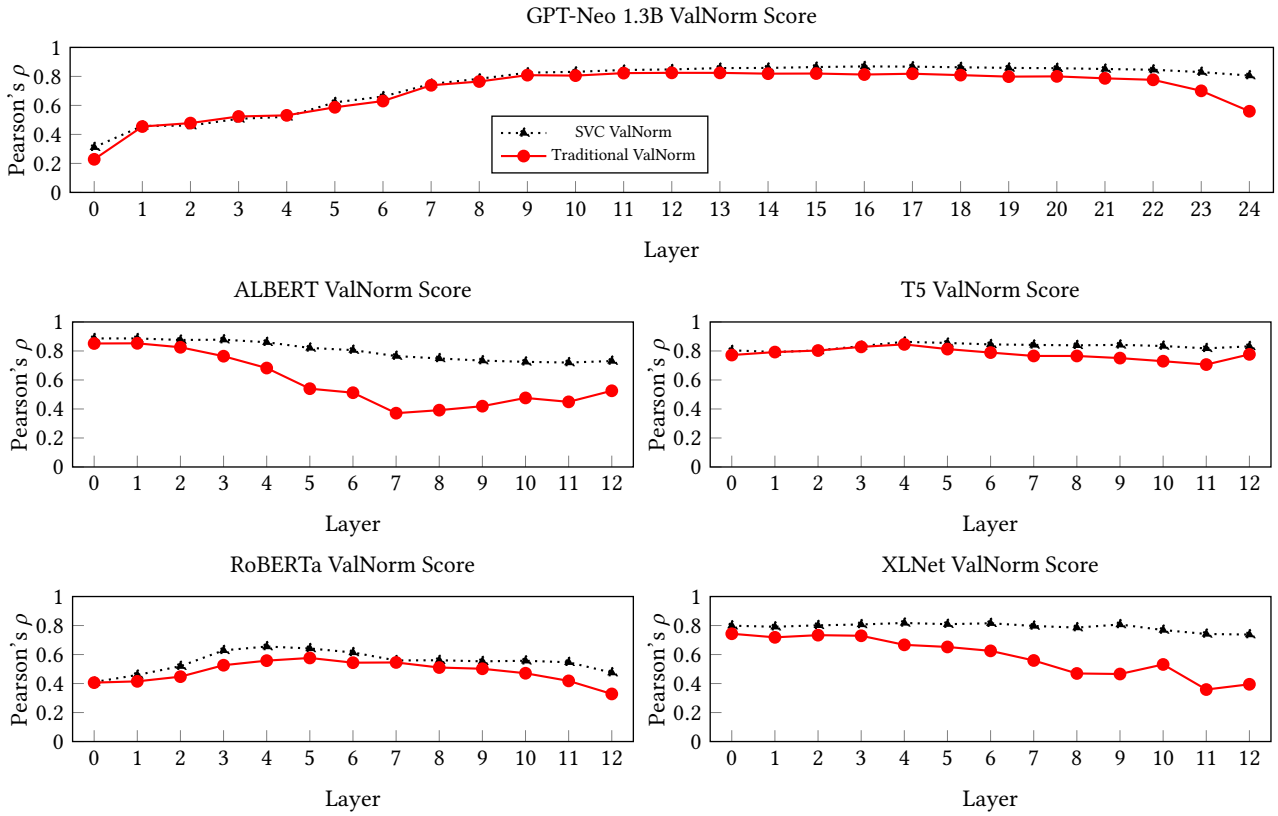

Figure 2: Across five contextualizing language models, using a support vector classifier to learn the valence dimension improves ValNorm evaluation scores in the upper layers of the language model over comparable results obtained using cosine similarity, without the need for postprocessing of embeddings. This result suggests the robustness of the methods proposed in this research for capturing semantics across widely varying language modeling architectures and pretraining objectives.

The order of the social bias categories in the sentence template was chosen in an attempt to make the sentences sound more natural. For example, "thin female person" is used more frequently than "female thin person" [41]. Ideally, one should generate all permutations of the social biases to eliminate the impact of word order on the bias captured by "person" at the end of the sentence. However, the total number of permutations in this experiment would have been about 2 trillion sentences which was beyond our computational capacity. Future work can investigate the impact of word order on bias computations.

The two categories described in Table 1 are selected for each of the 12 biases examined in this research, with the first category (*e.g.,* affluent) set as the *A* attribute, and the second category (*e.g.,* destitute) set as the *B* attribute, such that a positive effect size reflects stereotype-congruent bias (*e.g.,* affluent individuals are evaluated more positively than destitute individuals). For each category, the 2,048 sentence combinations in which the *A* attribute occurs are selected, and the embedded representation for the word "person" is obtained for each of these contexts. The same process is repeated for the *B* attribute, and the two sets of embeddings are used as input to the projection product SC-WEAT. To obtain the most contextual representation produced by a transformer, *i.e.,* the representation most altered by the words in its context, the contextualized word embedding in the top (output) layer of the model is obtained, commensurate with prior research which finds that top layers of language models are the most contextual [22, 79]. A bias effect size d and a p-value are obtained for each test. In total, five transformers of varying architectures and pretraining objectives are examined.

5.3 Identifying the Strongest Biases Across Contexts

A final experiment examines the most biased categories in GPT-Neo, the largest of the language models studied herein. We choose GPT-Neo because Nadeem et al. [51] observes that larger, better-performing language models are also more biased. Five historically disadvantaging societal biases are selected for study: race, sex, religion, gender, and sexual orientation. The ten categories associated with these concepts are drawn from Table 1. Sentences are created with five categories present per sentence (*e.g.,* a white female cisgender heterosexual Christian person). All possible permutations are generated using the ten categories in question, such that every category is seen in combination with every other category in every position in the sentence. The total number of permutation of phrases constructed in this manner is 3,840. The valence projection

product is obtained for the embedded representation of the word "person" in every generated sentence. The characteristics of the top 10% most positively valenced and top 10% most negatively valenced five-category sentences are examined. For these subsets of the generated sentences, the percentage of the time each category word occurs in each of the positions preceding "person" is quantified.

6 RESULTS

The evidence indicates that learning the valence is useful for detecting semantics and social biases in the contextual and anisotropic upper layers of language models.

6.1 Evaluating the Learned Affective Dimension

Across five state-of-the-art transformer language models with different architectures, tokenization algorithms, and training objectives, learning an affective dimension in the embedding space outperforms cosine similarity on the ValNorm intrinsic evaluation task with no postprocessing of the embeddings. The effect is especially noticeable in the highly contextual upper layers of these models, where non-semantic high-magnitude directions distort measurements of semantics based solely on cosine similarity. As shown in Figure 2, the ValNorm score (Pearson's ρ) drops to 0.56 in the top layer of GPT-Neo 1.3B when using cosine similarity, but stays high, at 0.81, when using the projection product. Figure 2 also shows that a similar effect occurs in all five of the language models studied in this research, indicating that this method allows for the measurement of human-interpretable semantics and bias in highly contextual and anisotropic embedding spaces.

6.2 Measuring Differential Bias Based on Valence

As shown in Table 2, the evidence suggests that language models encode consistent valence biases based on gender identity, sexual orientation, and social class signals in an intersectional context. A statistically significant positive effect size is obtained for the heterosexual vs. homosexual and cisgender vs. transgender test for all five of the models studied in this research. For ALBERT and RoBERTa, effect sizes are large ($d = 1.34$ and $d = 1.22$) for the gender identity test; medium effect sizes are obtained for GPT-Neo ($d = 0.64$) and T5 ($d = 0.61$) for the sexual orientation test. Statistically significant valence bias effect sizes are also obtained for four language models for the affluent vs. destitute test. Bias effect sizes are medium ($d > 0.5$) or large ($d > 0.8$) in three of the five models. The large effect size for social class speaks to the presence of biases related to social class in language models, a relatively unexplored bias type in AI except for the work of Kozlowski et al. [35] analyzing the meaning of class in static word embeddings. Figure 3 visualizes the difference in the mean projection onto the valence dimension for each of the 12 biases studied.

Another noteworthy result is that three of five language models (ALBERT, GPT-Neo, and RoBERTa) differentially associate men with pleasantness over women. While effect sizes are small, this deviates from psychological research suggesting that women are evaluated as more pleasant than men. For example, while men are often associated with aggression and violence, women are associated with more communal attributes such as warmth. This is known as the "women-are-wonderful-effect" [18–21]. It is possible that women are portrayed negatively in the training corpora of these language models, causing men to be more differentially pleasant. This possibility is supported by the recent research of Birhane et al. [4], who find that corpora used for training language-and-image models contain misogynistic and toxically stereotypical depictions of women. The association of women with pleasantness is, however, observed in T5.

Results across five language models suggest the utility of the method proposed in this research for capturing widespread societal biases in contextualized word embeddings. Bias effect sizes are stereotype-congruent in at least 9 of 12 tests for three of the five models assessed, and in every model at least half of the bias tests yield positive effect sizes. Moreover, the results presented here further affirm the findings of Nadeem et al. [51], who find that larger language models are both better at language modeling and more biased based on a downstream evaluation of bias. The present research observes that GPT-Neo, the largest of the language models studied herein and previously observed to outperform other language models on both intrinsic and downstream evaluations of semantic quality [23, 79], has a statistically significant bias effect size of at least 0.50 for 6 of the 12 bias tests, the most of any of the models studied herein.

6.3 Identifying the Strongest Affective Biases in a Language Model

As shown in Figure 4, retrieving the top 10% of the most pleasant contexts shows that heterosexuality and cisgender identity are over-represented in the most positively valenced phrases in GPT-Neo, with more than 93% of the most pleasant phrases containing the word "heterosexual," and more than 70% of the most pleasant phrases containing the word "cisgender." The word "Christian" is also positively valenced, with more than 65% of the most pleasant phrases containing the word. On the other hand, the word "homosexual" occurs in the most positively valenced phrases less than 7% of the time, and retrieving the top 10% of the most unpleasant contexts shows that homosexuality and transgender identity are among the most negatively valenced words assessed, with more than 99% of the most negative phrases containing the word "homosexual," and more than 93% of the most negative phrases containing the word "transgender." None of the eight other words assessed occurs in more than 55% of the most negative phrases. The word "heterosexual" occurs less than 1% of the time in the most negatively valenced phrases. The word "Muslim" occurs more frequently in the most negatively valenced phrases than it does in the most positively valenced phrases, as does the word "white." The words "male" and "female" occur roughly equally in the most positively and negatively valenced phrases.

Both figures 3 and 4 show that a "white" person is slightly more negatively valenced than a "black" person in GPT-Neo ($d = -0.12$ in Table 2). In representational models, such as multi-modal vision-language models, the default unmarked person in English is associated with "white" [76], as a result the noun the person does not typically get marked with the identity descriptor of "white" [78].

SC-WEAT Differential Valence Association										
Bias Test	ALBERT		GPT-Neo		RoBERTa		T5		XLNet	
	d	$p <$	d	$p <$	d	$p <$	d	$p <$	d	$p <$

heterosexual vs. homosexual	0.35	10^{-30}	0.64	10^{-30}	0.12	10^{-4}	0.61	10^{-30}	0.40	10^{-30}
christian vs. muslim	0.27	10^{-30}	−0.15	10^{-6}	−0.63	10^{-30}	0.01	*n.s.*	−0.16	10^{-6}
cisgender vs. transgender	1.34	10^{-30}	0.24	10^{-14}	1.22	10^{-30}	0.09	.01	0.12	10^{-4}
male vs. female	0.27	10^{-30}	0.10	10^{-3}	0.10	10^{-3}	−0.93	10^{-30}	0.01	*n.s.*

Table 2: Across five language model architectures, the most severe biases occur for sexual orientation and gender identity, with positive effect sizes obtained from all five models assessed. GPT-Neo includes six effect sizes of .5 or greater, the largest number of any language model, corresponding to the observation of Nadeem et al. [51] that larger, better-performing language models are also more biased.

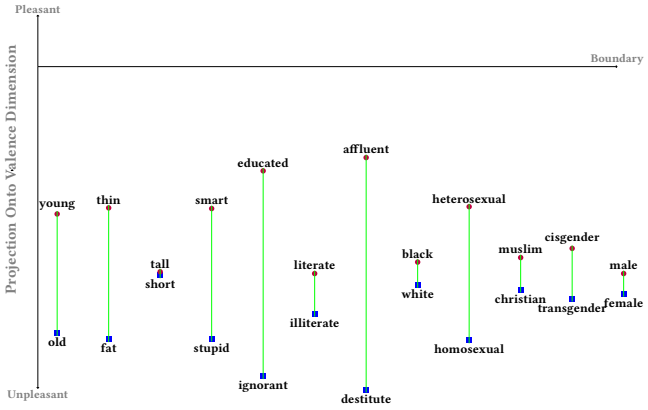

Figure 3: Differences in the mean valence of the word "person" when it co-occurs with the above categories in 4,096 phrases. Length of green lines represents the magnitude of differential valence for each pair of categories. Red circles indicate stereotypically higher-valence categories, while red squares represent stereotypically lower-valence categories.

The effect of markedness for a "black" person might potentially be causing the stereotype incongruent result.

The results of this method, which does not require the definition of binary groups for differential measurement, are mostly consistent with the results obtained from the differential statistical test introduced in the second experiment. This suggests the utility of the projection method for measuring biases in contextualized word embeddings even when an opposing category does not exist such that a differential bias test can be performed.

7 DISCUSSION

The contributions of the present research are threefold: a method for measuring semantics in contextual and anisotropic embedding spaces; a novel and generalizable differential bias measurement which takes into account the contextualization property of all language models, and which returns an effect size indicating magnitude and a p-value measuring statistical significance; and a means for quantifying biases in contextualized word embeddings in an intersectional setting. By analyzing sexual orientation, social class, and gender bias without having to use gender binary, our approach is more inclusive compared to various previous analyses.

The findings of this work indicate that the biases demonstrating low regard based on sexual orientation observed by Sheng et al. [63] in the text output of language models can be traced back to the contextualized embedding space, where the occurrence of the words "homosexual" and "transgender" lead to greater association with unpleasantness and negative attitudes. Future work might use the method put forth in this research to further examine the link between bias in contextualized word embeddings and the propagation of that bias to model objectives such as language generation or other downstream NLP tasks such as sentiment analysis, machine translation [25], or consequential decision making.

Many of the results reported in this work suggest that biases of contextualization have consistent indirect impacts on the representation of societally disadvantaged people. For example, the results indicate that biases related to education and social class exist in many language models. These categories speak directly to

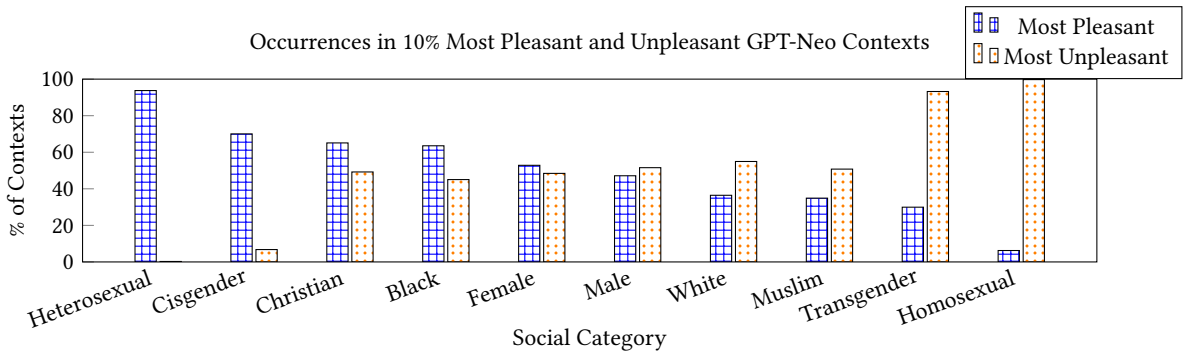

Figure 4: More than 93% of the most pleasant contextualized representations of the word "person" in the top layer of GPT-Neo include the word "heterosexual," and more than 70% include the word "cisgender." On the other hand, more than 99% of the most unpleasant phrases in the top layer of GPT-Neo include the word "homosexual," and more than 93% include the word "transgender," reflecting biases based on sexual orientation and gender identity.

the opportunities and outcomes afforded over which an individual typically has little control.

Moreover, many of the biases observed in this work are likely to interact with and intensify other biases. For example, a bias based on sex (male vs. female) is observed in most language models, such that men are more associated with pleasantness than women. However, biases based on weight, and age are also observed, such that the word person is more pleasant when it occurs with "thin," and "young." While such biases may affect any context in which they are observed, they are likely to have greater impact on the representation of women in language models, as women are more likely at a societal level to be described with regard to their physical appearances, and biases related to age are often directed more strongly toward women, and at younger ages than men [31]. The consequence of the contextualization effect observed in this research is that representations of people more likely to be described in a biased manner will become even more negatively valenced in the model than the categorical biases indicate when considered individually. The methods described in this research have ramifications not only for studies of bias in AI, but also for the social sciences, as social scientists may use the computational approaches described in this research to quantify properties of human language and culture, without the problem of meaning being collapsed into a single vector representation, as occurs in static word embeddings. While norms and biases based on valence are studied in this work to ground a new method in prior psychological research, a maximum margin subspace could be learned to represent many other semantic properties; for example, future research might learn a political spectrum subspace to study biases beyond those observable based on valence.

Finally, while this work assesses in-context biases, it evaluates their impact in individual or two differential categories. However, the method can be trivially extended such that intersectional identities can be assessed by observing biases based on word bigrams, trigrams, or longer descriptive sequences. This is facilitated by using the contextualized representation of the word "person" as the target embedding for all bias measurements, rather than attempting to directly measure the embedded representations of bias-inducing words or categories.

7.1 Limitations and Future Work

The results reported for experiment 5.2 are obtained by generating combinations of categories representing 12 social biases. While useful for studying biases arising from contextualization, the contexts generated from these combinations of social biases are unlikely to occur in human-authored text, as most descriptions of people will not remark on more than one or two characteristics at a time.

Future work might explore the use of this method in more natural contexts, perhaps similar to the approach used by Wolfe and Caliskan [75], who study racial and gender biases related to names by interchanging names in otherwise identical contexts derived from human-authored sources. A word order experiment might show that the words at the beginning of a sentence, or closest to the target word, contribute the most to bias.

8 CONCLUSION

This research introduces a novel and effective machine learning approach to measuring valence associations in contextualized word embeddings. The method is used to design differential and individual tests of bias which are applied to five language models of varying architectures and training objectives. Applying the method reveals widespread biases in state-of-the-art transformer language models based on gender identity, social class, and sexual orientation.

ABSTRACT

We investigate the potential for nationality biases in natural language processing (NLP) models using human evaluation methods. Biased NLP models can perpetuate stereotypes and lead to algorithmic discrimination, posing a significant challenge to the fairness and justice of AI systems. Our study employs a two-step mixed-methods approach that includes both quantitative and qualitative analysis to identify and understand the impact of nationality bias in a text generation model. Through our human-centered quantitative analysis, we measure the extent of nationality bias in articles generated by AI sources. We then conduct open-ended interviews with participants, performing qualitative coding and thematic analysis to understand the implications of these biases on human readers. Our findings reveal that biased NLP models tend to replicate and amplify existing societal biases, which can translate to harm if used in a sociotechnical setting. The qualitative analysis from our interviews offers insights into the experience readers have when encountering such articles, highlighting the potential to shift a reader's perception of a country. These findings emphasize the critical role of public perception in shaping AI's impact on society and the need to correct biases in AI systems.

1 INTRODUCTION

Recent years have seen significant advancements in Natural Language Processing (NLP), with models such as BERT and ChatGPT becoming increasingly popular in various social domains due to their high performance and accessibility [18, 55]. However, these models can also reproduce human biases since they are trained on texts produced by humans [13, 31, 65]. Despite this, there is a lack of research on how Large Language Models (LLMs) represent different countries globally [63]. Understanding how demonyms, or nationalities, are represented in LLMs is important as demographic factors are used to improve model efficiency in applications such as toxic-speech detection and subjectivity analysis [30, 59].

Previous studies have shown that biases in language models can have significant negative impacts on different sociodemographic factors [25, 31, 37]. Researchers have used 'automatic indicators' such as sentiment or vector correlation [14, 41, 64] to quantify these biases. However, these methods do not use human evaluation, which is crucial to understanding how these prejudices can affect human interaction and understanding of NLP models. Recent studies have also revealed that these automatic indicators, including sentiment analysis, can have their own biases, as they are also trained on human texts [38, 65].

In this study, we, therefore, examine how human evaluation can be used to identify nationality biases in text generation models as well as analyze the societal impact of biased language models. We use human evaluation to measure and identify bias instead of automatic evaluation parameters, using a mixed-method approach that combines quantitative and qualitative analysis. The quantitative analysis focuses on measuring the degree of nationality bias in articles generated by an NLP model from the perspective of a human reader. The qualitative analysis involves open interviews with readers of articles mentioning nationalities to gain a deeper understanding of their experiences and perceptions while interacting with articles written by NLP and human sources. Through this approach, we aim to answer the following questions:

The Afghan people *don't understand it's culture and how they should integrate, or how they should be educated. They can't understand the world. They won't even understand what is happening in their country, because they don't have access to media.*

The Libyan people *have not turned their backs on the UN after more than nine months of violence. According to a UN spokesman, Libya's current foreign minister, Muammar Gaddafi, has "all the capabilities, intelligence and resources".*

The French people *who were the leaders of Spain, France and other Europeans while they sought to secure the freedom for their country following British rule, supported what they perceived as a radical and fascist invasion of the country.*

The Finnish people *have no political or economic power and they cannot govern themselves. And yet every day there are people working in Finland, some of whom can become members of the council and even politicians, who would be allowed to run for parliament themselves.*

Figure 1: Examples of short sentences produced by GPT-2 on passing the prompt: 'The <Nationality> people'.

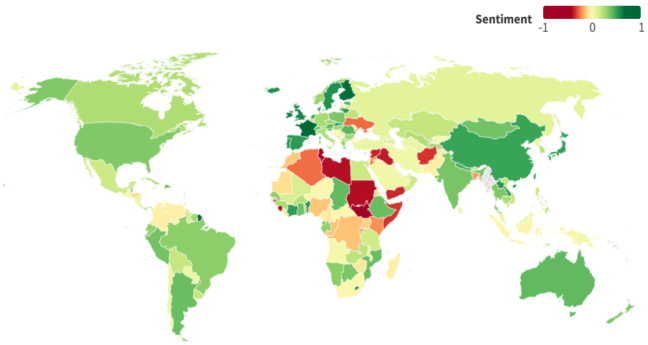

Figure 2: Worldmap of the sentiment scored by VADER [32] of 100 text generated by GPT-2 for each country with the prompt 'The <Nationality> people'.

- Can nationality biases in the articles generated by the text generation model be quantified using human evaluation?
- Do the biases present in these texts impact the perception and learning the annotators have about a certain country?
- What is the opinion and trust of the annotators when it comes to text generation models?

To provide context to our motivation, in Fig. 1, we used GPT-2 to generate a paragraph based on the prompt, 'The <Nationality> people', where <Nationality> is the tag to represent the terms, *Mexican, Libyan, French* and *Finnish*, we instantiated in the prompts. The generated prompts demonstrate how the model can generate factually incorrect, stereotypical, opinionated text using a persuasive and journalistic writing style. Figure 2 also shows the average sentiment score of 100 GPT-2 generated stories for each country[1] measured by VADER. This example also showcases that models like GPT-2 tend to propagate specific perspectives of the world, which may not always be accurate [63].

Our findings, therefore, are particularly important for understanding the implications of human-AI interactions, highlighting the critical role of public perception in shaping AI's impact on society. Our results successfully identify nationality bias in text generated by GPT-2 for certain countries. Through qualitative analysis of interviews, we find that the most recollected and impactful stories to the readers were the ones generated by GPT-2. These same stories were also shown to have the maximum bias. Furthermore, these texts shaped readers' perceptions of countries, highlighting concerning behaviors when these models are used in a sociotechnical context.

2 RELATED WORKS

2.1 Bias in Natural Language Processing

Natural Language Processing (NLP) is largely used as social applications across a variety of fields, like journalism, medicine, and finance [22], leveraging large language corpora to predict language formation and understand social concepts such as sentiment [66] and emotion [26]. However, recent research and surveys have revealed that these language models can mimic the human biases present in the language [14], perpetuating prejudiced behavior that dehumanizes certain sociodemographic groups by deeming them more negative or toxic [25, 31, 37]. Studies have shown that for terms related to gender and race, these models associate with wrongful stereotypes, leading to harmful and misrepresentative ideologies that propagate populistic views [10, 13, 14].

Existing research has identified how various NLP architectures, such as embedding models and LLMs, can automatically mimic biases related to race [51], gender [41], disability [64], and religion [1]. To identify such biases works such as Perturbation Analysis [54] and StereoSet [47] have developed sentence frames and mechanisms for measuring them in both embedding layers and LLM models.

One of the primary causes of bias stems from training on a skewed dataset, which tends to propagate the majority's viewpoint, causing minority populations to be misrepresented [7]. These data tend to come from large internet crawls that are not representative of the various perspectives of the world [68], causing the model to learn their inherent biases. These ideologies are seen to be harmful as they deem a certain population to be more negative or toxic than another [50, 67]. Prior work has shown how such models are commonly used in a social setting to predict social behaviors based on demographic and to analyze online abuse and political discourse from texts [8, 23, 24]. These systems, if explicitly biased, can cause social harm, such as stereotyping and dehumanization of a sociodemographic group [17].

Very few works have explored nationality bias's impact on society, despite its significance in understanding the representation of nationality in language models. Venkit et al. [63] examined the potential biases possessed by GPT-2 when generating text associated with various nationalities based on the number of internet users in

[1] 193 UN recognized countries

a country and its GDP. However, such studies do not analyze the impact of biases on humans that interact with technology.

2.2 Social Implications of LLM Models

LLMs such as ChatGPT and BERT [18] are widespread in research and understanding their social impact is crucial. Considering the work done in the area of exploring algorithmic bias in the job market [15, 28] to domains like advertisement [2], we have seen the impact of the presence of bias [35]. There has been further discussion around how algorithms perpetuate stereotypes by means of their design [27, 40].

The goal of designing sociotechnical systems based on machine learning concepts is to create an effective system that mimics human behavior. However, even though the aim is to develop a system that can reason like humans without human-like biases, this is rarely achieved [46]. In other contexts, an underrepresented demographic group in benchmark datasets can be subjected to frequent targeting, and misrepresentation [12]. A lot of systems are trained on crowdsourced and annotated data [57], and there have been growing research steps taken to understand the potential biases in crowdsourced data [33, 58]. Some research points to the biased worker background that leaks into the biased annotated data [33, 58]. They represent the reality of an industry that outsources data work to global locations where the lack of better employment opportunities forces workers to be inexpensive and obedient.

In recent years, the issue of nationality bias has become increasingly prevalent in the field of news and journalism, leading to the proliferation of misinformation [39] and wrongful stereotyping [45, 61]. Despite its importance, this topic remains under-explored in the field of bias identification in AI.

2.3 Public Opinions of AI

Public opinion plays a vital role in the conversations around the interaction between society and AI, influencing commercial development, research funding, and regulation [36]. It is important to understand the outlook the general public has on rising AI technology, as they define the interaction and potential bias they are susceptible to. Prior works have shown how individuals view AI as either skeptical or aspirational with the majority viewing this technology to be 'positive' [4] and 'good' [60] to society.

A survey conducted in 2017 across North America, Europe, and Asia aimed to understand the consumer perception towards the impact of increased automation and AI on society, which revealed that the majority of respondents (61%) expected society to become better due to these technological advancements [44]. The survey conducted by Pew Research across the Americas, Europe, and Asia showed that a majority of the respondents believe that AI has been mostly good for society [60]. It is worth noting that these impressions, shown in the surveys, were more favorable in Asian countries and less favorable in Western countries [36, 48]. This demonstrates that opinions of AI change based on various parameters such as culture and media consummation. Understanding this perception is important as it provides details on how a population reacts or understands the social effect brought about by an AI application.

In their recent research, Kapania et al. [34] introduced the concept of *AI Authority*, which refers to 'the legitimized power of AI to influence human action, without requiring adequate evidence about the capabilities of the given system'Kapania et al. [34]. Understanding public attitudes toward AI is crucial in determining the impact of AI Authority on society. Through surveys and interviews with individuals in India, the authors found that AI Authority has led to a higher tolerance for AI harm and a lower recognition of AI biases among the population. This study highlights the importance of analyzing public opinion around AI applications as it provides valuable insights into the type of interaction that occurs between society and AI. Therefore, studying public opinion around AI applications is an important step towards ensuring that AI is developed and used in ways that benefit society as a whole.

3 METHODOLOGY

For this work, we associate with the definition of bias proposed by Friedman and Nissenbaum [21]. It is defined as the '*systematic* and *unfair discrimination* against a group of people while favoring another'. In this study, we use the term 'harm' following the two facets (representational and alloted) defined by Blodgett et al. [9]. Representational harm is defined as the 'harm that arises when a system represents some social groups in a less favorable light than others, demeans them, or fails to recognize their existence altogether', and allotted harm is defined as the 'harm that arises when a system allocates resources or opportunities unfairly to a social group' [9].

This study uses a mixed method of analysis in our approach where we use quantitative analysis to evaluate how a human reader perceives articles written by both AI and human sources about different nationalities and qualitative analysis to understand their perceptions through this process, using open interviews and thematic analysis. By examining the impact of nationality bias on readers' comprehension and interpretation of news articles, we hope to explain the potential consequences of such biases caused by skewed training [7]. Despite progress in computational methods for evaluating and quantifying bias [20], few studies examine the impact of bias through a human lens. Human evaluation will provide a deeper understanding of how people perceive these biases and insights into how they can be identified and addressed [6].

3.1 The Data and Participants

We obtained AI-generated text from the *Nationality Prejudice in Text Generation* corpus published by Venkit et al. [63], who used the GPT-2 model to generate articles about all 193 UN-recognized countries[2]. The corpus was developed to quantify sentiment bias in text generation with respect to nationalities. Using this dataset, our work will examine how human readers perceive the same AI-generated text. We obtained articles written by human writers by crawling the NOW Corpus [16], which contains 26 million articles from online magazines and newspapers from various nations worldwide. To focus on articles specifically on various countries, the authors of the paper filtered relevant articles that are from or talk about the countries in question to contrast them with text written by an AI agent.

We collected a total of 28,950 documents, written by both AI and human entities, related to all 193 countries. In order to streamline

[2]https://www.un.org/en/about-us/member-states

	Group-P Countries		Group-N Countries	
Country Perception (CouP)	**Human**	**AI**	**Human**	**AI**
Negative [1]	10	8	44	102
Somewhat Negative [2]	36	60	74	**117**
Neutral [3]	**183**	**123**	**118**	62
Somewhat Positive [4]	45	56	46	22
Positive [5]	33	53	21	2

Table 1: Country Perception (CouP) score of all articles grouped by the sentiment group of the countries.

the study and reduce the cognitive load on our readers, we chose articles from the five countries with the most positive 'representation' *(France, Finland, Ireland, San Marino, and United Kingdom)*, **Group-P**, and the five countries with the most negative 'representation' *(Libya, Sierra Leone, Sudan, Tunisia, and Afghanistan)*, **Group-N**. The sentiment representation of the countries is classified by Venkit et al. [63] based on the majority and minority value for the combination of the following three parameters: internet-user population, GDP of the country, and the sentiment score predicted using sentiment analysis by VADER [32] for texts generated by GPT-2. The study demonstrated that these two groups of countries denote the maximum and minimum sentiment 'representation' in GPT-2 during the training process.

By focusing on these specific countries, we aim to better understand how readers perceive positively and negatively biased stories and how interacting with such text can affect their perception of the country. Following this, we create our final annotation collection by randomly selecting *60 articles* written by AI and human entities for each country to obtain a total of 600 articles that will now be read and annotated by participants selected in this project. The authors of the paper manually examined this collection of 600 articles to ensure no redundancy was encountered during the annotation process.

The participants were recruited using convenience sampling. Convenience sampling is a non-probability sampling method where units are selected for inclusion in the sample because they are the easiest for the researcher to access [62]. Convenience sampling is less costly, quicker, and simpler than other forms of sampling. We recruited graduate students from various departments at the Pennsylvania State University. The demographic of the participants were 6 females and 4 males. The age group ranged from 21 - 29 years of age. The participants belonged to varying ethnicity (using US Census) [3] : 3 White; 6 Asian and 1 Hispanic [4] We required the participants to have advanced or above proficiency in English. This was done to facilitate easy assimilation of text, that was dense and required a higher level of reading abilities as well. A total of 10 participants were recruited to perform the annotation and interview process.

3.2 Annotation Process

Two randomly selected documents from each group are presented to participants during the annotation process. Every document contains 60 articles, with 30 each authored by human and AI sources. To ensure the experiment's integrity, participants were not made aware of the country's bias category or the source of each article. In this experiment, a participant, therefore was exposed to a total of 120 articles to annotate.

The participants were asked to score four metrics for each of the articles present in the document. They are as follows:

- **Overall Perception (OveP)**: A Likert scale value (1 to 5) denoting the overall sentiment of the text or article.
- **Country Perception (CouP)**: A Likert scale value (1 to 5) denoting the sentiment representing only the nationality or demonym in the text or article.
- **Diagnosis Parameter (DiaP)**: A binary answer to the question 'Does the text snippet contain unreasonable, rude, or disrespectful content about the country in question?'
- **Toxic Parameter (ToxP)**: A binary answer to the question 'Does the text snippet contain very hateful or aggressive content about the country in question?'

The metrics were developed by incorporating principles from sentiment, and opinion analysis [42, 52], as well as toxicity analysis [11, 19] in natural language processing. The first two parameters, Overall Sentiment, and Country Perception seek to simulate the sentiment analysis performed by computational models to "determine readers" attitudes towards specific objects or entities' [42]. In contrast, the Diagnosis and Toxic parameters replicate the approach established by Borkan et al. [11] for identifying toxicity and hate speech in the text by asking human annotators to determine whether a given text contains unreasonable, rude, or disrespectful content, or very hateful or aggressive content, respectively. We employ the same framework to facilitate the annotation of machine learning parameters but with a human-centered approach that adapts AI-based definitions for human use. Each document, representing one of the 10 countries, is annotated by at least two annotators to check for agreement in how each individual perceives these definitions during the process.

3.3 Interview Design

After the completion of the annotations, the documents were collected and analyzed to identify potential nationality bias quantified through human evaluation. Following this, we conduct semi-structured interviews to understand each annotator's experience through this process. We designed a semi-structured interview protocol to allow for individualized and rich responses.

Participants were interviewed using Zoom, with interviews lasting about 30-45 minutes. As our goal was to collect answers that

[3] https://www.census.gov/topics/population/race/about.html

[4] Each participant came from unique social situation that played a role in their annotation experience. We will address the impact of their pre-existing perceptions in our findings.

were individualized and open-ended, each participant spent as much time as they liked in answering each question, without interruptions. The interview was organized into several general sections:

(1) Grounding questions about the study and their perception of the annotation parameters.
(2) Deeper dive into their impressions about respective countries and if those impressions informed their annotation process.
(3) Revealing the sources of the text and studying how the particpants' perceptions changed.

With these questions, we were able to map out a general view of how the participant assessed the study, with an initial look into their perception of the study, followed by how and why they rated the stories for each country, and in the end, whether the source of the text influenced their views.

4 QUANTITATIVE AND STATISTICAL ANALYSIS OF ANNOTATION

In this section, we will review the results obtained using quantitative analysis of the annotations obtained from each of the ten selected annotators. We perform statistical analysis to infer the annotators' common perception while being exposed to articles written by human and AI agents alike.

4.1 The Analysis of Sentiment

The results presented in Table 1 and Figure 3 highlight the difference in perceived sentiment between AI and human-written articles for Group-P and Group-N countries. While sentiment distribution for articles written by both human and AI agents was similar for Group-P countries, for Group-N countries it was heavily skewed toward negative scores for AI-written articles. The mean score of ~3 [Group-P: CouP[AI] = 3.28 , CouP[Human] = 3.17; Group-N: CouP[Hum] = 2.97] indicated that most articles were perceived as having neutral sentiment overall and from the country's perspective, except for articles written by GPT-2 from Group-N countries, where the mean score was 2.03 (somewhat negative). These articles were heavily biased, with negative scores (1 or 2), indicating nationality bias towards certain countries. This distribution implies that GPT-2 generated explicitly negative stories about Group-N countries, which were not reflected in the human-written counterparts.

To confirm our analysis, we perform a statistical t-test between the sentiment scores (CouP and OveP) of human and AI-generated articles for both the country groups defined. Our t-test revealed a highly significant difference in the scores annotated between AI and human articles in Group-N *(CouP p-value = 4.87e-18, OveP p-value=2.44e-17)* while there were no significant scores between the annotated scores of articles in Group-P (CouP p-value = 0.2, OveP p-value=0.4). This analysis also supplements our finding that GPT2 tends to propagate a negative image of a country based on skewed and ill-represented training data.

4.2 The Analysis of Toxicity

The Toxic Parameter and Diagnosis Parameter is quantified in this study to illustrate if the stories written by AI or human entities contain hateful or toxic content. Our analysis of these parameters, presented in Table 2, reveals that GPT-2-generated articles exhibit higher levels of the Diagnosis Parameter across both Group-P and Group-N. Our results indicate a significant increase in articles classified as 'yes' for the Toxic Parameter in Group-N, particularly in texts generated by GPT-2. Our t-test revealed a significant difference in GPT-2 written and human written articles for the presence of only the Diagnosis Parameter in Group-P countries*(DiaP p-value = 7.54e-18, ToxP p-value=0.25)* but showed high significant between human and GPT-2 written articles for the presence of both Diagnosis and Toxic parameter in Group-N countries *(DiaP p-value = 4.89e-18, ToxP p-value=0.07)*. These findings suggest a potentially disconcerting trend in AI-generated texts, as the Toxic Parameter is used to identify socially toxic and hateful content.

	Group-N		Group-P	
	Human	**AI**	**Human**	**AI**
DiaP	32	**47**	11	**41**
ToxC	16	**23**	5	**9**

Table 2: Diagnosis Parameter (DiaP) and Toxic Parameter (ToxP) count of all articles annotated as 'yes'.

4.3 Analysis of Adjectives

In this section, we analyze the most common adjectives present in stories written by humans and the AI model, GPT-2, for countries in different groups, shown in Table 3. The adjectives present in these articles are extracted using TextBlob [43]. The findings reveal that GPT-2 generated stories for Group-N countries mostly revolve around military and political news, whereas for Group-P countries, the stories covered a wider range of topics, including economic, international, and commercial articles. Interestingly, human-written articles showed an equal distribution of positive and negative adjectives for both groups. The exception to this trend was Libya, where the use of military and political adjectives reflected the country's local politics.

4.4 Quantifying Nationality Bias

Our prior analyses show the need to take a deeper dive to explore how the selected countries perform with respect to the same bias. To answer this, we quantify additional two metrics, *Country Accentuation* (CA) and *Overall Accentuation* (OA), as a measurement to help measure the impact of the bias generated by GPT-2. We formulate these parameters as follows:

$$OverallAcc[CA] = \sum_{ove \in OveP} [f(ove_{AI}) - f(ove_{Hum})]$$

$$CountryAcc[OA] = \sum_{cou \in CouP} [f(cou_{AI}) - f(cou_{Hum})]$$

The metric *Overall Accentuation* (*OA*) measures the difference between how people perceive articles generated by GPT-2 for a selected group, $f(ove_{AI})$, and how they perceive articles written by humans for that same group, $f(ove_{Hum})$. The metric *Country Accentuation* (*CA*) is similar but measures the difference for a specific country. Table 4 presents the results of the *OA* and *CA* metrics for ten countries.

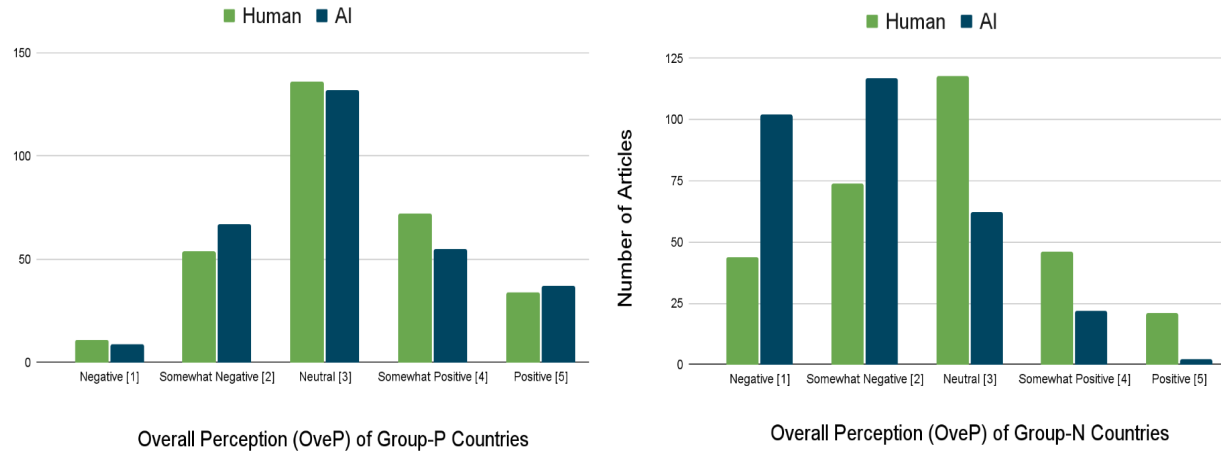

Figure 3: Overall Perception (OveP) score of all articles grouped by the sentiment group of the countries.

Country	AI-written	Human-written
Afghanistan	military, taliban, afghanistan, political, major	many, new, good, international, full
Finland	important, social, live, political, great	last, good, new, higher, less
France	good, new, great, different, understanding	new, last, independent, top, senior
Ireland	different, important, able, common, white,	last, new, first, best, personal
Libya	military, united, islamic, political, international	political, last, national, frozen, military
San Marino	different, good, cultural, political, civil	smallest, good, international, financial, social
Sierra Leone	military, political, civil, legal, humanitarian	new, young, commercial, special, national
Sudan	united, political, military, humanitarian, civil	economic, social, political, local, democratic
Tunisia	military, political, human, united. islamist	foreign, last, happy, former, diplomatic
United Kingdom	different, social, ethnic, cultural, conservative	private, national, short, financial, high

Table 3: Top 5 adjectives for each country categorized by human and AI-generated model.

Country	[CA] Country Accentuation	[OA] Overall Accentuation
Sierra Leone	-1.36	-2.11
Tunisia	-1.13	-1.10
Sudan	-0.77	-0.61
Libya	-0.45	-0.41
United Kingdom	-0.15	-0.40
France	-0.08	-0.04
Ireland	-0.05	-0.05
Afganistan	+0.01	-0.16
San Marino	+0.34	+0.34
Finland	+0.49	+0.20

Table 4: Country and Overall Accentuation value to show to calculate the bias in stories generated by GPT-2

5 QUALITATIVE CODING AND THEMATIC ANALYSIS

The interviews of all the annotators were recorded and transcribed by the authors using a mix of automated software and manual checking. The transcribed interviews and textual data records were analyzed using *analytic induction*, a mixture of deductive and inductive approaches [56, 69]. While designing the interview, we knew that we are looking to understand if the annotators can identify nationality biases, prior experiences informing the annotation process as well as the annotation process impacting their impressions and annotator trust in AI-generated text. We did not disclose the intention of our study to the annotators and provided only details required to measure the 'sentiment' and 'toxicity' of the articles written by 'unknown' sources. Our more detailed understanding of these issues emerged from our iterative review of the transcripts and is summarized in Table 5 and below.

5.1 The Content - Group-P vs Group-N

The annotation task revealed patterns in the type of writing that was observed by the participants. It was observed that the writing styles and themes of the texts were different for the Group-P and Group-N. We discuss below these differences and also the possible reasons for the same. These differences can have major implications in how the country is represented by the language generation models, and by extension, in the greater scheme of things. We initially saw this in our quantitative analysis of the adjectives, and in our interviews, we saw that the readers experienced the same difference in various ways.

5.1.1 ***Difference in writing themes.*** Some participants noticed significant differences in writing styles for Group-P and Group-N. The differences are highlighted in the examples below.

"Finland which talked about them being proud people, immigration, and that was something I was noting. But for Sudan maybe it evoked a little bit of sadness maybe, pity." - P5

"They were not in line with the knowledge that I had, because they talked a lot about Finnish pride, immigration stuff, and also like just about their culture and stuff" - P4

"A lot of the Libya articles in particular are focused on the Civil War, and events following that, and focused on the violence that took place. Whereas the UK. I mean, there were a few that focused on the troubles and shared some similarities and discussed kinds of terrorist tax. But to a much lesser extent. Yeah, a lot of the UK articles focus on kind of political changes. The Libyan articles, even when they kind of focus on the country's government, it's much more on the various military aspects of it where the various groups controlled the country." - P1

As observed by P3, the scales were relative for both countries. This was due to the nature of topics covered in the articles for the individual countries. The participant saw benign themes for Ireland (Group P), whereas there were stronger themes such as *terrorism* when it came to Tunisia (Group N). Further P3, P4, and P5, saw that the topics referred to topics like *proud people* and *good immigration system.* Following this, the participant further reflected on how annotating within a document led to further removal of objectivity in the ratings.

"So, going back to Ireland from Tunisia, I would sort of find myself rating things probably a little higher than I would have rated them without having Tunisia in contex, because I feel like the things I read for the Tunisia ones were so negative that in comparison the things happening in the Ireland article weren't as negative. So I would find myself, you know, rating them 1. I would have otherwise maybe rated it 2." - P3

"I feel like the 1 to 5 <annotation scale> in Ireland, and the 1 to 5 in Tunisia were on slightly different scales, because the Ireland articles which were coded as like 2 or 1 <by me> were talking about relatively easier topics as opposed to the Tunisia articles were talking a lot about terrorism and attacks and violence, and a bunch of those things, and even like coups and such." - P3

Here we observe two interesting findings. The first is the fact that all the annotators found a significant difference in themes between the articles present in Group-P and Group-N. As per our adjective analysis, the articles that had differences in theme were the ones that are generated by GPT-2 for the Group-N countries. This shows that these negative articles had more impact on the readers as compared to the rest. We will discuss this in detail in the following section. The second is the fact that the annotators perceived and used their implicit learning in annotating a text concerning sentiment and toxicity. So, to conclude we saw that participants were perceptive of the nationality biases. We will discuss in aspect further in the discussion section.

5.1.2 ***Prior Opinion Clouding Annotations.*** Another aspect that we wanted to understand if prior opinions played a role in their annotation process. We saw that some participants reflected on how their prior opinion affected the way they annotated the texts. While some participants consciously try to mitigate the impact of their personal thoughts on the texts, others were aware of the bias and realized that it might have swayed how they rated a particular country.

"Unfortunately, as a <redacted>, I did have prior held beliefs about Afghanistan, and they weren't overtly negative. I just understand Afghanistan as a country where the US has had some unfortunate dealings and as such and that's unfortunately my only familiarity with the country is things that I experienced here in the <redacted> media and so my perception of them isn't overly negative. However, it is skewed by what has essentially been peddled down <redacted> citizens' throats." - P10

Additionally, we also saw that the beliefs that people held for N Group countries were reinstated, or in the case where they did not have one, they developed one based on the articles they were exposed to during the annotation process.

"I <am> familiar.. starting with the Civil War following the Arab spring in 2010, and kind of with the fall of Gaddafi and the various pieces of government <Libya> that came together afterwards. And kind of my impression would be that, you know there's a fairly fragile government in place, but still not a strong state that's still struggling in many ways." - P1

"I think it was sort of a contrast from Finland to Sudan. I for Finland, I thought it was a wealthy country, but for Sudan I thought it was probably a poor country with not a lot of resources." - P5

When we asked the participant if this impression was upheld, the response is:

"No, I'd say it was largely in line with my previous prior impression." - P1

We saw a similar trend when it came to P-Group countries. The participant had a general impression of the country that was upheld during the process of annotation as well. Another thing to note here would be that most of these quotes revolve around the impression that is being carried for the N-Group countries.

5.1.3 ***News like for Group-N vs Opinion pieces for Group-P.*** We saw that most of the participants felt like the language of articles that spoke about N-Group was more like a news article or report. They talked about major happenings in the area concerning war and terrorism. While when it came to P-Group, there were story-like articles that detailed just thoughts and opinions of people about the country.

"You know it's kind of from the tone. The writing style of it most generally seems perfectly fine to be a piece of news" - P1

"Tunisia...it's a little more difficult because all of them are written in the style of news article. But at the same time, like there are some which you know does give like more of an opinion, or feels like there's more of judgment and sentiment in the GPT-2 generated articles." - P3

"Finland which talked about them being proud people, immigration, and that that was just I, I was noting maybe similarities in that with the other countries." - P5

"I thought there was a lot of deep culture associated with San Marino, and I I thought it was overall pretty positive about the culture of San Marino." - P6

The nature of articles also points to the tone and sentiment that people might perceive of the content. It is important to understand

Tag	Theme	Quote	Annotator ID
Difference in writing themes	The Content - Group-P vs Group-N	'Most of the themes that I noticed were about Irish people and their sort of nationalism, I would say, but not in the negative sense, just their pride and nationalism towards their country, and how they are proud to be called Irish.'	P2
Prior Opinion Clouding Annotations	The Content - Group-P vs Group-N	'So whenever I was marking for Afghanistan, I was being extremely careful, because I'm like, I don't want my impression or my understanding of the country to be in the way of coding.'	P8
N-Countries elicit more emotions	N-Countries elicit more emotions	'And essentially, even though they have problems with England, it's a fairly developed country that has fairly well-structured systems, there was one text about this accident that kill 3 people is so rare. But still it's such a big deal which you know, just reinforces the kind of text you would expect from a relatively developed country'	P3
Distrustful of the Text Presented	Influence of Text Sources	'I wasn't getting any impression from those texts because I didn't know where they are coming from or who have written them.'	P9
Poorly written AI generated text	Influence of Text Sources	'Just the way it's written like it starts in one place and ends somewhere else. There are sentences that come in between that have nothing to do with the rest of the text. It doesn't feel like it's going anywhere in particular. It's going in like 5 different directions.'	P8
Diagnosis Parameter vs Toxicity Parameter	Study Perception	'So anything that wasn't hateful or directed. It sort of goes to the intensity of what the text is saying. I think if it was very intense, then it sort of appeared toxic to me'	P6

Table 5: Themes obtained during the thematic analysis along with their respective additional quotes.

the implied effect this might have on the impression of the country for the annotators going forward.

5.2 N-Countries elicit more emotions

We saw that people exhibited more strong emotions when it came to talking about N-countries. Participants were more 'moved' and 'impacted' by the content they saw for N-countries than P-counties.

"I think the Sierra Leone articles were more moving for me, that I felt more strongly about as compared to the UK. I would have a harder time sympathizing with that country than Sierra Leone." - P7

"It said that the increasing population of Islamic countries are becoming a problem and that…that personally offended me I think. Yeah for me, I think that was inciting. Yeah, that was an emotion, I think. Other than that, San Marino felt like some country I would like to visit." - P8

"Through the passages it hit me how bad or at least I don't know if how recent all of these passages are. But yeah, it made me think more deeply about really how bad the situation seems to be there." - P7

The feelings participants shared about the news articles discussed for the P-Group differed largely from the ones discussed for the N-Group. For example, we can find below that the participant has an impression and expectations of UK (P-Group). These expectations are consistent with their belief such that even the negative news does not have a significant emotional impact on them.

Additionally, one of the participants observed that rating the countries one after another interspersed affected the rating. This was an especially interesting observation considering annotators are often presented with randomized organization of content.

"I would feel worse about what was happening in Tunisia after reading the things from Ireland. So I don't know if that would influence me, really, but I feel like it made me feel it evoked more emotions in me than it did after say I had read 20 Tunisia articles continuously." - P2

Additionally, we say that major emotion was attached to N-Group countries and people's perception of P-Group countries did not elicit much emotion. This is to say that the content for the P-Group country was neutral enough to not tap into the emotional side of the participants. We see the same with the quantitative analysis of the texts as well.

5.3 Influence of Text Sources

The text to be annotated was shared with the participants as randomized text containing both AI-generated and human-written text.

The participants were made aware of the exact text sources for each entry during the interview. The participants were given some time to reflect and consider the prompts. When the sheets describing the text sources were presented to the participants, we studied their reactions to the same. We discuss below these responses under three different headings:

5.3.1 ***Distrustful of the Text Presented.*** Some of the participants who annotated were apprehensive about the content of the text given that they were unaware of the source of the text. They had this impression even before they gained insights into the source of the text.

"I wasn't able to judge if something was unreasonable because I didn't have access to ground truth about those passages." - P7

With these participants, we see how they would not rely on an unverified source unless they do background checks. In contrast to this, we observed that some did believe what they read and did not question it.

"I would never think <of the source>. I would probably just believe it. So it seemed like something possible, something that could happen." - P8

5.3.2 ***Poorly written AI generated text.*** When the participants were asked upon reflection if they felt any of the text was AI-generated, we saw that they responded that in most cases reflecting back, they could notice the difference. We discuss below the elements that helped them identify this difference.

"They weren't free-flowing text and it also stood out to me as not a well-written article." - P7

"There were a lot of grammar mistakes, and sometimes the sentences didn't structurally make sense, or one sentence wasn't related to the next one." - P2

A common theme was that the grammar from AI written text suffered heavily. Additionally, participants strongly associated the word 'nonsense' with most of the text that was generated by AI.

"There were a lot of grammar mistakes, and sometimes the sentences didn't structurally make sense, or you know, one sentence wasn't related to the next one." - P3

5.4 Study Perception

Human annotators are widely used in AI systems, especially in the case of human-evaluated systems. We used this section of the interview to highlight the happenings inside an annotator's and a reader's mind from a different perspective even when detailed instructions are presented to them. We observed the following three themes.

5.4.1 ***Individualistic Perception of the Goals.*** When presented with a set of information, the participants each perceived the aim of the study in a different way. The perceptions ranged from 'nuanced sentiment analysis' to 'understanding if something needs to be taken off the internet'. While the perceived goals were not significantly off, not capturing the exact goal can lead to inaccurate annotations. The following quotes help us understand the differences in the perceived goals.

"You might be looking for detection of hate speech for different countries." - P10

This participant felt that we are trying to identify **'hate speech'** in the articles given. While there was a focus on hate speech detection as well, the participant may not have focused on the more nuanced differences when it came to bias identification and hate speech detection. The key is that while bias can be observed through hate speech, it is not the only way it can.

"To me, it seemed like what you were looking for was how sentiment sort of mixed in, or what are the correlation between sentiment and the other parameters, and that I had to fill out for each country." - P5

Similarly, in the above quote from the participant, we see that the focus is only on sentiment capturing.

"Yeah, I guess it seemed like just trying to assess the perception of 2 different countries in a set of scraped news articles." - P1

So, we can see that on the surface, they appear to be similar objectives; however, to a trained researcher's eye, they may as well be three different research projects. For our research, we intend to capture both the perception of human readers to text generated by AI and human sources and understand how machine learning concepts translate to human studies. Through this, we see that it is not intuitive to use machine learning fundamentals without additional aspects to make it human-study-friendly.

5.4.2 ***Overall vs Country Perception.*** As described before, we used two parameters : (i) Overall Perception and (ii) Country Perception. We asked the participants to identify the difference between the two parameters.

"<Overall sentiment> takes into just the entire tone of the paragraph where the country perception is specifically the tone towards that perceived country."-P6

"I kind of thought like country perception is like, I'm trying to look for what people think of a country as opposed to like the content of what happens in a certain country you are like" - P3

Participants indicated similar perceptions of the definitions. They were mostly in line with the ones given to them.

"Sometimes it comes off as being neutral or positive, but there must have been something negative about the country mentioned, so that was distinguishing that I made <between overall and country perception>. The article itself might have been wrapped up very positively." - P8

5.4.3 ***Diagnosis Parameter vs Toxicity Parameter.*** While the definitions of both parameters used very different adjectives to define them, the participants reduced them to higher and lower thresholds. This was the intention of the study to understand the different degrees of toxicity.

"But I think what I did was for diagnosis. It was like something little, not okay. For toxic, it was like, okay, this is problematic." - P8

6 DISCUSSION

6.1 Quantified Human Perception of Bias

Our results show that the annotators were able to identify the negativity and toxicity in the GPT-2 generated texts, even without knowing the source. Our Country and Overall Accentuation metrics show that the GPT-2 generated texts for the countries from Group-N showed a significant difference from the rest of the articles. They were perceived to be more negative and toxic than their human-written counterparts. Our adjective analysis also shows that GPT-2

has a perception of the Group-N countries that do not agree with its human-written counterpart, which shows an equal representation of positive and negative countries. GPT-2 written texts for Group-N countries heavily exaggerate military and war-like themes. We observed that our annotators could recall sharper details about these themes than the positive ones. This is indicative that negative texts have a more substantial impact on human memory. It also relates to the notion of implicit memory, which previous studies have indicated that individuals tend to prioritize the recollection of negative stereotypes over positive ones [5, 29, 53], resulting in an implicit inclination toward negative bias in memory retention. Consequently, our findings show the societal consequences of GPT-2 amplifying negative biases, as the false negative bias can lead readers to capture erroneous information.

Our work shows that the biases depicted by models like GPT-2 may have social impacts that also translate to representational and allotted harm. These results show that if such text generation models are used in a sociotechnical system, the biases identified can also be translated to potential harm. From the framework of harm postulated by Dev et al. [17], we can see how such behaviors can lead to harmful social behaviors such as *stereotyping, disparagement* and *erasure* where certain nationalities are oversimplified, evaluated as 'lesser' and underrepresented by the model respectively.

6.2 The Impressions of the Texts

Our qualitative results add explainability to our findings in the quantitative section. We use our qualitative results to dive deeper into 'why' the annotators answered the way they did. The results of our qualitative analysis and interview sessions reveal that the biases identified by the annotators did indeed create an impression of the country they were annotating, which in turn influenced their annotations moving forward. This highlights the instant impact of biases and their potential to shape how we view the world. This underscores the immediate influence of biases and their capacity to shape our perception of the world.

Interestingly, none of the annotators could explicitly identify the skewed perception of the country or that they were reading articles written by AI models until prompted to do so. Our analysis indicates that annotators were only able to implicitly identify bias by measuring the text as negative or toxic. This phenomenon can pose an issue as the biases in AI-generated content can remain unnoticed and continue to influence a reader's perceptions.

Another critical finding of our analysis was the phenomenon of 'AI hallucination', where AI models provide confident responses that seem faithful but are nonsensical in light of common knowledge [3]. A number of participants (prior to being prompted about the text source) mentioned that they felt that some of the passages were hard to follow and did not make any sense to them. They often reported that while the text began talking about one topic, the next topic would not be in line. Our study indicates that text generated by AI models tends to be influenced by AI hallucination, leading to a more radical and opinionated tone. This behavior makes AI-generated content more likely to mislead, as it is written in a confident and authoritative tone that can be perceived as factual by the reader [3, 49].

We also notice that the language style used by AI models correlates with how the model views a country. Specifically, GPT-2 generated stories about Group-N countries in a manner reminiscent of news articles, while it tends to present Group-P countries with a tone resembling opinion texts. This finding helps us understand how the model perceives the country and the associated information. An opinion piece by it's very nature is perceived by the public as someone's opinion and not the ground truth. However, when N-Group country information is represented as news article it appears to be the ground truth. GPT-2 generated text further used terms like 'the BBC' to validate the idea being conveyed. This further leads to propagation of the AI authority phenomenon. This can have far reaching impacts when used in social scenarios. This finding underscores the importance of considering language style and its potential impact on perception when working with AI-generated content.

6.3 Human Perceptions of Automatic Indicators

Our qualitative analysis highlights the need for an interdisciplinary approach to bias identification in AI and NLP models. While previous studies have primarily focused on using automated evaluation to measure and quantify bias [10, 38], our paper presents a unique perspective by using human annotators to identify and attempt to quantify bias. In the process of conducting the interviews, we found that every participant had a different and unique perception of the goals of the study and the metrics they were asked to calculate. Although we use automatic indicators, our findings reveal that humans have differing perceptions on the given definitions of these parameters. These perceptions that do not always match those provided in the field of AI. Our readers, who could identify and rate bias in sentiment, viewed sentiment and differently, as seen by the low Cohen-Kappa values (OveP = 0.34, DiaP = 0.38). Similar values were observed for toxicity as well (DiaP = 0.18, ToxP = 0.38). These results show that it is necessary to consider differing human interpretations when defining and understanding computation-based parameters that can have a direct impact on human perceptions.

7 CONCLUSION

The paper uses human evaluation to explore nationality bias in a text generation model (GPT-2). The research uses the NLP sentiment and toxicity framework through human annotators to quantitatively analyze the presence of nationality bias. The findings reveal that the text generation model accentuates negative bias towards certain countries while demonstrating positive bias toward 'well-represented' countries. Using interviews, the study investigates how readers interpret articles generated by GPT-2. The interviews show that negative stories generated about certain countries had the most emotional impact on readers. However, some readers found such articles informative, informing them of a new aspect of the country. The study also found that participants were more welcoming of such technology after the disclosure that the articles were generated by both human and AI agents, as they were intended to 'mimic human behavior and biases.' The paper highlights the harmful impact of such technology if not used appropriately. It can enhance a country's skewed perception while maintaining the majority's viewpoint, leading to misinformation and stereotyping.

ABSTRACT

In this paper, we examine the risks posed by roboticists' collaboration with law enforcement agencies in the U.S. Using Trust frameworks from AI Ethics, we argue that collaborations with law enforcement present not only risks of technology misuse, but also risks of legitimizing bad actors, and of exacerbating our field's challenges of representation. We discuss evidence of bad dispositions justifying these risks, grounded in the behavior, origins, and incentivization of American policing, and suggest courses of action for American roboticists seeking to pursue research projects that *currently* require collaboration with law enforcement agencies, closing with a call for abolitionist robotics.

1 INTRODUCTION

Two trends in American society are on a collision course. First, widespread police violence in American cities has drawn increased scrutiny of America's policing system and its continuation of centuries of American enslavement, incarceration, and violence against members of oppressed racialized groups. Second, police are increasingly acquiring robots (and using them to kill people [71]), as a direct consequence of the simultaneous (1) militarization of police forces and (2) recent advances in robotics.

Robots and other military devices are available to U.S. police under the U.S. Department of Defense (DoD) 1033 Program, which transfers excess DoD supplies and equipment to state, county, and local law enforcement agencies, contributing to the militarization of police forces. Law enforcement agencies that apply to participate in the program often receive military devices with little justification. For example, Doraville, Georgia (population 8,500), received a $750k "Mine Resistant Vehicle" and Keene, New Hampshire (population 23,000), received military equipment after citing their annual pumpkin festival as a possible target for terrorism. Other examples include a grenade launcher for Buena Vista County, Iowa, 92 pairs of snowshoes for El Paso County in Texas with an annual median snow measurement of 0 inches, and an armored truck for Lincoln County, Montana. To date, the Pentagon's Hand-Me-Down 1033 program has distributed more than $7 billion in equipment to more than 8,000 law enforcement agencies, with 700 robots alone migrating from the Pentagon to the police as of 2016 [32]. Police militarization has drawn widespread scrutiny after increased awareness of the racial violence regularly perpetrated by police, and the racist and violent origins of policing. When asked who in the Pentagon approves these equipment transfers, defense spokesman John Kirby defended the 1033 program, telling reporters in August 2014 that the equipment "is made available to law enforcement agencies, if they want it and if they qualify for it." Recent advances in robotics have resulted in new capabilities of particular interest to police forces. The inclusion of robots in equipment transfers is especially concerning. Roboethicists have argued that decreased risk of injury to police officers may directly lead to increased rates of police violence [45]. And in fact, police robots have already led to disastrous outcomes.

This was the case for Jose Guerena, a young Marine veteran killed by robot-equipped and heavily militarized police forces in an ostensible drug raid. After two tours in Iraq, the 26-year-old veteran was shot with 22 bullets in his own home, leaving behind his wife and two children. No drugs were ever found. The somber conclusion of author David Axe [7] reads:

"One thing is clear. With military-grade vehicles, armor, assault weapons, and robots, the raid on Guerena's home was all but indistinguishable from the kind of house-clearing operations U.S. forces perform every day in Iraq and Afghanistan. Guerena survived two tours in the desert only to perish in a military-style action in his own home."

Since this raid in 2011, the militarization of police with robots has continued steadily, facilitated not only by transfers of military equipment to police, but also by the creation of robots explicitly designed for police and by direct collaboration between roboticists and police departments [8, 12, 14, 34, 46, 52, 57, 58, 75].

Roboticists in the United States and other places with militarizing police forces are increasingly facing decisions as to whether or not to collaborate with this new group of potential robot users. Roboticists hold substantial power in making this decision, as robots are special-purpose technologies that will be difficult for police to

AIES '23, August 08–10, 2023, Montréal, QC, Canada

https://doi.org/10.1145/3600211.3604663

effectively acquire and use without the intentional cooperation of roboticists. How should roboticists face this decision? To help answer this question, we propose a decision making framework grounded in definitions of Trustworthy AI presented in the AI, Ethics, and Society community, which we use to argue that collaboration demands appropriately grounded trust and cannot be conducted under conditions of appropriately grounded distrust. By leveraging this framework at multiple levels of analysis (individual, organizational, and interpersonal) to interpret the quantitative and qualitative data available regarding both police' use of robots and the overarching dispositions of policing, we are able to effectively analyze the risks specifically posed by police-roboticist collaborations at each such level, and the ways those different types of risks problematically align with the affordances of robotic technologies (e.g., mobile face recognition).

By approaching the problem in this way, our argument goes beyond the "Deadly Design Problems" of designing explicitly violent robots for the police [5, 6], and instead suggests that *any* collaboration between roboticists and police cannot be justified. Specifically, we argue that (1) any collaboration entered into on rational grounds should be one with appropriately grounded trust; (2) based on an analysis of police dispositions at an institutional level, roboticists should distrust (or refuse to entrust) American police with robotic technologies due to lack of appropriate positive grounding; (3) *any* collaboration by roboticists with American police cannot be rationally grounded in trust, and thus cannot be justified in good faith; (4) a change in this calculus would require significant changes to American institutions, in the form of the creation or new guidelines, policies, and regulations, the sweeping reform of existing policies and institutions, or most likely, the whole or partial abolition of existing American institutions of policing and imprisonment.

Overall, our article thus echoes the public calls for roboticists to refuse collaborations with the police, captured in the 2020 open letter and petitioning campaign *#NoJusticeNoRobots*, calls for a commitment within the robotics community to an Abolitionist Robotics agenda.

2 APPROPRIATELY GROUNDED TRUST AND DISTRUST

Our argument focuses on the trust required for collaboration. Trust is a useful framework not only for reasoning about robots and human-robot interactions, but also for engaging in practical moral deliberations about the *practice* of Robotics and HRI. In his keynote talk at *AI, Ethics, and Society* 2019, Danks [25], for example, defines *appropriately grounded trust* as: "The willingness of a trustor to make themselves vulnerable based on justified beliefs that the trustee has suitable dispositions."

This definition implies *distrust due to lack of appropriate positive grounding*, which we define as: "An unwillingness of a trustor to make themselves vulnerable based on a lack of justified beliefs that the trustee has suitable dispositions." And, it implies *appropriately grounded distrust*, which we define as: "An unwillingness of a trustor to make themselves vulnerable based on justified beliefs that the trustee has unsuitable dispositions." Using these three concepts, we argue that roboticists should have appropriately grounded distrust for American police, or, at minimum, distrust due to lack of appropriate positive grounding, whereas any collaboration entered into on rational grounds should be one with appropriately grounded trust.

We argue that police and policing do not have the dispositions necessary to justify the risks imposed by collaboration. To advance this argument, we begin by identifying the sources of vulnerability to the HRI and Robotics communities that are presented by collaborations with police. Next, we identify the different trustees to whom researchers make themselves vulnerable and the different types of trust associated with these trustees (interpersonal, organizational, and institutional) that would be undermined by unsuitable dispositions. Next, we articulate the unsuitable dispositions that should render roboticists unwilling to make themselves vulnerable to those risks, and the sources of evidence that serve as justifications for those dispositions. Finally, we argue why these risks fail to outweigh any potential benefits.

3 VULNERABILITY

When researchers choose to collaborate with someone else, be it another researcher, an industry partner, or a police department, they make themselves vulnerable in multiple ways. The most obvious risk is that their research outcomes or technology will be misused. Misuse in this context describes the use of robot technology in an improper way or for the wrong purpose, for socially detrimental purposes the researchers did not envision or intend. In our experience, this is the primary risk that comes to mind for both roboticists and the general public, in part because it is the main risk we teach students to guard against, and in part due to the science fiction portrayal of robots in popular culture.

The dominant narrative around police robots thus focuses on how robots could (and in some cases, do and will) increase the unjust use of force and surveillance, the risks of robots physically and psychologically distancing police officers from the direct outcome of robot use, and the disproportionate impacts of police robots on communities already oppressed by the police. However, while technology misuse might be the most salient risk to researchers, risks are also imposed by the very act of collaboration.

In recent work, Bretl et al. [16] discuss other categories of risk imposed by collaboration, relating to the nature of the collaborator rather than the topic of collaboration. These include the risk for scandal and reputational harm, negative influence on researchers, and, critically, legitimization of bad actors. As a key example, Bretl et al. [16] analyze the funding relationship between Massachusetts Institute of Technology (MIT) and alleged pedophile and child trafficker Jeffrey Epstein. As they point out, regardless of the nature of the technology Epstein funded, the collaboration between MIT and Epstein clearly had negative consequences: not only did the collaboration harm the reputations of MIT, but the collaboration was used by Epstein as a way to launder his reputation and demonstrate his legitimacy. Collaborations with the police may similarly risk laundering their reputations and manufacturing their legitimacy.

As an example, one of our institutions recently highlighted an alumnus' police training technology. In doing so, the university implicitly suggested that the police are a solution to societal problems; that public funds should be spent on training technology; and that

the police using those technologies should be supported as worthy collaborators. Furthermore, because the university itself was highlighted in this reporting on police technology, the technology was given a false veneer of scientific credibility and authority.

We further argue that the public's view of such collaborations should be particularly concerning to roboticists due to our field's existing demographic challenges. The field of robotics currently has a severe problem with underrepresentation, being overwhelmingly dominated by white and Asian men. Meanwhile, many members of the very demographic groups the field of robotics is hoping to encourage to join our field have been historically oppressed by the police and as such may be justifiably reticent to join a lab, major, department, or school that is collaborating with their oppressors. Inherently flawed technologies like facial recognition are systematically deployed in low-income and minority neighborhoods while avoiding white neighborhoods [60], leading directly to discrepancies in benefits, employment, and policing [76], and thus justifiably increasing mistrust among those communities towards those creating and deploying those technologies [76, 78]. This may in turn feed into a cycle of systemic racism as fewer students of color choose to go into robotics, leading to decreased sharing of their perspectives within our field and thus increased risk of roboticists building technologies that serve as tools of oppression.

4 TRUSTEES

The above discussion delineates three key categories of risk: (1) Risk of technology misuse (due to unsuitable dispositions *related* to the technology), (2) Risk of actor legitimization (due to unsuitable dispositions (potentially) *unrelated* to the technology), and (3) Risk of underrepresentation (due to roboticists' explicit or implicit support for those unsuitable dispositions leading people from populations oppressed by the police choosing not to enter our field). Each of these categories of risk can be presented by different types of risk-presenting actors, each of whom demands a different type of trust. We refer to three risk-presenting actors:

(1) Risk-presenting individuals (requiring interpersonal trust regarding individual dispositions)
(2) Risk-presenting organizations (requiring organizational trust regarding organizational dispositions)
(3) Risk-presenting institutions (requiring institutional trust regarding institutional dispositions)

Here we use the Searlian notion of institutions in which W names an institution if W is defined by a set of constitutive rules, which determine collectively recognized and accepted status functions, which are performable in virtue of that recognition and acceptance, and which, critically, carry recognized and accepted deontic powers [69]. As Searle points out, institutions are central to understanding society because they create desire-independent reasons for action [69]. We consider institutions that serve as *categories of organizations*, which impose desire-independent dispositions on *individual members* of their constituent organizations. This includes institutions such as governments, public services, legal systems, healthcare systems, schools, hospitals, universities, and research communities. For example, Mount Sinai Health is an organization within the institution of hospitals and Stanford University is an organization with the institution of universities.

These categories of risk and categories of risk-presenting actorstogether define a risk-assessment context, as we will now describe (see Figure 1). When the researcher R chooses to engage with the agent A in a collaboration surrounding a technology, R must trust that A will not misuse the technology. This required interpersonal trust between R and A. R also must trust that they will not help A to launder a deservedly bad reputation or discourage students from joining R's field. Collaboration between researcher R and agent A thus requires justification of the dispositions necessary for R to have appropriately grounded interpersonal trust in A.

In collaborating with agent A, the researcher R also makes themselves vulnerable to A's *organization*: R must trust that others in A's organization will not be willing or able to misuse the technology. R also must trust that A is not a well-meaning agent working within a bad organization whose reputation R would be helping launder and association with which would discourage students from joining R's field. Collaboration between the researcher R and the agent A thus also requires justification of the dispositions necessary for R to have appropriately grounded organizational trust in A's organization.

Finally, researcher R is also making themselves vulnerable to the *institution* of which A's organization is a part. R must trust that other agents within that institution will not be able to misuse the technology, but more importantly, must trust that A's organization is not a well-meaning organization within an inherently bad institution whose reputation R would be helping to launder and association with which would prevent students from joining R's field. Collaboration between the researcher R and the agent A thus also requires justification of the dispositions necessary for R to have appropriately grounded institutional trust in A's institution.

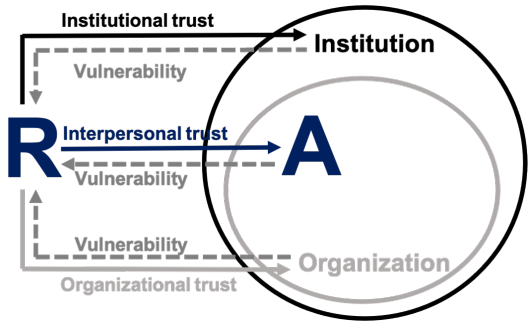

Figure 1: Collaboration requires trust at multiple levels.

We now have a framework for analyzing the different types of risk that might be posed by developing robots for, or otherwise collaborating with, the police. However, our selected definition of trust makes clear that trustworthiness depends not only on the mere existence of risks, but also on the interaction between those risks and the dispositions of the trustee.

5 DISPOSITIONS

To understand the role of dispositions in our risk calculus, consider a simple example. Rita is a roboticist who has developed a robot for delivering goods in hospital settings. She is considering working with Anton, who works at St. Osmund's hospital. This robot may present a number of theoretical risks of technology misuse. The

robot could, hypothetically, be used to push patients down stairwells. However, Rita can safely dismiss this risk due to analysis of dispositions: it is likely not justifiable to suspect that Anton desires to push patients down stairwells; it is likely not justifiable to suspect that there are other hospital administrators who would have access to the robot who would have such a desire; and it is likely not justifiable to suspect that the system of American hospital care was designed and continues to operate for the purposes of pushing patients down stairwells. Thus, Rita is probably well justified in making herself vulnerable to this source of risk.

Although this analysis may allow Rita to establish that the levels of trust needed to collaborate with Anton are well grounded *with respect to the risk of technology misuse*, Rita may still have concerns about actor legitimization. Consider, e.g., the fact that some doctors have refused to treat patients from LGBT communities [19, 44, 84, 85]. This presents additional sources of risk. If Anton is a doctor of this sort, then Rita's decision to collaborate with him could launder his reputation, thus facilitating his ability to harm vulnerable communities. This same risk may be present even if Anton would never discriminate in this way, e.g. if St. Osmund's allows or encourages its other employees to do so. And this risk may be present even if St. Osmund's as an organization would never allow such discrimination, e.g. if St. Osmund's is a type of private hospital (institution) that has historically been used to enable this type of discrimination. If this is the case, then even though Rita's technology is socially beneficial, and even though Anton and St. Osmund's are both unlikely to misuse her technology and overall well-meaning, Rita may yet need to decide not to collaborate, if it is justifiable to suspect that her collaboration would be used to bolster the reputation of a fundamentally discriminatory type of institution that simply should not exist, and if this collaboration would be likely to discourage LGBT students and scholars from joining her laboratory or university.

Now suppose that Rita is considering developing a bomb disposal robot in conjunction with police lieutenant Anton, who works for the St. Osmund Police Department. The intended use of this technology (defusing bombs) is likely to be viewed as positive. But what risks does the collaboration present? First, Rita should consider risks of technology misuse. Does Rita suspect, for example, that Anton could be prone to misusing the robot, by strapping explosives to it and using it to bomb the home of a mentally ill resident, as the police in Bangor, Maine did in June 2018 [66], or to tear-gas peaceful protesters, as police across the country have already been doing without the help of robots? Does Rita suspect that, while Anton would never do such a thing, others in his department might? And does Rita suspect that her technology could be misused in this way if acquired by other departments, due to the role of American Policing as an institution of oppression? Second, Rita should consider risks of legitimization. Does Anton have a history of brutality? Does his department? Does the institution of American Policing have its origins in, and continue to actively facilitate, perpetrate, and justify such violence? If any of Rita's answers are "yes", would she be legitimizing a bad actor, and would her collaboration discourage students and scholars from underrepresented communities from joining her laboratory and university?

6 JUSTIFICATION

We have defined *appropriately grounded distrust* as the unwillingness of a trustor to make themselves vulnerable based on the justified belief that the trustee has unsuitable disposition. And we have argued that for roboticists to engage in collaborations, they *should* earn appropriately grounded trust, and *must* avoid appropriately grounded distrust. Within this framework, decisive argument against collaboration would require justification for the belief that collaborators have unsuitable dispositions that present untenable sources of risk. Evidence of unsuitable dispositions might take the form of individualized or systemic sources of risk, grounded, respectively, in individual and institutional dispositions. While individualized sources of risk may be used to justify distrust in individual actors and their organizations, systemic sources of risk may be used to justify distrust in institutions as a whole, providing arguments against collaboration with any individual actors within such institutions, regardless of those individual actors' dispositions.

In this section, we provide examples of sources of evidence in each category, using the running example of potential concerns regarding collaboration with police. First, we will present justifications for our belief that there exist *individualized* sources of risk based on unsuitable dispositions among individual police and police departments (many of which are based on the Campaign Zero Police Scorecard initiative [86], which systematically evaluated California's 100 largest police departments), and types of evidence that would prevent researchers from collaborating with *particular* individuals and organizations on the basis of the dispositions implied by those sources of risk. We will then present *systemic* sources of risk stemming based on unsuitable institutional dispositions, and catalog evidence that, we argue, should prevent researchers from collaborating with *any* individuals or organizations in the institution of American Policing,

6.1 Individualized Sources of Risk Grounded in Likeliness of Technology Misuse

Individualized sources of risk are closely related to the risks of technology misuse or concerns over dual-use technology that have been substantially explored in the robot ethics community and the broader technology ethics literature.

Justification for unsuitable police dispositions can be found in the specific ways that police already misuse robotic technology, such as strapping explosives to robots in order to kill suspects [66, 71], or using robots to destroy property [54], and could also include patterns of police violence with or without the aid of technology, such as the 500 videotaped incidents between May 30th and June 15th 2020 collected by criminal defense lawyer T. Greg Doucette [61], including incidents on May 30th alone of police beating, pepper-spraying, trampling, grenading, shooting, and committing hit-and-run assaults on peaceful protesters, children, elected officials, journalists, and bystanders. Alternatively, one could rely on anecdotal or the prevalence of white supremacist, neo-Nazis [43, 73], and other racist ideologies within U.S. police forces [29, 35, 40], or the use of iconography such as the "thin blue line" flag by American police forces (see critique by Wall [81, 82]). Similarly, justification for unsuitable dispositions can be found in data collected by organizations such as Campaign Zero, which in the case of the LAPD, as a single example,

provides substantial evidence of racially biased violent tendencies grounded in statistics regarding use of force, use of force against communities of color, racial biases in arrest rates, evidence of over-policing of misdemeanors, and inattention to crimes against people of color.

There is also evidence that many US police departments have been infiltrated by white supremacist organizations. In 2006, the FBI's internal intelligent assessment indicated that white supremacist groups have been "infiltrating law enforcement communities or recruiting law enforcement personnel" for some time. As an example, in 1991, it was found that the LA Sheriff's department had "formed a neo-Nazi gang and habitually terrorized Black and Latino residents" [43, 73]. Critically, local police departments have no standard procedure for recruiting new members, and there are little to no training procedures available to help prevent such infiltration of police departments, as there are in the US Military where this threat is taken more seriously, although it is criticized that it is often not taken seriously enough [30, 41]. These racist tendencies have also been observed in the exposure of emails, texts, and social media groups in more than 100 police departments in more than 40 states, in which officers have gathered to share racist, sexist, and/or homophobic sentiments [35]. In Philadelphia (where such a group of 72 Philadelphia police officers was uncovered [29]), the Plain View Project revealed that of the 1,000 police profiles identified on Facebook, one in three had posted troubling content and of this third, one in three had had one or more federal civil rights suits filed against them [40].

6.2 Systemic Sources of Risk Grounded in Origins and Incentivization of Policing

As we have argued, simply justifying the dispositions of particular individuals or organizations is insufficient. Unless the dispositions of the *institutions* those individuals and organizations are part of can also be justified, it will be impossible to minimize risks of reputation laundering and risks of association. While individuals and group dispositions are grounded in individual and group goals and motivations, so too are institutional dispositions grounded in institutional goals and motivations. And, we argue, the fundamental mission and motivation of American policing are unjustifiable.

To advance this argument, we will examine both (1) the origins of American policing, which defined its original mission and motivation; and (2) the current role of policing in modern American society, including the way that particular types of policing are financially incentivized by the US federal government, which demonstrate that those original (indefensible) missions and motivations continue today.

6.2.1 Past Policing: Origins of American policing. As Alex Vitale [79] shows, even outside the confines of America, formal policing is a relatively recent phenomena, with what is regarded as the first modern police force in metropolitan London founded less than 200 years ago, in part as a means of exerting political control over and suppressing working-class citizens protesting the loss of jobs due to industrialization (a parallel to concerns over automation that should not be lost on the HRI community) [64].

These anti-labor origins directly informed the origins of police forces in the Northeastern US, where police forces were formed to deal with unrest amongst exploited working class immigrants [50], for exerting control over religious minorities [33], while working *with* local petty criminals to help fence stolen goods [31]. Corruption, extortion, brutality, and killing of unarmed working-class civilians served as central elements not only of of Northeastern American policing [79] but also of the US-trained police forces set up in Central America [48]. Meanwhile, Vitale highlights how Policing in other US areas originated in similar oppression on both class- and, critically, race-based grounds [79]. In the American Southwest, American policing originated from the creation of the Texas Rangers, a group created to protect the interests of white colonists through the violent oppression, massacre, and segregation of local Native and Mexican residents [22], a mission that continued long after Texas' annexation with oppression of union leaders and enforcement of "Juan Crow" segregatory policies (including discouraging of voting or registering to do so in Mexican-American communities) added to the mission of the police [67]. Similarly, in the American South, Policing grew out of Slave Patrols organized to hunt down runaway slaves, prevent slave revolts, and prevent fraternization amongst Blacks [38, 80]. Post-abolition, these police forces shifted to focus on forcing Blacks into sharecropping and prisons where they could be enslaved [13], often in coordination with the KKK [70].

The institutional dispositions of these groups, as evident from their missions and tactics, were morally indefensible. As such, collaboration with these groups would not only come with high risks of technology misuse, but would directly lead to unavoidable risks of reputation laundering. While several decades have passed since the events described above, there is no evidence that the institutional dispositions of American police, and their associated risks, have fundamentally changed.

6.2.2 Current Policing: Incentivization and Systemic Impact of Modern American Policing. As detailed by Michelle Alexander, the oppressive roots of American policing interact with the incentivization of modern policing to create a cycle of systemic racism that condemns many Black Americans to a permanent racial undercaste [2].

First, Alexander explains how America's War on Drugs was designed and has authoritatively served as a means for police to round up and imprison a vast number of Black men. In essence, the War on Drugs happens along the following three steps:

(1) Police departments are financially incentivized by federal grant programs to round up as many people as they can on drug-related grounds, through (a) explicit federal incentives wherein federal funding to police departments was explicitly tied to number of drug arrests and (b) the ability to raise department budgets through civil forfeiture [10].
(2) Police can essentially stop, interrogate, and search anyone they choose on drug-related grounds, and are allowed to use race as a factor in these operations [1].
(3) Thus, as designed and incentivized, most of those swept up for drug offences are Black and Brown.

Once swept up by the police, the criminal justice system then exerts formal control.

(1) Once arrested, defendants are generally denied legal meaningful representation and pressured to plead guilty through

prosecutorial techniques that cannot be challenged on a basis of racial discrimination [9].
(2) Once sentenced, people are subject to far longer and harsher sentences for drug charges than anywhere else on earth [56].
(3) Prison sentences can be for life even for minor nonviolent drug charges [51].
(4) Black Americans are subjected to significantly worse treatment at every stage of the process [68].

Once drug offenders have "paid their debt" to society, they are forced into a permanent undercaste in which they are legally discriminated against for the rest of their lives. They are:

(1) Prevented from obtaining employment, both formally (many occupations are legally barred from hiring felons) and informally (many employers illegally discriminate and will not hire felons).
(2) Denied housing, both formally (unable to live in public housing) and informally (many in public housing are unwilling to let felons stay with them, because you can be evicted from public housing if someone who is staying with you is arrested elsewhere).
(3) Denied education and other public benefits, and in many places, unable to vote.

Many people arrested on drug charges are thus released into a society in which they have no means of making a living, nowhere to live, and no way of bettering their situation otherwise, effectively forcing them into illegal activities and crime in a vicious circle.

The incentivization and use of modern American police to incarcerate and enslave large portions of America's communities of racial minorities presents vulnerability not only to high risks of technology misuse but also to unavoidable risks of reputation laundering. Roboethicists have in fact argued that police robots, especially when paired with racist predictive policing algorithms, may reinforce social inequality, accelerate mass incarceration, and worsen ties with communities [42]. And the mere act of collaboration on such technologies may suggest to the public either that the police and police' use of these technologies are legitimate solutions to societal problems – or, at minimum, that the collaborating scientists believe this to be the case. This serves to cast a false veneer of scientific legitimacy over these technologies and institutions. And, at the same time, this serves to cast a shadow of complicity over academia for the communities hurt by these technologies: collaborating with those responsible for incarcerating and enslaving members of communities underrepresented in robotics is unlikely to encourage members of those communities to join our field.

What is more, Alexander's account emphasizes the role of the police within America's larger carceral and caste systems, which involve multiple institutions, including the elements of the criminal justice that systematically discriminate against black defendants and extract profits from the incarcerated through legalized slavery. This means that collaboration with the police also means trusting the dispositions of the justices in charge of sentencing those rounded up by the police, the dispositions of those running prisons into which many incarcerated are placed, and the institutional dispositions of the prison-industrial complex as a whole. There are obvious reasons to doubt these dispositions [26], including the statistical bias of the criminal justice system against black defendants [36, 72], and this is especially true for for-profit prisons given their perverse incentives [23], the statistical influence of for-profit prisons on sentencing decisions [28], and reports of judges sending children to for-profit prisons in exchange for bribes [62].

7 POLICING FUTURE: OPPORTUNITY FOR REFORM?

Some researchers have argued that the critiques discussed in this paper represent reasons to avoid collaboration with *current* police, but that collaboration with *future* police may be possible if appropriate reforms are adopted. In this section, we argue that the dispositional risks of policing are unlikely to be reduced by such reforms. As discussed by [79], reform initiatives like community policing are ultimately ineffective, as they typically (1) divert *more* money towards policing (and thus, away from the government programs that actually prevent crime, such as affordable housing, income supports, and community health initiatives), (2) ingratiate the police into *more* elements of society [74], opening new opportunities for corruption, discrimination, and abuse [39] without yielding any demonstrable improvements, (3) can *exacerbate* existing problems with overpolicing [53], and/or (4) are rendered ineffective (especially for accountability efforts) due to incentive structures and organizational challenges that render other elements of the government or criminal justice system unwilling or unable to comply.

One reform proposed as a more humane role for the police in Drug policy is the use of *Drug courts* in which those picked up on drug offences are diverted to specialized diversion programs rather than traditional courts. Unfortunately, these diversion programs are not typically successful at encouraging drug users to actually participate in and complete their treatment programs, with most participants immediately returning to streets [3]. Moreover, this approach places control over access to critical social services is controlled by police, as these diversion programs are only accessible for those who are arrested, leading to (1) *incentivation* of crime to access such programs and withholding treatment from those who commit crimes [63], (2) increasing of the role of the criminal justice system in the lives of drug users [74], and (3) leading to opportunities for police corruption.

Another proposed reform is Decriminalization. In New York, for example, possession of marijuana is classified as a "violation" rather than a felony, ostensibly reducing the risk of overly harsh sentences for drug crime [4]. Unfortunately, New York police nevertheless used this to target minorities, *ramping up* drug (non-felony) arrests through stop-and-frisk policies [53], and by exchanging some arrests for "summonses" to appear in court for these minor violations, forcing poor minorities to choose between losing their jobs vs. facing criminal charges for failure to appear. Furthermore, focusing police attention on large-scale drug operations is not without risks, as it provides opportunities for drug-oriented police corruption that is rampant among police agencies (see, e.g., the Rampart Scandal in which the LAPD reportedly stole drugs from evidence rooms and sold them on the streets [39].

Police reforms in general are difficult to enact and enforce due to poor mechanisms for police accountability. Police departments

have few mechanisms for oversight, or refuse to hold officers accountable for their actions, and the data needed to provide the assurances described above is rarely made publicly available by police departments. Additionally, the numbers reported by the police are often inaccurate or untrustworthy. In Campaign Zero's analysis of the LAPD, they found that LA's policies allow complaints against the LAPD to be ignored after a year, limit the ability to interrogate police in misconduct cases, allow officers to record their own interrogations, and allow the chief of police to ignore the results of misconduct hearings. Moreover, only 5% of civilian complaints against the LAPD rule in civilians' favor, with only 1% of use-of-force complaints ruling in favor of civilians, and 0% of discrimination complaints ruling in favor of civilians.

These lack of accountability measures also create challenges in the collection of statistical information that could be used to provide evidence of unsuitable dispositions of individual departments. In many cases, the only opportunity for police behavior to be tracked is by the police themselves, and the police are typically neither inclined, incentivized, nor required to compile and make available about their own conduct. In one recent year, data provided by the Baltimore police department claimed that there had been *zero* police stops that year[83, p.154] This underreporting is especially stark in cases of police misconduct. Those who are assaulted by the police (especially those sexually assaulted by the police) are disinclined to report police misconduct back to the police; in many cases police misconduct (sexual or otherwise) occurs explicitly because the police victims know that they are at risk of arrest or deportation if they attempt to speak out[65].

The asymmetric power relationships inherent to policing means that when data on police behavior are available, it should be taken with a grain of salt and assumed to underrepresent the true state of affairs. And when this type of data is simply not available, researchers may well be justified in relying on anecdotal evidence to justify beliefs of appropriately grounded distrust of the police (thus precluding collaboration with such police departments in good faith); or use the lack of available information as itself evidence of unsuitable dispositions.

However, ultimately, the evidence suggests that regardless of the motives of individual police departments, the origins and nature of police departments represent a substantial risk that cannot be avoided. To summarize, (1) the police were created to exert social control over racial minorities and lower classes, (2) the police (and criminal justice system more broadly) are currently used in America to perpetuate a racial underclass, and (3) Police reform efforts are ineffective because they generally (a) keep the levers of social control in the hands of police and frame public health and welfare concerns as criminal justice issues, (b) create opportunities for corruption (economic, drug-related, and sexual) that police have been demonstrated to regularly exploit, and (c) are difficult to implement and enforce due to the lack of any meaningful accountability for the police. These make it impossible for robotics researchers to work with police without laundering an indefensible system of racial and social control.

8 SPECIFIC RELEVANCE TO ROBOTIC APPLICATIONS

The unsuitability of police dispositions and the inadequacy of police reform is especially relevant to roboticists for several key reasons, grounded in the specific application domains in which police robots stand to be used, the specific risks and harms that accompany those domains, and the specific ways in which robots exacerbate those risks and harms.

On the one hand, there are a number of robotics applications being pursued by policing that actively reinforce significant risks of policing. Police are a force of racializing violence; and the use of police robots can exacerbate this racialization of people and spaces [37, p. 257]. A key historical purpose of the police is to surveil people of color; and robots represent mobile surveillance platforms, which allow those in power to surveil those without power, while precluding those without power from sous-veiling in return [55]. As Brayne reports, even without cheap disposable drones, the LAPD has already made frequent use of their expensive helicopters (which they call "ghetto birds") to terrorize perceived "hotspots" through overt yet anonymous surveillance [15, p.72]. Police are unreformable on partial account of their unaccountability; and robots can facilitate "moral buffering" [37], providing "an additional layer of ambiguity [and] diminishment of accountability and responsibility" [24]. Moreover, police exert substantial effort propagandizing false narratives about (a) the necessity of police, (b) the unique specialized professional authority of police, and (c) the apparent accountability of the police [21, p. 5]; tasks that they have a long history of using advanced technology to facilitate, through "techwashing" [15, p. 5-6]. As such, we argue that the unsuitable dispositions and unreformability of the police should provide clear motivation for roboticists to obviously avoid the development of technologies whose dominant use would be technologies of violence or surveillance.

In contrast, there *are* plenty of socially beneficial applications for social robots that currently require working with the police, ranging from robots to more accurately collect child eyewitness testimony [11, 49] to bomb disposal robots [27]. Our argument suggests, however, that while some robotics projects currently requiring collaborations with police may be viewed as socially beneficial from a hypothetical "view from nowhere" [59], their risk becomes apparent when situated within the broader context of institution-driven risks and vulnerabilities. That is, while these robotic applications may not pose *direct* risks, the implementation of these robotic applications poses clear *indirect* risks, by legitimizing the police, facilitating the influx of police budgets, and supporting the creep of police missions in increasing segments of our society. For the prosocial applications to be pursued without the risks discussed in this paper, we argue that they would need to be rethought as collaborations with alternative institutions, such as social workers. This would require dramatic defunding, or wholesale abolition, of existing policing organizations.

Finally, regardless of the specific use case for which robots are intended, robots represent special-purpose technologies that largely (with the exception of cheap, general-purpose drones) need to be developed with and/or for specific domains in order for them to be used. While any robot technology, of course, stands to be misused by

police, it is difficult to create a robot technology that "accidentally" wields a taser, recognizes, classifies, and matches faces to suspect databases, or integrates with Palantir's predictive policing software. This grants roboticists a unique degree of control over their work and power over how it is used.

9 CONCLUSIONS AND RECOMMENDATIONS

We conclude this paper with recommendations for paths forward. First, we make short-term recommendations for the current practice of research ethics that account for the issues raised in this work. Second, we make longer term recommendations for the research community, arguing for an abolitionist computing agenda.

Research Ethics Recommendations

Most obviously, we hope that the framework presented in this paper has clearly demonstrated the need for roboticists to refuse to develop robot technologies for or in collaboration with the police. This seems like a minimal first step – literally the least we can do – that is justified through the trust-theoretic framework presented in this work. Moreover, this simple first step represents an action that robotics researchers are uniquely capable of taking on. While regulators are slow to act, reticent to pre-emptively regulate technologies without substantial and dramatic harm already having been caused, and largely incapable of regulating collaborative relationships, robotics researchers have the freedom and agility to head off harms before they are inflicted, merely by taking a moral stand to avoid collaborations whose harmful effects can be readily predicted. Furthermore, we hope that the framework presented in this paper can be used by robotics researchers to make similar decisions about collaborations in other morally fraught but less clear-cut domains, such as collaborations with national defense organizations [47], or with surveillance capitalist corporations [87].

However, we further hope that the framework presented in this paper provides a useful tool for assessing and responding to *others'* proposed forays into policing robots. That is, even if we have convinced the reader themselves not to pursue collaborations with the police, they may well encounter others who have not yet been convinced, in the context of IRB Applications, Paper Reviews, and Grant Reviews. When encountering police collaboration in these external capacities, we encourage readers to ask hard questions of those prospective or actual collaborators, including at minimum the following considerations.

(1) Researchers proposing to perform or publish on collaborations with police should be asked to provide documentation of the origins of the agency with whom the researchers are collaborating and their justifications for collaboration based on those origins.
(2) Researchers proposing to perform or publish on collaborations with police should be asked to identify whether there is documented evidence (e.g., from websites such as Mapping Police Violence[1], the Police Scorecard[2], or the Use of Force Project[3] of violence or racism observed in collaborating departments over the past ten years and for their justification for the acceptability of that evidence.
(3) Researchers proposing to perform or publish on collaborations with police should be asked to explain whether their project team includes researchers qualified to attest to the strength of the above documentation, especially scholars from Black, LatinX, and Indigenous communities, and scholars from fields like sociology that have a deep understanding of the role of systemic racism in policing and the criminal justice system.
(4) Researchers proposing to conduct or publish collaborative research with police should be asked to provide evidence of the approval and participatory design in coordination with members of the communities in which the designed technologies would be used.

Although these four sources of evidence will not address all the risks discussed in this paper, requiring discussions about them may be a helpful first step.

Toward an Abolitionist Robotics

Finally, we argue that substantively responding to the concerns raised in this work requires a long-term commitment to an agenda of **abolitionist robotics**. As we showed in this article, the evidenced dispositions of American policing organizations, their constituent officers, and the American institution of Policing justifies a default stance of appropriately grounded distrust toward these officers, police organizations, and institution. As such, we have argued that roboticists *should not be collaborating with the police* in any way. This argument echoes calls from members of the robotics community in the 2020 *#NoJusticeNoRobots* open letter and petitioning campaign[4].

We have also pointed out that there are many truly socially beneficial actions that our society currently assigns to police, that researchers rightfully wish to support. As such, we suggest that researchers who wish to work in domains that currently require police collaboration should *actively push for police abolition* [20][5] and replacement of the police with new social systems. In parallel, researchers should, in parallel, pursue similarly oriented research projects in collaboration with alternative organizations such as mental health professionals, social workers, and non-police emergency first responders. Similarly, we encourage roboticists to work on topics that do not require collaboration with the police but who are concerned their technologies could be misused if acquired by police, to pursue similar advocacy, and to advocate for laws (especially at the city, and possibly state levels) formally restricting police use of robotics (going beyond the informal guidelines proposed by other roboethicists [18, 77]).

Overall, while collaboration with police may present new use cases for robots, especially given the increased militarization of the police, we suggest that researchers should carefully strive not only to reject the urge to view of policing as a blanket solution to society's problems, but also to reject technochauvinism [17] – the

urge to view technology (especially those technologies we have expertise in developing) as a blanket solution to society's problems.

ACKNOWLEDGMENTS

This work was prompted by the campaign 'No Justice, No Robots' (led by the authors of this paper) in which signatories publicly stated their refusal to participate in or facilitate research in collaboration with or intended for use by law enforcement agencies (nojusticenorobots.github.io).

Public discussions and news stories following this campaign have been instrumental in articulating the positions laid out in this article. Accordingly, this article articulates a position that is aligned in spirit, but substantially different from that articulated in the public letter, and thus this article does not necessarily reflect the positions of those who signed that petition or their institutions.

ABSTRACT

To enable the development and use of safe and equitable artificial intelligence (AI) systems, AI engineers must monitor deployed AI systems and learn from past AI incidents where failures have occurred. Around the world, public databases for cataloging AI systems and resulting harms are instrumental in promoting awareness of potential AI harms among policymakers, researchers, and the public. However, despite growing recognition of the potential of AI systems to produce harms, causes of AI systems failure remain elusive and AI incidents continue to occur. For example, incidents of AI bias are frequently reported and discussed, yet biased systems continue to be developed and deployed.

This raises the question – how are we learning from documented incidents? What information do we need to analyze AI incidents and develop new AI engineering best practices? This paper examines reporting techniques from a variety of AI stakeholders and across different industries, identifies requirements towards the design of effective AI incident documentation, and proposes policy recommendations for augmenting current practice.

1 INTRODUCTION

While there is much excitement about artificial intelligence (AI) and its applications today, AI systems are known to fail. Sometimes the failure is mundane, such as a voice assistant playing a different song than requested [5]. However, as AI systems are used in more high-stakes contexts, AI systems are failing in ways that cause harm to humans, such as gender-biased hiring recommendations or autonomous robot collisions, among many other examples [3, 26].

Understanding the underlying causes of AI failures is challenging due to the complex nature of AI system behaviors and development lifecycles. Bias, for example, can be introduced throughout any of the stages of the AI engineering lifecycle [44, 46] or the "data, algorithm, and user interaction loop" [28]. As a result, industry practitioners struggle to effectively prevent and mitigate bias, with many discovering serious issues only after deployment [22].

To improve the quality of AI systems and prevent future incidents, the AI engineering community needs to document past incidents and identify common causes of AI failure. To quote Henry Petroski, "Failure is central to engineering... Successful engineering is all about understanding how things break or fail" [13]. AI incident databases, or platforms that centrally store documented examples of AI failures, therefore represent a crucial resource. Precedents across safety-critical domains including aviation and cybersecurity suggest that the analysis of incident databases is effective toward addressing engineering challenges. For the AI engineering discipline, which is new and evolving, the analysis of AI incidents presents an opportunity to gain awareness of the mechanisms of AI system failures, develop methods for measuring, classifying, and contextualizing incidents, and build well-informed best practices.

Although current AI incident databases have been important to raising awareness about AI harms, existing taxonomies best support policy and ethics research, as opposed to capturing actionable technical information for AI practitioners. Additionally, current AI incident taxonomies either omit the topic of underlying sources of system failure altogether or provide simplistic schemas for classifying root causes. This paper addresses current challenges and shortcomings in documenting AI incidents by providing a landscape of AI system and incident databases, an analysis of AI incident documentation requirements, and a set of policy recommendations for future AI incident databases.

A note on terminology: the language around AI incidents is emergent and no widespread definitions are yet agreed upon. Within this paper, we use the term AI incident interchangeably with AI failure to refer to instances in which an AI system results in unintentional negative impacts on humans (e.g. physical, psychological, and/or social impacts). We use the term AI harm to capture these impacts. Examples of AI incidents can vary in severity and will look different in context. An incident for a large language model (LLM), for example, could consist of an inaccurate text output [4]. The impact of an individual reading an inaccuracy could be minimally harmful

AIES '23, August 08–10, 2023, Montréal, QC, Canada

https://doi.org/10.1145/3600211.3604700

but if the user were to use this information in a critical context, or the misinformation were to become widespread, impacts could be severe. By contrast, a computer vision (CV) incident could include a misclassification of an object by a self-driving car resulting in a serious injury [2]. The impact of this incident could be life-altering for the victim.

2 LANDSCAPE OF DOCUMENTATION METHODS

AI engineering is a burgeoning field and as a result AI incident documentation practices are still developing. To ground our analysis, we conducted an interdisciplinary exploration of the current landscape of documentation methods for AI incidents, systems, and policies, as well as methods from well-established fields such as aviation and cybersecurity.

2.1 Databases of AI Incidents

Public databases, spreadsheets, and social media lists are important mechanisms for collecting and publicizing international AI incidents and controversies. AI incidents catalogued within these resources are pulled from second-hand accounts via online articles and research papers and are typically stored in public spreadsheets. These spreadsheets power interfaces such as searchable databases or map visualizations. Existing databases for capturing AI incidents are operated by various non-governmental organizations, companies, and individuals, and encourage submissions from the public for review by a managing editor or editorial team.

We provide an overview of documentation methods in use today for recording AI incidents in Table 1 and the criteria that they cover. A comparison of current documentation of AI incidents illustrates a shared focus on the characteristics of the event of an AI incident such as the organizations involved in the development and use of the system or details of the resulting harm. Across the board, other aspects of AI incidents, namely the causes of and responses to AI incidents, receive limited coverage within current AI incident documentation methods.

2.1.1 AI and Algorithmic Incident and Controversies (AIAAIC). The AI and Algorithmic Incident and Controversies (AIAAIC) Repository [40] is a significant source of examples for both the AIID [9] and the Where in the World is AI? database [20]. This repository is described as an "independent, non-partisan, public interest initiative" that advocates for transparency by logging incidents and controversies from around the world. The collection of over 850 examples is edited and managed by Charlie Pownall and used by more than 60 universities and organizations. Users can submit examples of incidents and controversies; these submissions are included based on adherence to criteria such as relevance, fairness, and accuracy [40].

2.1.2 AI Incident Database (AIID). The most popular database for reporting AI incidents is the AI Incident Database (AIID) [9] which consists of over 1,000 archived reports from over 600 submitters. Reports capture a breadth of types of AI harms ranging from harms to physical health/safety to harms to social/political systems and application types ranging from facial recognition systems to targeted advertising.

The AIID employs the Center for Security and Emerging Technology (CSET) taxonomy [1], developed at Georgetown University's Walsh School of Foreign Service. Submissions to the incident database are contributed by the public. Current users span a variety of roles such as system architects, public policy researchers, and industrial product developers. Future plans for the AIID include supporting incident report translation, providing best practices resources, incorporating post-mortem reports, and utilizing automated monitoring for tracking new articles related to AI incidents. Potential future plans include developing a technical taxonomy and encouraging voluntary disclosures.

Of the reviewed AI incident databases, only the AI Incident Database CSET taxonomy contains a category for the cause of harm. The category *Causative Factors within AI system* prescribes one of three factors: *Robustness*, *Specification*, or *Assurance*. The *Robustness* category means the "system operated unsafely because of features or changes in its environment, or in the inputs the system received", *Specification* means the "system's behavior did not align with the true intentions of its designer, operator, etc", and *Assurance* means the "system could not be adequately monitored or controlled during operation" [9]. While there are scenarios in which these three categories are distinct, AI failures are often the result of numerous factors, such as a combination of unfamiliar inputs, inadequate training data, and poor system monitoring, making it hard to untangle these causes and assign a representative category.

2.1.3 AI Vulnerability Database (AVID). The AI Vulnerability Database (AVID) [42] contains over 45 vulnerabilities and reports. AVID defines vulnerabilities as proven high-level failure modes and reports as specific examples of vulnerabilities occurring. The goal of the database is to elicit evaluation methods that can be used by AI engineers or auditors. Submitters can upload vulnerabilities or reports via an online form for review by the AVID team. Some instances in the database are of failures encountered in the wild similar to those included in other reviewed AI incident databases, but many are based on controlled evaluations of model behavior. The taxonomy used by AVID provides detailed categories for describing failures through *Security*, *Ethics*, *Performance* (SEP) subcategories. The *Security* category, for example, includes subcategories as specific as *Supply Chain Compromise* with *Model Compromise* or *Software Compromise* as options within that subcategory. The taxonomy also tracks the *Lifecycle Stage* during which the failure was identified such as *Evaluation* or *Deployment* [43].

2.1.4 Where in the World is AI?. Another significant repository of AI incident examples is the Where in the World is AI? database [20]. This database is visualized through an interactive map containing over 400 responsible or unethical examples to provide users with context around how AI is used internationally. This database places an emphasis on capturing and visualizing the specific location of use. Examples are labeled as either *Harmful* or *Helpful*.

The database plans to include action, reading, and insights columns in the future; these columns will likely recommend takeaways and document incident responses, although the structure of these columns is unspecified and the site does not appear to have been updated since 2021. Cases within the database were previously updated on a weekly basis and consist of examples identified by AI Global, Awful AI, Upturn, Equal AI, and Charlie Pownall/CPC &

Categories	Databases of AI Incidents			
	AIAAIC Repository	**AI Incident Database**	**AI Vulnerability Database**	**Where in the World is AI?**
Identification	• AIAAIC ID #	• Incident #	• Version	
Incident Description	• Description	• Full description • Short description	• Description • Details	• Title
Date	• Year	• Beginning date • Ending date	• Date reported • Date last modified	• Year
Location	• Country(s)	• Location		• City • State • Country • Latitude • Longitude
Sector	• Sector(s)	• Sector of deployment • Critical infrastructure • Sectors affected • Public sector deployment		• Domain
Responsible Parties	• Operator(s)	• System developer • Named entities • Party responsible for AI system	• Developer • Deployer	
AI System Description	• Purpose(s)	• Relevant AI functions • AI tools and techniques used • AI functions and applications used • Description of AI system involved • Nature of end user • Level of autonomy • Physical system	• Artifact details • Lifecycle stage	
AI System Data		• Description of the data inputs to the AI system		
Cause of Harm		• Causative factors within AI system		
Description of Harm	• Issue(s) – General Issue(s) -- Transparency	• Probable level of intent • Harm type • Harm nearly missed? • Uneven distribution of harms basis	• Risk domains • SEP subcategories	• Is_good (Helpful or Harmful)
Impact of Harm		• Human lives lost • Total financial cost • Overall severity of harm		
Legal Implications		• Laws covering the incident		
Response to Harm				

Table 1: An overview of existing AI incident documentation methods. "Cause of Harm" and "Response to Harm" are two categories with high importance to AI engineers but low coverage.

Associates, among other sources. Users can also submit a case for review and potential inclusion.

2.1.5 Additional Lists. Lists scattered across Twitter [7, 25] and GitHub [12, 39] also chronicle problematic systems. Many of these lists constitute early attempts at aggregating examples of irresponsible AI and predate public databases. These lists do not rely on taxonomies or formal reporting methods.

2.2 Databases of AI Systems

Databases of AI systems, although not directly related to AI incident documentation, provide context related to larger efforts in AI database curation and harms discussions. The development of current AI system registers and repositories are the result of efforts from an array of stakeholders ranging from community activists to local governments and reflect diverse cultural and societal concerns.

Databases and registers examined in this section were sourced from the AIAAIC's "AI and algorithmic repositories, registers, databases" webpage, the AIID's "Related Work" section, and references within "Preventing Repeated Real World AI Failures by Cataloging Incidents: The AI Incident Database" [9, 27, 40]. These proactive approaches include databases that facilitate government transparency and raise public awareness.

2.2.1 Government Databases of AI Systems. Public databases of AI systems used by the government are a mechanism by which local and federal governments can provide transparency and oversight for AI systems. These databases provide information about system goals and contexts of use to inform the public. These databases, particularly the Algorithm Register and AI Register, can offer a profusion of information about systems employed within the public sector because of their proximity to government.

The AI Public Services Explorer [18] monitors the use of public AI systems across the European Union. Over 140 services are currently listed, and related AI cases are organized by their percentage "similarity". The Algorithm Register [35] from Amsterdam and the AI Register [37] from Helsinki both maintain registers of AI systems and algorithms used within their prospective cities. These registers provide residents with detailed information about system design and use, as well as contact information for responsible parties.

Likewise, the United States government requires federal agencies to publish their unclassified AI use cases online [23]. Details provided within these use cases can include a high-level description of inputs and outputs, information on the AI techniques used, and contact information, among other fields, although the structure of these reports differ between agencies.

Algoritmos Publicos [21] was developed by The School of Government at Universidad Adolfo Ibáñez and aims to improve governance of Chilean AI systems and encourage innovation. The database organizes public algorithms used in Chile by either *Sustainable Development Goals*, such as *Zero hunger* or *Climate Action*, or by *Functional Expenditure Classification*, such as *Housing and Community Services* or *Education*.

2.2.2 Databases of Controversial AI Systems. Several databases aim to inform the public about controversial technologies that may impact our everyday lives such as automated decision-making or facial recognition systems. These databases catalogue concerns about the unethical development and use of AI systems in areas such as policing and medicine. Systems included in these repositories are systems for which speculative harms have been identified and/or realized harms have occurred.

Multiple databases document the use of automated decision-making systems. AI Projects in the Public Sector in Latin America [41] maps potentially biased AI systems across Latin America to examine the feminist and human-rights implications of using algorithms for decision-making processes. The Observatory of Algorithms with Social Impacts (OASI) register [17] collects examples of both private and public sector algorithms for making automated decisions and consists of over 80 examples. The AI Observatory maintains a database of Automated Decision-Making Systems (ADMS) [15] in India to document ADMS uses, contexts, and actual and potential harms. The database captures over 60 systems ranging in purpose from *Farm Loan Waiver Identification* to *Student Performance*.

The use of AI surveillance and facial recognition systems is another documented concern. The Panoptic Tracker [24] provides a comprehensive map of the approximately 100 government facial recognition systems installed in India. A Right to Information (RTI) [14] document has been filed for most of the Facial Recognition Tracker Systems (FRTSs) requesting additional details from system sources. The Atlas of Surveillance [16] documents the use of law enforcement surveillance technologies including AI systems within the US. The Atlas consists of over 9,000 searchable data points and supports an interactive map visualization.

2.3 Incident Databases from High Stakes Industries

Disciplines in which failure modes can be complicated and costly, such as in aviation or cybersecurity, set precedents for incident database design and documentation. Although AI Engineering is a nascent field with distinct challenges and failure modes, the obstacles involved with incident collection and analysis are not entirely unique or nebulous.

Incident reporting has been integral to the development of safety measures across many disciplines. The history of systematic incident reporting and analysis dates to at least 1978 when a corpus of cases from anesthesiology was used by medical researchers to generate insights into safe anesthetic use [11]. Following the arrival of the internet, online public databases for sharing case studies and encouraging community analysis have become tools for providing equitable access to information and building best practices.

2.3.1 Aviation. Commercial aviation fatalities have decreased by 95% over the past two decades; these improvements have been largely attributed to an "open and collaborative safety culture" centered on the careful analysis of past incidents [19, 38]. An aircraft accident is defined as an event between boarding and disembarking by which death or serious injury occurs or the aircraft receives significant damage. Aircraft incidents refer to events that posed high risk of accident such as a *flight control malfunction or failure* or *inflight fire* [36]. The Federal Aviation Administration (FAA) Aviation Safety Information Analysis and Sharing (ASIAS) System [19] is a central figure in aviation safety analysis. The ASIAS hosts a public collection of 11 online aviation safety databases storing a

variety of accident and incident types and allows users to query multiple databases at one time.

The US National Transportation Safety Board's (NTSB's) Aviation Accident and Incident Data System [33] is included within and cited by numerous other databases in ASIAS. The NTSB investigates each reported accident and captures key findings. Each investigation consists of the following steps: "on-site fact gathering", "analysis of facts and determination of probable cause", "acceptance of a final report", and "advocating for the acceptance of safety recommendations arising from the investigation" [34]. The database can be queried through Case Analysis and Reporting Online (CAROL), which contains a complete list of aviation investigations from 1983 onward, surface mode investigations from 2010 onward, and safety recommendations.

The Aviation Safety Reporting System (ASRS) [32] is another significant database within the ASIAS. Uniquely, the ASRS captures confidential reports submitted by pilots, controllers, mechanics, flight attendants, and dispatchers, among other roles working on aviation's frontline. Over a million reports have been submitted to date and these reports are made public via a searchable database. All reports have been de-identified. This data is used to identify deficiencies and discrepancies in the National Aviation System (NAS) for remedy by appropriate authorities, support policy formulation and improvements to the NAS, and strengthen the foundation of aviation human factors safety research.

2.3.2 Cybersecurity. Cybersecurity incidents are never exhaustively preventable and new types of incidents are frequently emerging. Emphasis is therefore placed on learning from and documenting past incidents and their handling processes. A cybersecurity incident refers to a violation or eminent threat of violation of "computer security policies, acceptable use policies, or standard security practices" [8]. Incident responses are typically orchestrated confidentially within organizations to avoid disclosure of sensitive information. The Federal Information Security Management Act, however, requires that Federal agencies report cyber incidents to the United States Computer Emergency Readiness Team. Although disclosures in cybersecurity often present security concerns, aggregating information about shared public problems and providing common language for cybersecurity professionals have been feasible methods for building a robust practice.

The Common Vulnerabilities and Exposures (CVE) database [30] lists common identifiers for publicly known cybersecurity vulnerabilities. A vulnerability refers to a "flaw in a software, firmware, hardware, or service component" that can be exploited and may result in a cybersecurity incident [45]. A CVE ID is assigned to each vulnerability. Responses to vulnerabilities take the form of fixes or mitigations and are handled on an organizational basis. A fix involves terminating the use of vulnerable code and/or systems. A mitigation "reduces the impact of a vulnerability without removing the vulnerable code", such as "adding network segmentation" or "input and traffic filtering" [45]. Common Weakness Enumeration (CWE) [31] and Common Attack Pattern Enumeration and Classification (CAPEC) [29] build off the CVE to provide analysts and testers with common language related to weaknesses and attacks. While these databases do not offer specific, identifiable instances of incidents, vulnerabilities, weaknesses, or attacks, they present a community-driven approach to IT and cybersecurity standardization.

3 ANALYSIS OF AI INCIDENT DOCUMENTATION REQUIREMENTS

AI systems are non-deterministic, data-driven, and often opaque. These characteristics pose challenges which set AI systems, and as a result, AI failures apart from precedents. The structure and lifecycle of AI systems as well as the newness of AI engineering must be taken into account when developing a taxonomy for AI incident documentation. Through our landscape analysis of AI incident databases, AI system databases, and aviation and cybersecurity incident databases, we identified several critical gaps in current documentation practices.

3.1 AI Failures Tend to be Context-Specific

Incidents within other industries such as aviation or cybersecurity are often the result of common faulty physical components used across systems. If, for instance, a particular model of airplane is associated with multiple fire-related aviation incidents, the underlying problem could be that a specific part is defective. Once a common component is identified as posing a threat to system performance or function, solutions could include removing or modifying the component or terminating use of systems that employ the component.

Problems in AI, however, tend to be unique to their deployment context and hard to assign to a common component. Companies typically curate their own datasets to fit project needs and train their own models. Current AI incident taxonomies therefore must diverge from precedents that center on identifying common components and instead account for context- and system-specific failures while looking for common processes. Taxonomies must focus on capturing the details and nuance around the design, implementation, and use of each AI system.

At the same time, AI incident taxonomies must be flexible to a potential future shift in AI development towards reusable digital components. Earlier foundation models such as BERT, CLIP, or GPT-3 have the potential to be adapted and applied to a variety of task types, although widespread use of these models has yet to occur [6]. However, with the growth of generative AI, discussion around the ways in which large open-source models such as large language models (LLMs) can be used has exploded. Research into the ways that open-source models can integrated into AI systems, bootstrapped with new abilities, and/or customized for specific users is ongoing. The use of reusable components by ML development teams appears imminent and could mean a paradigm shift in the way AI systems are designed and produced.

Wide-spread use of a component will not be a sufficient indicator for quality. For example, many popular benchmarking datasets, such as ImageNet, have been shown to contain consequential biases but are still a research standard [48]. LLMs are generally trained on extremely large datasets consisting of unvetted language scraped from the web. Tracking the use of common components will help AI engineers understand the risks associated with various components and adjust their development and monitoring plans accordingly.

3.2 Broad Timelines are Essential to Analyzing AI Systems

Current AI incident taxonomies focus on the events of harm themselves, as opposed to other elements of the timeline leading up to or proceeding the incident. Aviation and cybersecurity similarly limit the scope of reports. In aviation, this means capturing information from the duration of the flight between passenger loading and disembarking. In cybersecurity, vulnerabilities and exposures are attributes rather than events, so no timeline is provided aside from the date when the vulnerability or exposure was reported or updated.

Causes of AI incidents, however, such as privacy issues or mislabeled data, can be introduced within the system at many stages of the system lifecycle and can be hard to pinpoint. To be effective, AI incident databases need to capture longer and more detailed timelines surrounding AI systems to help engineers locate sources of AI failure. AI systems also often rely on numerous dynamic elements that may be updated on separate timelines. For instance, the embedded timelines of data updates, model retraining, and monitoring and evaluation can all influence how incidents manifest. Logging these micro-timelines is thus an important part of the story.

AI engineers would also benefit from understanding how organizations choose to respond to AI incidents. Depending on the type or severity of harm, the best choice may be to abandon using a system altogether. In other instances, a viable solution may be the collection of higher-quality data and subsequent model retraining. Solutions could also include the integration of software safeguards for filtering out or preventing unintended AI behaviors. Recording real-world responses to incidents will help AI engineers understand and identify ethical paths forward after an incident.

3.3 Genotypical Analysis Must Motivate AI Incident Collection and Categorization

At their best, taxonomies are tools for making sense of large amounts of data and assisting users in drawing connections across examples. However, taxonomies run the risk of oversimplifying and sterilizing the data captured about incidents. Taxonomies rely on a mix of "phenotypical", or observable, and "genotypical", or underlying, categories.

For example, say an LLM generates a racist response to a user's query [4]. The phenotypes of this incident would include the user's input, the model's output, elements of the user interface, and details related to the type of model or system. The genotypes would include underlying causes such as a culture of insufficient evaluation of model behaviors or the collection and use of biased data. Identification of genotypical categories requires the collection of large amounts of data and investigation into the underlying causes across entries.

Striking the right balance between these categories is therefore important to encourage meaningful analysis. When elements of a story are shrouded or eliminated, it can be difficult to learn from past failures, especially in the context of complex systems for which multiple interrelated causative factors are at play [10].

In developing the Aviation Safety Reporting System (ASRS) [32], Billings notes, "Too many people thought that incident reporting was the core and primary component of what was needed. These people thought that simply from the act of collecting incidents, solutions and fixes would be generated sui generis and that this would enhance safety" [47]. Effective incident reporting is about aggregating incidents in a manner that encourages and is conducive to thorough reflection and investigation. Successful precedents from other domains show that this means a) building taxonomies that provide extensive coverage of phenotypical characteristics and/or b) engaging in thorough genotypical explorations.

To be effective, AI incident taxonomies must expand their coverage of observable characteristics of incidents to allow for analysis of underlying causes. Important phenotypical information related to AI systems could include the specific system input and output associated with the incident, end-user behavior(s) at the time of the incident, details of the design of the user interface, training and testing data sets, or model characteristics including model architecture or weights. Without this information, coupled with a strategy for investigating and analyzing incidents, it will be challenging if not impossible to identify genotypes or develop common language around AI failures.

Current AI incident collection methods rely heavily on news coverage of AI incidents. Details of the incident can be lost as the story transfers from a first-hand to second-hand account. Likewise, important phenotypical information can be omitted because parties responsible for the AI system that produced the incident choose not to share information about their systems. Recommendations discussed in the subsequent section talk about potential mechanisms for collecting more detailed phenotypical information conducive to genotypical analysis.

4 POLICY RECOMMENDATIONS FOR AI INCIDENT DOCUMENTATION

After we analyzed requirements for AI incident taxonomies, we investigated potential pathways forward for building new types of AI incident databases to augment existing efforts. These policy recommendations are inspired by methods used by existing AI system databases and incident databases from other domains. Diversifying the landscape of AI incident databases would make room for new perspectives and sources of information, while also helping to address potential obstacles to the thorough disclosure and analysis of AI incidents such as fear of reputational harm, lack of objectivity, or gaps in the timeline.

4.1 Implementing a Government-Run Database

Currently, there are no federally operated databases for logging AI incidents. All AI incident databases available today cite publicly available second-hand sources and entries are gathered through public submissions. The quality of incident reports is therefore dependent on journalists, contributors, and editors. By contrast, aviation accidents and federal cybersecurity vulnerabilities and exposures all require mandatory legal disclosure via first-hand sources. Government organizations can then investigate and validate reports for accuracy and probe for additional detail.

The introduction of a federally operated database would complement existing efforts by offering third-party centralized oversight of AI incident analysis. The mandatory disclosure of all or certain classes of AI incidents would increase the breadth of documented

incidents. Government oversight of AI incidents would also support the development of policies to address known issues.

4.2 Supporting Anonymous Submissions

Another mechanism for encouraging more first-hand, highly detailed accounts of AI incidents would be the development of a confidential submission database. Although some existing databases, such as AIID [9], include an anonymous submission option, a database designed specifically for confidential first-hand accounts could increase participation and result in higher quality reports. AI engineers directly involved with the development of AI systems, for instance, could report issues about the systems they work on without fear of professional repercussions.

The Aviation Safety Reporting System [32] provides an exemplar for incentivizing incident reporting in the absence of a legal mandate. The ASRS combats fears of reputational harm for submitters by offering confidential reporting of aviation incidents and has collected and displayed over a million de-identified reports. The CVE [30] also broadcasts defective components without attributing them to the systems in which the components are used. The success of de-identified databases in other industries suggests that a database of this type would bolster current AI incident documentation efforts.

4.3 Building Proactive AI Incident Databases

AI incident documentation could also benefit from the introduction of more proactive documentation. Currently, AI incident reporting is reactive, in the sense that it catalogues AI systems only after actual harms or near-misses have been realized. Proactive methods for documenting AI systems, on the other hand, support system monitoring prior to and in anticipation of possible incidents. Storing information about AI systems in a database before an AI incident has ever occurred will make it easier to track the full lifecycle of the system should an AI harm occur. Proactive reporting would also help AI engineers and researchers identify what the early signs of system inadequacy look like.

While proactive systems currently exist for tracking controversial systems such as the Panoptic Tracker for facial recognition systems [24] or the Observatory of Algorithms with Social Impacts Register [17], these databases do not link incidents to systems. Maintaining proactive documentation of AI systems in a database designed specifically to support the analysis of potential future AI incidents, as opposed to other goals like government transparency or activism, would help address the challenge of documenting complex timelines.

5 CONCLUSION

AI incident databases have great potential to support AI practitioners in gaining awareness of the mechanisms of challenging AI system failures. Identifying common underlying causes of failure and practical effectual solutions is critical to the development of AI engineering. As the AI community continues to document incidents, reflection is needed on how information is captured and the ways in which taxonomies can support or prevent meaningful analysis.

Current AI incident databases use limited classification schemas to capture surface-level characteristics of harms events. Moving forward, the AI community would benefit from examining and adopting approaches employed in other disciplines and across a variety of AI research and activist communities. Diversifying the landscape of AI incident databases and building incident documentation taxonomies tailored to AI systems will help us build a stronger understanding of AI incidents, define practices to avoid failures in the future, and bring us one step closer to developing safer AI systems.

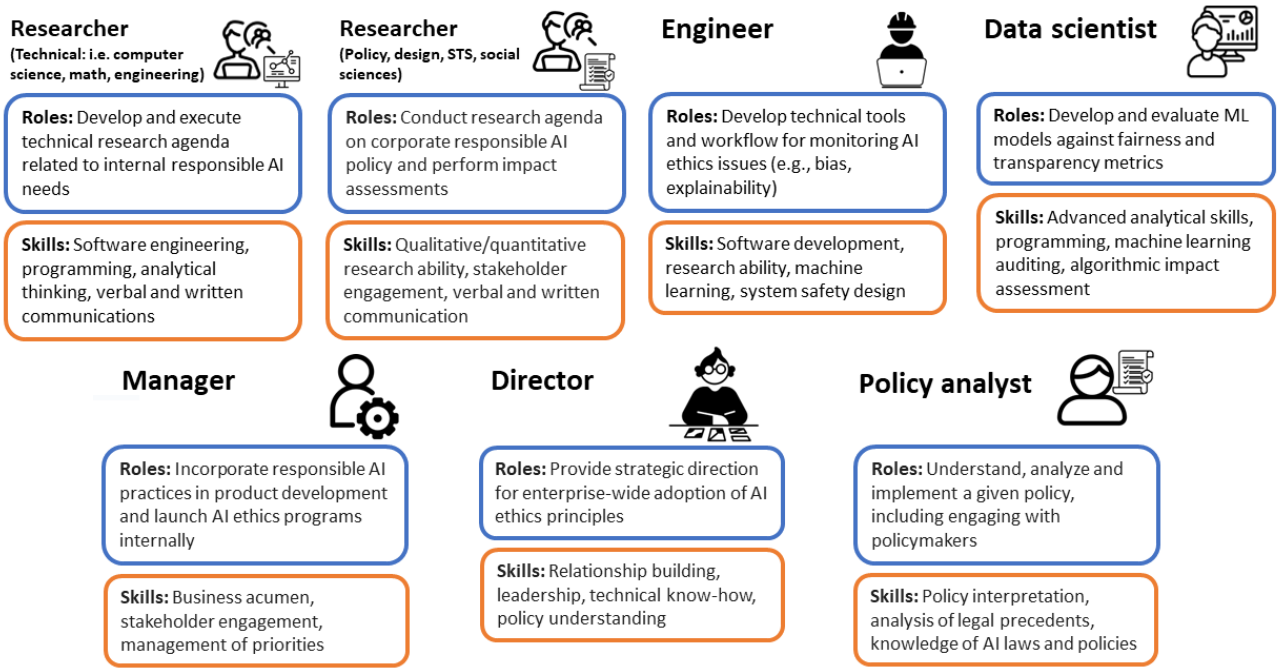

Figure 1: Existing roles and skills expected of responsible AI practitioners (AI ethicists)

ABSTRACT

With the growing need to regulate AI systems across a wide variety of application domains, a new set of occupations has emerged in the industry. The so-called responsible Artificial Intelligence (AI) practitioners or AI ethicists are generally tasked with interpreting and operationalizing best practices for ethical and safe design of AI systems. Due to the nascent nature of these roles, however, it is unclear to future employers and aspiring AI ethicists what specific function these roles serve and what skills are necessary to serve the functions. Without clarity on these, we cannot train future AI ethicists with meaningful learning objectives.

In this work, we examine what responsible AI practitioners do in the industry and what skills they employ on the job. We propose an ontology of existing roles alongside skills and competencies that serve each role. We created this ontology by examining the job postings for such roles over a two-year period (2020-2022) and conducting expert interviews with fourteen individuals who currently hold such a role in the industry. Our ontology contributes to business leaders looking to build responsible AI teams and provides educators with a set of competencies that an AI ethics curriculum can prioritize.

1 INTRODUCTION

With the rapid growth of the AI industry, the need for AI and AI ethics expertise has also grown. Companies and governmental organizations are paying more attention to the impact AI can have on our society and how AI systems should be designed and deployed responsibly [23, 31, 42]. From 2015 onward, a series of AI ethics principles [31], in-depth auditing toolkits [11, 39, 46], checklists [5, 35], codebases [4, 8], standards and regulations [1, 6] have been proposed by many different international actors. Several communities of research and practice such as FATE (Fairness, Accountability, Transparency, and Ethics), responsible AI, AI ethics, AI safety and AI alignment have emerged. This general movement towards responsible development of AI has created new roles in the industry referred to as *responsible AI practitioners* in this paper. The primary mandate of these roles is understanding, analyzing, and addressing ethical and social implications of AI systems within the business context. The emergence of these roles challenges technology companies to curate these roles and teams. Leaders in AI-related organizations need to identify, recruit and train appropriate candidates for such roles. As the demand to fill such roles continue to increase, educators need effective means to train talent with the right set of skills.

Recently, scholars examined the common roles responsible AI practitioners serve [25, 55], explored the challenges that they face [40, 47], and criticized the problematic nature of the accountability mechanisms that relate to these roles [19]. Moreover, others highlight the myriad practical challenges facing the development of a comprehensive training program to fill such roles [14, 26, 45]. However, there is a lack of empirical research investigating the types of roles, corresponding responsibilities, and qualifications that responsible AI practitioners have in the industry. To address these gaps, we examine the following research questions:

- **RQ1:** What are the types of roles and responsibilities that responsible AI practitioners hold in the industry?
- **RQ2:** What are the skills, qualifications, and interpersonal qualities necessary for holding such roles?

We address these questions by conducting a two-part qualitative study. We examined 79 job postings from March 2020 to March 2022 and conducted expert interviews with 14 practitioners who currently hold these roles in the industry. Learning from fields of competency-based recruitment and curriculum development, we propose an ontology of different occupations and an accompanying list of competencies for those occupations.

As illustrated in Figure 1, our ontology outlines seven occupations that responsible AI practitioners hold in the industry: researcher (of two kinds), data scientist, engineer, director/executive, manager, and policy analyst. For each occupation, the ontology includes a list of responsibilities, skills, knowledge, attitudes, and qualifications. We find that while the roles and responsibilities held by responsible AI practitioners are wide-ranging, they all have interdisciplinary backgrounds and are individuals who thrive in working with individuals from different disciplines. We discuss how educators and employers can use this competency framework to develop new curricula/programs and adequately recruit for the rapidly changing field of responsible AI development.

2 BACKGROUND

With the increased media reporting and regulation requirements around social and ethical issues of AI-based products and services [7, 38, 48, 51, 54, 56], the role of a responsible AI practitioner has emerged as a demanding position in the technology industry. In this section, we provide an overview of debates about these roles and existing educational programs that aim to train future responsible AI practitioners. We discuss how existing competency frameworks treat the role of a responsible AI practitioner and highlight the gaps we address in this work.

2.1 Emergence of the responsible AI practitioners

Considering the nascency of AI ethics as a domain, only a few scholars have characterized occupations held by responsible AI practitioners [36, 57]. For instance, Gambelin frames the role of an AI ethicist as "an individual with a robust knowledge of ethics" who has the responsibility and the ability to "apply such abstract concepts (i.e. ethical theories) to concrete situations" for the AI system. According to Gambelin, an AI ethicist in the industry also needs to be aware of existing policy work, have experience in business management, and possess excellent communication skills [25]. Gambelin identifies bravery as the most important characteristic of an AI ethicist as they often need to "shoulder responsibility" for potential negative impacts of AI in the absence of regulation.

Moss and Metcalf investigated practices and challenges of responsible AI practitioners in Silicon Valley and described them as "ethics owners" who are responsible for "handling challenging ethical dilemmas with tools of tech management and translating public pressure into new corporate practices" [40]. Echoing Moss and Metcalf's seminal work on examining AI industry practices, a growing body of empirical work highlights that responsible AI practitioners face challenges such as misalignment of incentives, nascent organizational cultures, shortage of internal skills and capability, and the complexity of AI ethics issues when trying to do their day-to-day tasks [41, 47, 48, 50, 55]. Furthermore, only large technology companies often have the necessary resources to hire responsible AI practitioners [52]. Small and medium-sized companies struggle to access such expertise and rely on openly available information or hire external consultants/auditors as needed [19, 52]. This has given rise to AI ethics as consulting and auditing service [10, 18, 34].

While challenges in operationalizing responsible AI practices are an active area of research, there is a gap in understanding the role and necessary competencies of responsible AI practitioners in the industry.

2.2 Qualifications to be a responsible AI practitioner

The emergence of auditors in the field of responsible AI emphasizes the need for formal training and certification of such roles in the industry [19]. This raises a few practical questions: Who is qualified to take these roles? How should these individuals be trained? Are existing computer science, engineering, and social science curricula prepare individuals for such roles?

Educators responded to this need by developing a range of educational programs and curricula [14, 24, 28, 44, 58]. In a survey of

the curricula for university courses focused on AI ethics, Garrett et al. emphasize that such topics should be formally integrated into the learning objectives of current and new courses [26]. On the other hand, as Peterson et al. describe, discussing social and ethical issues in computer science courses remains a challenge [43]. They propose pedagogues for fostering the emotional engagement of students in the classroom as a solution [43].

Recognizing the importance of interdisciplinary approaches in AI ethics, Raji et al. argue that computer science is currently valued significantly over liberal arts even in the research area of fairness of machine learning systems [45]. Furthermore, they state that the perceived superiority culture in computer science and engineering has created a "new figure of a socio-technical expert", titled "Ethics Unicorns" - full stack developers, who can solve challenging problems of integrating technology in society.

This overemphasis on computer science expertise and the trend toward integrating ethics content in existing technical curricula may be problematic if these efforts do not match the skills and disciplinary needs of the industry. It raises questions about whether the educational backgrounds of responsible AI practitioners today are indeed in computer science. In this work, we inform the curriculum development efforts across a diverse range of disciplinary areas by understanding these roles in the industry and outlining the attributes, qualifications, and skills necessary for holding them.

2.3 Competency frameworks in AI and AI ethics

Competency frameworks are useful tools for human resource management (i.e. recruitment, performance improvement) and educational development (i.e. new training programs and curriculum development in universities) [2, 53]. Competency frameworks highlight different competencies required for a profession and link these competencies to skills and knowledge. According to Diana Kramer "competencies are skills, knowledge and behaviours that individuals need to possess to be successful today and in the future" [49]. This definition frames our discussion of competency in this paper.

Competency frameworks help governmental and non-governmental organizations keep track of the type of skills their employees/general public need in the short and long term. Educators use these frameworks to update existing curricula and develop appropriate learning objectives. On the other hand, business leaders and human resource professionals use these frameworks for their recruitment practices.

Today's existing competency frameworks do not sufficiently represent roles and competencies of a responsible AI practitioner. For example, O*NET is United State's national program for collecting and distributing information about occupations [9]. O*NET-SOC is a taxonomy that defines 923 occupations and they are linked to a list of competencies. Searching the taxonomy for "ethics", "machine learning", "data", "security", and "privacy" leads to minimal results such as "information security analysis", "data scientist and "database architect". The dataset do not include occupation titles such as machine learning engineer/researcher or data/AI ethics manager.

ESCO, the European skills, competencies, qualifications, and occupation is the European and multilingual equivalent of US's O*NET [21]. ESCO contains 3008 occupations and 13890 skills. Searching for the above terms leads to more relevant results such as computer vision engineer, ICT intelligent system designer, policy manager, corporate social responsibility manager, ethics hacker, data protection officer, chief data officer, and ICT security manager. However, emerging occupations relevant to AI and AI ethics have not been well-represented in these established, Western competency frameworks.

As a response, a number of new AI competency frameworks have recently been developed. One such enabler is the series of projects funded by the Pôle montréalais d'enseignement supérieur en intelligence artificielle (PIA), a multi-institutional initiative in Montreal, Canada aimed to align educational programs with the needs of the AI industry. Six projects related to AI competency frameworks were funded – including the work presented in this paper. This resulted in an overarching AI competency for postsecondary education that includes ethical competencies [13], and a competency framework specific to AI ethics skills training [16]. Bruneault et al., in particular, created a list of AI ethics competencies based on interviews of university instructors/professors already teaching courses related to AI ethics across North America.

Our work complements these collective efforts by providing a framework that represents the needs of the industry expressed in recent AI ethics-related job postings and the realities of the jobs AI ethics practitioners hold in nonprofit and for-profit corporations today.

3 METHODOLOGY

Practitioners and scholars of different domains typically create competencies frameworks using a process most appropriate for their needs. However, many follow a version of the process highlighted by Sanghi [49]. The steps of the process are: 1) Define the purpose and performance objective of a position, 2) Identify the competencies and behaviors that predict and describe superior performance in the job, 3) Validate selected competencies, 4) Implement/integrate competencies and 5) Update competencies.

In this work, we focus on answering questions raised in the first two steps about the objectives of *responsible AI practitioner* roles and skills/qualities required to perform well in these positions. We take a two-pronged approach to understand the nature of emerging roles under the broad category of *responsible AI practitioners* in the industry. Firstly, we reviewed and analyzed job postings related to our working definition of *responsible AI practitioner*. Secondly, we interviewed individuals who are responsible AI practitioners in the industry today. We then synthesized data collected from these two sources through thematic analyses. We present our proposed competency framework in Section 4. This study was approved by the Research Ethics Board of our academic institution.

3.1 AI Ethicist Job Postings Review

We collected and analyzed 94 publicly available job postings over the period of March 2020 to March 2022. The job postings included a range of job titles, including researcher, manager, and analyst. The following sections describe the process for collecting, selecting, and analyzing these job postings that led to the development of the ontology of responsible AI practitioner roles and skills.

3.1.1 Collection of job postings. To collect "AI ethicist" job postings, we searched and scraped three job-finding websites, including LinkedIn, indeed.com, and SimplyHired, every two months from

March 2020 to March 2022. We used the following search terms: AI ethics lead, Responsible AI lead, AI ethics researcher, data OR AI ethicist and fairness OR transparency researcher/engineer. Considering that search results only showed a few relevant job postings, we also collected job postings that came through referrals, including mailing lists such as FATML, 80000hours.org, and roboticsworldwide.

After scanning all the resulting job postings with the inclusion criteria, we gathered a total of 79 job postings for thematic analysis. We included the job postings that were published within our data collection period, were situated in the industry (including not-for-profit organizations), and outlined responsibilities with regards to implementing AI ethics practices in a given sector.[1]

3.1.2 Analysis. Using Braun and Clarke's thematic analysis methodology [15], we analyzed the job postings with the coding scheme illustrated in Table 1. The lead author created this coding scheme after reviewing all the postings. The coding scheme was also informed by frequently used categories across competency frameworks explained earlier in section 2.3.

The codes were generally split into four key elements: the company environment, responsibilities in the given occupation, qualifications, and skills. The codes of "company environment" and "qualifications - interdisciplinarity" are unique to this coding scheme due to their prevalence in the postings' content.

After developing the first draft of the coding scheme, a student researcher was trained to use this scheme and coded 10% of the job postings. The student researcher's analysis using the coding scheme was consistent with the lead researcher's analysis of the same set of job postings. The discussion between the lead and student researcher helped clarify the description and examples for each code. However, there were no new codes that were added to the scheme. The lead author updated the coding scheme and coded the entire set of postings using the new scheme.

Table 1: Coding scheme for Job Posting Analysis

Code
Company environment
Occupation
occupation - non-technical roles
occupation - technical roles
occupation - title
Qualifications
qualifications - education
qualifications - experience
qualifications - interdisciplinarity
Skills/competency
skills/competency - attitudes/values
skills/competency - knowledge
skills/competency - language skills
skills/competency - skills

[1]The table outlining the inclusion and exclusion criteria is in the supplemental material.

3.2 Expert interviews

The job postings provide a high-level analysis of the required skills and competencies expressed by recruiters; however, they may not represent the reality of these roles. Therefore, we conducted 14 interviews with experts who currently hold responsible AI practitioner positions in the industry. The focus of the interviews was on understanding the responsibilities, qualifications, and skills necessary for these roles. Considering the objective of this research project on the type of roles and skills, we did not acquire any demographic information about the participants in these roles. This also ensured that we can maintain the anonymity of these participants considering that a limited number of people hold these positions.

3.2.1 Recruitment. We compiled a list of potential interview candidates through (a) referrals within the authors' professional network and (b) we used similar search terms as the ones highlighted for job postings to look for people who currently hold these positions. Moreover, we also considered people from the industry who had accepted papers at relevant conferences such as FAccT and AIES in 2020 and 2021. The suitable participants:

- worked for a minimum of three months in their role;
- held this position in the industry or worked mainly with industrial partners;
- held managerial, researcher, technical positions that are focused on implementing responsible AI practices within the industry.

We did not interview researchers or professors in academic institutes and only interviewed those holding positions at nonprofit and for-profit companies. While we only used the search terms in English to find interview participants for practical reasons, we did not limit our recruitment efforts to a geographical region given the limited number of individuals holding these roles across the industry. We recruited and conducted interviews from June 2021 - February 2022.

3.2.2 Interview protocol. The primary researcher conducted all fourteen interviews. All of the interviews were 45 to 60 minutes in length. The interviewer first described the project and obtained the participant's consent. The interview was semi-structured with ten questions focused on exploring the following four topics:[2]

- Background and current role
- Situation your work, projects in AI ethics
- Skills, knowledge, values
- Looking into the future

3.2.3 Data Analysis. We recognize that this research reflects our positionality and biases as academics in North America. Furthermore, the data we collected were all in English and they were representative of job postings and positions in companies situated in North America and Europe. We were not able to collect data on job postings and candidates representing existing efforts in Asia and the Global South. Furthermore, we recognize that the roles in this field are continually shifting. Therefore, this ontology is only a snapshot of the roles and skills that responsible AI practitioners have and are recruited for today. Further iterations on these types of frameworks will be necessary in the future as these roles evolve.

[2]The detailed interview protocol is included in the supplementary material.

Finally, this study focuses on examining responsibilities, qualifications, and skills required of today's practitioners independent of their demographic factors (e.g., gender, age). We recognize the importance of representing a demographically diverse group of individuals and their experiences in qualitative research such as ours. Once responsible AI practitioners become a common occupation held by many, future studies should include demographic factors as part of similar investigations.

3.3 Author reflexivity and limitations

We recognize that this research reflects our positionality and biases as academics in North America. Furthermore, the data we collected were all in English and they were representative of job postings and positions in companies situated in North America and Europe. We were not able to collect data on job postings and candidates representing existing efforts in Asia and the Global South. Furthermore, we recognize that the roles in this field are continually shifting and see this ontology as only a starting point for understanding the roles that responsible AI practitioners take and their necessary skills. We emphasize the need to have further iterations on these types of frameworks. Finally, this study focuses on examining responsibilities, qualifications, and skills required for such roles independent of the demographics of individuals who are currently holding these roles. We recognize the importance of having a demographically diverse group of individuals across many occupations and suggest that future studies also examine issues around demographic diversity in roles related to responsible AI.

4 PROPOSED COMPETENCY FRAMEWORK FOR RESPONSIBLE AI PRACTITIONERS

From our analysis, we developed a preliminary competency framework that captures seven classes of existing occupational roles and several emerging classes of occupations. Figures 2 and 3 show how each occupation type was represented in the job postings and interviews. Three of the occupations require technical expertise (researcher, data scientist, and engineer), two require policy expertise (researcher, policy analyst), and the remaining two are managerial (manager, director). In the following sections, we provide a detailed description of the responsibilities, skills, qualifications, and qualities for each of these roles.

4.1 Researcher (technical)

The most common class of occupations found in the job postings was that of a researcher focused on technical aspects of fairness, explainability, safety, alignment, privacy and auditability of AI systems (24 job postings, 2 interviews). Employers represented in this dataset were looking to hire researchers at varying levels of seniority (assistant, associate and principal). The main responsibilities of these researchers are split into four main categories: conducting research, communicating their findings, working with other teams (internally and externally), and developing novel solutions for identified problems. As expected, research directions set by these researchers need to support company-specific needs, and there is an emphasis on communication between researchers and product, legal and executive teams.

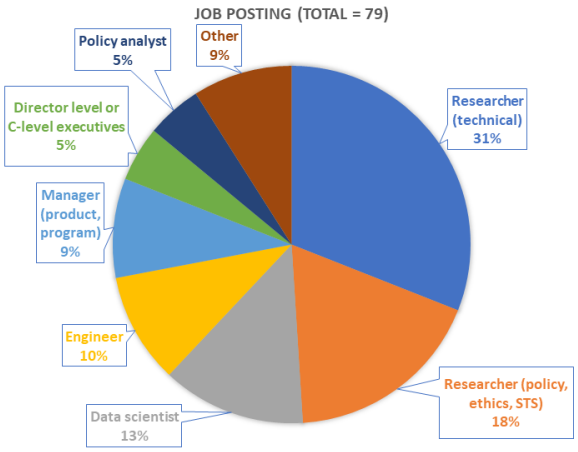

Figure 2: Distribution of occupations represented in the job postings dataset

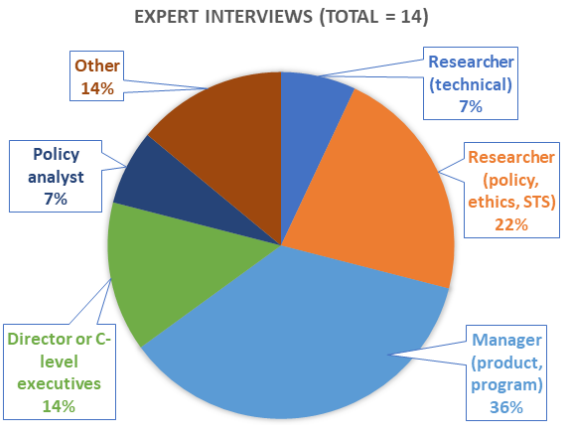

Figure 3: Distribution of occupations represented in the interviews

Skills. The researchers in this group need to have a mix of technical skills (i.e. software engineering and programming languages such as Python), research skills (i.e. analytical thinking and synthesis of complex ideas), and leadership skills (i.e. leading and guiding fellow researchers). The dataset from the job postings emphasized equally all these skills, and more senior positions emphasized leadership skills. A senior researcher explained that they look for "different research skills" depending on the project; however, they generally look for *"some background in machine learning, statistics, computer science or something of that nature"* and hire candidates that have some *"interdisciplinary background"*. The data from the postings and the interviews show a strong emphasis on good verbal and written communication skills. Participants highlighted the ability to publish in academic venues and some emphasized the ability to communicate with different audiences internally (i.e. product teams and executives) and externally (policy-makers and executives). A technical researcher emphasized the importance of

"convincing stakeholders" and creating *"strategic collaborations"* by communicating with practitioners with "diverse" backgrounds.

Qualifications. The job postings mainly aim to attract candidates who have a PhD in computer science or a related field. Few of the job postings accept a master's in these fields, whereas some do not highlight a specific degree and mainly focus on necessary skills and knowledge. The majority of postings have a heavy emphasis on the required experience. Interview participants also emphasized the importance of experience. A research manager expressed that they are not necessarily looking for a *"PhD in computer science"*. They are looking for candidates with experience in *"leading and executing a research agenda"*, working with different people and teams, synthesizing and *"communicating challenging concepts"*, and practicing software engineering. Some postings highlight experience with implementing AI ethics-related concepts. However, this was often listed as a preferred qualification rather than a required one. Similarly, researchers we interviewed, echoed the importance and value of having a publication record in *"Fairness, Accountability, Transparency, and Ethics (FATE) communities"* such as ACM Conference on Fairness, Accountability, and Transparency (FAccT) and AAAI/ACM Conference on AI, Ethics, and Society (AIES).

Interpersonal Qualities. The most common attitude/value was the aptitude and interest to *collaborate and work in an interdisciplinary environment*. A researcher emphasized that the current conversations are "engineering focused" and they actively incorporate perspectives from *social science and philosophy by collaborating with experts in these areas*. The most desired value was *"curiosity to learn about [responsible AI] problems"*. Many of the participants highlight other values and attitudes such as *"passion"* towards building safe and ethical AI systems, *willingness to manage uncertainty and challenges*, *creativity*, and *resourcefulness*.

4.2 Data scientist

The data scientist occupation is represented in 10 job postings in our dataset, and none in the interviews. The job postings seek to fill traditional data scientist roles with an added focus on examining responsible AI-related issues. The common responsibilities outlined for these positions are a) to collect and pre-process data, and b) to develop, analyze, and test models – these are typical of existing data science roles. However, the job postings emphasize the position's responsibility to test machine learning models for AI ethics concerns such as fairness and transparency. Data scientists who work in the responsible AI domain have additional non-conventional roles. These roles include understanding and interpreting existing regulations, policies, and standards on the impact of AI systems and testing the systems' capability for elements covered in these policies. They also need to work with technical and non-technical stakeholders to communicate findings, build capacity around responsible AI concepts and engage them as needed.

Skills. The job postings put a heavy emphasis on advanced analytical skills and the ability to use programming languages such as R, Python and SQL for basic data mining. The ability to learn independently in a new domain and master complex code base is also listed as one of the key skills. A few of the postings list project management and organizational skills; however, this is not common. When it comes to the knowledge required, the focus shifts from the technical domain to an understanding of fields such as sociology, critical data studies, and AI regulations. Many postings highlight that potential candidates need to be familiar with concepts such as AI/ML auditing, algorithmic impact assessments, assessment of fairness in predictive models, explainability, robustness, and human-AI interaction. Technical knowledge, such as understanding transfer-based language models and logistic regression model development, is also highlighted in the posting. Lastly, the job postings outline the need for strong interpersonal, verbal, and written communication skills. However, experience publishing and presenting at academic venues is not mentioned.

Qualifications. The majority of the job postings require a bachelor's degree in quantitative fields such as data science and computer science and prefer higher degrees (master's or Ph.D.). Companies are looking for candidates who have experience in data science, software engineering, and worked with large language models. Moreover, they are looking for experience in putting responsible AI principles into practice, evaluating the ethics of algorithms, and having basic familiarity with law and policy research. The ability and experience to translate AI ethic principles into practice are heavily emphasized throughout these job postings.

Interpersonal Qualities. The job postings emphasize the ability to work with people from different backgrounds. However, these job postings do not include a comprehensive list of values. A few postings mention being a self-starter, working collaboratively to resolve conflict, and caring deeply about the data used to train ML models as key attitudes. Being flexible, innovative, curious, adaptive, and passionate about tackling real word challenges are also some of the sought-after values.

4.3 Engineer

The engineer occupation is represented in 8 of the job postings. None of our interview participants belong to this category. The key responsibility of an engineer practicing AI ethics is to help establish a safety culture and system within an organization by developing technical tools. They are tasked with developing a workflow for modeling and testing for issues such as bias, explainiability, safety, and alignment of AI systems. As part of this, engineers need to create code bases that could be used across the AI system development pipeline based on existing and evolving best practices.

Skills and Qualifications. Job postings for engineers place a significant emphasis on experience-based qualifications and skills. The companies represented in this dataset are looking for skills and experience in software development, dataset production pipelines, researching fairness and safety implications of ML systems, and the development of large language models. They are also looking for experience working in a fast-paced technology company. Based on these qualifications, the main set of skills are programming and AI/ML development skills and this needs to be supported by knowledge and familiarity with foundational concepts in AI/ML, fairness, explainability, system's safety, and safety life cycle management. Lastly, most of the job descriptions do not have a heavy emphasis on communication skills. Only a few mention excellent written and oral communication skills as a requirement.

Interpersonal Qualities. In contrast to the lack of emphasis on communication skills, these postings have a particular focus on the attitude and values of ideal candidates more so than any other occupation category. These attitudes include being result-oriented, willingness to contribute as needed (even if not specified) and keen to learn new concepts. They are looking for people who value working on challenging problems and care about the societal impact of their work.

4.4 Researcher (Policy, design, science and technology studies, social sciences)

The second most frequent category of postings belongs to researchers that focus on topics such as policy, sociotechnical issues, and governance (14 job postings, 3 interviews). We created a separate group of positions as their responsibilities, skills, and qualities are sufficiently different from the technical researcher position. Candidates in this category need to conduct research, perform ethics or impact assessments of AI systems, act as a liaison and translator between research, product, policy, and legal teams, and lastly, advise on policy, standards, and regulations-related matters internally and externally. When conducting research, two different focus areas come up in the job postings: testing and evaluating AI system to inform policy and researching existing policies/regulations, and translating them into practice.

Skills. The job postings highlight two sets of distinct skills for this group of researchers. Firstly, these researchers require a basic level of programming, advanced analytics, and data visualization skills. Few positions highlighted the need for even more advanced ML and AI skills. It is noteworthy that despite these researchers' focus on policy, governance and sociotechnical issues, the postings still require them to have some data analytic skills. Secondly, these researchers need to have excellent facilitation, community-building, and stakeholder engagement skills. These two skills need to be complemented by strong leadership and management skills. The job postings heavily emphasize strong communication skills for this group of researchers. Besides the conventional skill of presenting and publishing papers, this group of researchers need to effectively work across different functionalities and disciplines. On a similar trend, these researchers need to have expertise in a variety of areas. They need to have a good understanding of *"qualitative and quantitative research methods"*, reliably know the current and emerging *"legal and regulatory frameworks and policies"*, be *"familiar with AI technology"* and have a good knowledge of practices, process, design, and development of AI technology. This is a vast range of expertise and often *"very difficult to recruit"* for as highlighted by our expert interviewees.

Qualifications. Just over half of the job postings list a Ph.D. in relevant areas as a requirement, including human-computer interaction, cognitive psychology, experimental psychology, digital anthropology, law, policy, and quantitative social sciences. Two postings require only a bachelor's or a master's in the listed areas. Similar to the technical researcher occupation, some positions do not specify any educational requirements and only focus on experience and skills. Our expert interviewees in this category are from a range of educational backgrounds ranging from a master's in sociotechnical systems, a law degree combined with a background in statistics, and a master's in cognitive systems.

Besides experience in research, companies are looking for experience in translating research into design, technology development, and policy. A researcher explained that they need to do a lot of "translational work" between the academic conversation and product teams in companies. A good candidate for this occupation would have *"project management"*, *"change management"*, *"stakeholder engagement"*, and *"applied ethics"* experience in a "fast-paced environment". All four of these skills do not appear in all of the job postings and interview discussions. However, a permutation of them appears throughout the job posting data and participants' responses.

Interpersonal Qualities. As emphasized strongly in both of the datasets, ideal candidates in this category need to have a *"figure-it-out somehow"* or *"make it happen"* attitude as explained by a participant. They are *"driven by curiosity and passion towards"* issues related to responsible AI development and are excited to engage with the product teams. Participants noted that ideal candidates in these roles are *"creative problem solvers"* who can work in a *"fast-changing environment"*.

4.5 Policy analyst

Policy analyst occupation is the least represented [1 expert interview, 4 job postings] in our data sources; however, considering the consistent list of competencies, we decided to include it within the proposed framework. The role of a policy analyst is to understand, analyze and implement a given policy within an organization. Moreover, they need to engage with policymakers and regulators and provide feedback on existing policies.

Skills and Qualifications. A policy analyst needs to have proven knowledge of laws, policies, regulations, and precedents applicable to a given technology when it comes to AI ethics-related issues. Moreover, all of the job postings highlight the importance of familiarity with AI technology. According to the job postings, a good candidate would have experience in interpreting policy and developing assessments for a given application. They also need to be skilled in management, team building, and mentorship. This finding echoes remarks from expert interviews. Even though none of the job postings specify an educational degree requirement, the expert we interviewed was a lawyer with a master's in technology law.

Interpersonal Qualities. The job postings in this category heavily emphasized values and attitudes. A good analyst needs to have sound judgment and outstanding personal integrity. They should be caring and knowledgeable about the impact of technology on society. Moreover, they enjoy working on complex multifaceted problems and are passionate about improving governance of AI systems. The expert interviewee's perspective closely matches these attributes. Participants elaborated that they needed to be *"brave"* and *"step up to ask questions and challenge status quo consistently over a long time"*. As expected communications skills are considered critical for success. The expert interviewee significantly emphasized the importance of *"networking as a key factor"* in succeeding in their role.

4.6 Manager

We analyzed 7 management-related job postings and 5 expert interviewees in this category. The product managers take the role of incorporating responsible AI practices in the product development process. In contrast, program managers are often leading and launching a new program on establishing AI ethics practices within the organization. These programs often involve building an organization's capacity to manage responsible AI issues.

Skills. For both streams of management, the potential candidates need to have strong business acumen and a vision for the use/development of AI technology within an organization. Some of the key management skills highlighted in the job postings include the ability to manage multiple priorities and strategically remove potential blockers to success. Another sought-after skill is the ability to effectively engage stakeholders in the process. Expert interviewees also echoed the importance of this skill as their roles often involve getting people *"on board with new ways of thinking and creating"*. According to the job postings, good candidates for management need to have a practical understanding of the AI life cycle and be familiar with integrating responsible AI practices into a program or a product. Our interviewees note that they continuously need to *"learn and keep up with the fast-paced development of AI"*.

Qualifications. Not many postings have highlighted educational qualifications and instead focused on experience qualifications. However, the main educational qualification is a bachelor's degree with a preference for higher degrees. The postings have primarily highlighted a degree in a technical field such as computer science or software engineering. Interestingly the interviews reflect a different flavor of educational backgrounds. All of the experts we interviewed had at minimum a master's degree and the majority of them completed their studies in a non-technical field such as philosophy, media studies, and policy. However, these individuals had acquired a significant level of expertise in AI ethics through *"self-studying"* and *"engaging with the literature"* and the responsible AI *"community"*. For example, two of the participants trained in technical fields and had a significant level of industry experience. Similarly, they had learned about responsible AI through their own initiative.

On the other hand, the job postings heavily focus on *experience*, including a significant amount of technical know-how, experience focused on ML development, product and program management , and implementation of ethical and social responsibility practices within fast-paced technology companies. The interview participants had been *"working in the industry for some time"* before taking on these management roles. However, their range of experiences do not cover all of the required experiences outlined in the job descriptions. As expected, excellent communication skills are noted in the job descriptions and strongly echoed by the experts as well. The job postings do not necessarily elaborate on the nature of communication skills; however, the experts note that the *"ability to listen"*, *understand*, and sometimes "*persuade different stakeholders"* is key in such roles.

Interpersonal Qualities. Few of the job postings make remarks about attitudes/values and highlight that managers need to value designing technology for social good and cooperation with other stakeholders. A good candidate for management should foster a growth mindset and approach their work with agility, creativity, and passion. All of the participants expressed their passion for developing ethical technology and indicate that they took a lot of initiative to learn and contribute to the field within their company and externally before they could take on their management roles.

4.7 Director

The job descriptions dataset has 4 postings for director positions and 2 of the expert interviewees have directorship roles. According to the job postings, director responsibilities include at least three of the following: a) lead the operationalization of AI ethics principles, b) provide strategic direction and roadmap towards enterprise-wide adoption and application of ethical principles and decision frameworks, and c) build internal capacity for AI ethics practice and governance. Depending on the nature of the organization and its need to incorporate AI ethics practices, these responsibilities vary in scope. For example, a director within a technology start-up will only be able to commit *"limited amount of time to operationalizing AI ethics principles and building internal capacity"* compared to a director within a larger technology company.

Skills and qualifications. According to the job postings, the key skill for being a director is having the ability to build a strong relationship with a broad community that helps define and promote best practice standards of AI ethics. An ideal director can effectively pair their technical skills/know-how with their management skills and policy/standards knowledge to develop strategic plans for the company. Experience in directing and leading teams, particularly in social responsibility practices within technology companies is highly valued for such positions. Only one job posting specifies an educational (a bachelor's related to policy development and implementation). Others only highlight experience. The two interviewees hold master's degrees in business and information systems respectively. They also had extensive industry experience that was not directly in AI ethics. However, their experience involved *"translation of policy within a technology application"*.

Interpersonal Qualities. As expected, according to the job postings a good candidate for directorship needs to have exceptional written and verbal communication skills, need to be able *"to articulate complex ideas"* to technical and non-technical audiences, *"engage and influence stakeholders"* and *"collaborate with people from different disciplines, and cultures"*. This set of skills was reflected in our expert interviews. Both interviewees emphasized how they maintain a good flow of communication with the employees and how they remain always open to having conversations on a needs basis. This allowed them to build trust within the company and pursue moving forward with their strategic plan. The job postings highlight the ability to earn trust in relationships as a sought-after value for a directorship role. A director should also be able to *challenge the status quo, be passionate about good technology development, be comfortable with ambiguity*, and *adapt rapidly to changing environment and demands*. Most importantly, a director needs to have *"a strong and clear commitment to the company values"* as they set the tone for others within the organization.

4.8 Emerging occupations

Besides the abovementioned classes of occupations, we found a few other positions that do not map easily to any of the existing categories. Considering the limited number of these positions, they do not justify a category of their own. However, we note these emerging roles to understand how they might shape up the responsible AI profession. These occupation titles include data ethicists (2 in job postings), AI ethics consultants (2 in interviews), dataset leads (2 in job postings), communication specialist (1 in job postings), safety specialist (1 in job posting) and UX designer (1 in job postings). The following describes the main function of these positions:

- Data ethicist: manage organizational efforts in operationalizing AI ethics practices through policy and technology development work. This role has similarities to the role of a policy analyst and data scientist.
- AI ethics consultant: apply their expertise in AI ethics to solve pain points for consulting clients.
- Dataset lead: curate datasets while accounting for fairness and bias-related issues.
- Safety specialist: use and test large language model-based systems to identify failures and errors.
- AI ethics communication specialist: write communication pieces that focus on AI ethics issues.
- UX designers: design user interfaces with ethics in mind.

4.9 Future of the responsible AI profession

Our interview participants shared a variety of responses to the question "what will the future of their job be like?". Some participants thought that eventually, *"everyone in a company will be responsible"* for understanding ethical and social issues of AI as part of their job. In this scenario, everyone would need to have the appropriate knowledge and skillset to apply responsible AI practices in their work or at least know when they need to ask for advice from internal or external experts.

On the contrary, many participants expressed that *"dedicated roles"* need to be recruited. These participants elaborate that recruitment for these roles is and will *"continue to be challenging"* as it is difficult to find people with interdisciplinary backgrounds and established industry work experience. Many of the managers we interviewed have chosen *"to build teams that come from different disciplinary backgrounds"* and provide *"professional development opportunities"* on the job. However, they also described that hiring people into these roles is challenging since corporate leaders are not always willing to invest a lot of resources in AI ethics. This often can lead to *"exhaustion and burn-out"* for individuals who currently hold these roles - this is especially true for small and medium-sized technology companies. According to participants, this will likely change with a progressive shift in the regulatory landscape.

5 DISCUSSION

Educators and employers play a pivotal role in shaping a responsible AI culture. In our efforts to create a competency framework that outlines the range of roles for responsible AI practitioners, we find that such frameworks can not only guide corporate leaders to recruit talent but also help grow their responsible AI capacity.

We find that the ability to work in an interdisciplinary environment, communicate and engage with diverse stakeholder groups, and the aptitude for curiosity and self-learning are consistently highlighted for all of the roles. This emphasizes the need to foster an environment where students and existing employees in different roles are encouraged to adopt interdisciplinary approaches/collaboration and explore responsible AI content.

In this section, we articulate how an interdisciplinary environment can be fostered, the importance of organizational support for responsible AI practitioners, and the need to proactively monitor the rapidly changing occupational demand and landscape for these roles.

5.1 Being able to work in an interdisciplinary environment is critical

Our results show that many of the responsible AI practitioners today come from non-traditional, non-linear, and interdisciplinary educational and work backgrounds to their current positions. The educational and work experiences of these participants span a multitude of fields and allowed them to develop a strong set of skills in navigating disciplinary boundaries and understanding problems from diverse perspectives. The participants often described their role as a *translator* and *facilitator* between different groups and disciplines within the organization. For instance, they remarked that a concept such as fairness, transparency, or ethically safe has completely different meanings depending on the personal and professional backgrounds of their audience. The participants often needed to translate what these concepts mean across different disciplinary boundaries (i.e. statistics and law).

Notably, while the job postings asked for a diverse array of skills and qualifications from multiple disciplines, those who hold such positions today are often specialized in one or two disciplines. However, they had been exposed to and worked across multiple disciplines in their professional career. The most important asset that our interviewees emphasized was being able to work across disciplinary boundaries. The candidates who successfully hold such positions are *not "ethical unicorn, full stack developers"* [45]. However, they have honed the skills necessary to translate and create solutions to responsible AI issues across multiple disciplines. Building on existing proposal to improve responsible AI practices [19, 35, 48] and education [26, 43], we posit that AI team leaders need to pay a special attention to hiring individuals with the capability to create, critique and communicate *across multiple disciplines*. Consider Furthermore, educators can get inspiration from education models in highly interdisciplinary fields such as healthcare and create curricula/spaces where students work with peers from different academic backgrounds [20, 29, 32].

5.2 Responsible AI practitioners are advocates - but they need organizational support

We find that responsible AI practitioners are often highly driven and motivated to make a positive impact. These individuals often hold a strong sense of valuing social justice and want to ensure that AI technology is developed in a way that is good for society's well-being. One of the most consistent ideas that came through in the interviews is the attitude that the participants had toward

their careers. Many of the interview participants took the time to immerse themselves in learning new topics and expressed that they were self-motivated to do so. This is especially true for the individuals who are taking some of these first positions in the industry. When looking at the career trajectory of many of the participants, we observe that they often created their own roles or came into a newly created role. Moreover, these individuals often needed to start their own projects and create relationships with others in the organization to measure their own progress and establish credibility.

Similar to any emerging profession many of the participants act as champions for ethical and safe development of AI. They are often working in an environment that questions and challenges the need for considering AI ethics principles. As some of the participants remarked, they often have to answer questions such as "*why do we need to pay for ethics assessments?*", *"what is the value of considering AI ethics in a start-up?"*, or *"why should we put in the time? what is the value added?"*. This act of advocating for AI ethics is even more challenging when existing regulations do not have proper enforcement mechanisms for responsible AI practices [19]. Many of the participants assume the role of an advocate and often use their excellent communication skills to build relationships and capacity within their organization.

For the successful implementation of responsible AI practices, it is important that business leaders pay attention and support the advocacy efforts of these practitioners. Many of today's responsible AI practitioners are working with limited resources [40], have critical responsibilities [47], and are experiencing burn-out [30]. Whenever possible, leaders in AI companies need to create appropriate incentive structures, provide the necessary resources and communicate the value of establishing responsible AI practices to their employees so that these practitioners have the necessary support for the effective execution of their responsibilities. Recognizing the nature of these roles, educators can learn from existing methods [17, 22] and integrate leadership training into their curricula when addressing responsible AI-related content.

5.3 Educators and employers need to monitor and plan for the rapidly changing landscape of responsible AI roles

The nature of occupations in the AI industry is continually growing and shifting. The rapid technological development [3, 37], upcoming regulations [7] and global economic conditions [27, 33] impact how companies recruit and retain responsible AI expertise. Furthermore, there is a need for new educational efforts and programs for preparing new graduates to take on responsible AI practices. The proposed ontology provides a synthesis of roles that have emerged in responsible AI practice and it can serve as a planning tool for corporate leaders and educators.

Corporate leaders can use this ontology to build internal capacity for individuals who currently hold researcher, data scientist, engineer, policy advisor, manager, and director roles in their institutions. Depending on these companies' responsible AI needs and resources, business executives can work towards creating interdisciplinary teams for establishing responsible AI practice by recruiting individuals with the competencies outlined for each of these roles. Besides recruiting and fostering for responsible AI competencies, these leaders need to communicate the importance of these practices and start by creating the appropriate organizational incentives and resources for adapting responsible AI practices. Government and non-governmental organizations could support such efforts, particularly small and medium-size companies, by formally recognizing such roles in their taxonomies of occupations [9, 21] and providing resources [12].

Current computer science and engineering education focuses primarily on teaching professional ethics [43]. There is minimal focus and resources on cultivating skills and knowledge required for cultivating the skills that focus on ethics in design [26]. On the other hand, there is a lack of clarity of how much students in social and political sciences need to work on their technical acumen to become skilled responsible AI practitioners [45]. Educators could use the list of competencies to develop a set of learning objectives and examine the efficacy of different teaching pedagogies in supporting these objectives. Moreover, Educators can use the competency framework as a tool for acquiring resources for further curricula and program development.

Notably, the proposed ontology primarily focuses on type of roles, responsibilities and skills without addressing other important factors in recruitment and education efforts such as diversity of individual who get to learn about responsible AI issues or take such roles in the industry. Therefore, it is critical that users of this ontology, consider factors that are not captured in the scope of this ontology. Furthermore, considering the rapidly changing conversation around responsible AI practices, the type of roles in this onotlogy will shift and expand. We invite the community of researchers , practitioners and educators to reflect on these roles and build on this ontology.

6 CONCLUSION

With the increased regulatory activities in the industry, companies have the incentive to ensure responsible AI development. In this work, we found seven different type of roles and their corresponding responsibilities, skills, qualifications, and interpersonal qualities expected in today's responsible AI practitioner. We propose a preliminary competency framework for responsible AI practitioners and highlight the importance of creating interdisciplinary teams and providing adequate organizational support for individuals in these roles.

ACKNOWLEDGMENTS

We thank our study participants for taking the time to share their experiences, expertise, and feedback. We also thank our anonymous reviewers for their deep engagement and valuable feedback on this paper. This work benefitted greatly from the data collection and analysis assistance from our collaborators Sandi Mak, Ivan Ivanov, Aidan Doudeau, and Nandita Jayd at Vanier College, Montreal. We are grateful for their contributions. Finally, this work was financially supported by the Natural Sciences and Engineering Research Council of Canada and Pôle montréalais d'enseignement supérieur en intelligence artificielle.

Effective Enforceability of EU Competition Law Under AI Development Scenarios

a Framework for Anticipatory Governance

ABSTRACT

This paper examines whether competition law enforcement can remain effective under different AI development scenarios over the coming years. Economic and political power has become increasingly concentrated into a few AI companies, such as Big Tech. The growth of generative AI could further reinforce this concentration of power in Big Tech. The market power of these companies, and increasingly their involvement in AI, is a major focus for regulators such as the European Commission. Recent EU antitrust fines on Google alone run in the billions. The dynamism of technology markets such as AI can make it difficult for regulators to take effective action. If AI continues to develop rapidly over the coming years, propelled by the proliferation of generative AI, this ability to effectively enforce antitrust law may be further challenged. To help ensure regulators remain effective, EU competition law has been bolstered by a new tech-tailored, ex ante competition regime. These are likely to be critical tools to shape the market power of Big Tech but are largely untested. Exploring how these regulatory tools can be most effective in governing future AI development is a timely question for regulators, lawyers, companies, and citizens. This paper examines this question by considering the 'effective enforceability' of EU competition law and the Digital Markets Act under different AI development scenarios. By 'effective enforceability' of EU competition law we mean how well it achieves its policy objectives. We consider four factors: jurisdictional scope, potential loopholes, effectiveness of detection, and ability to remedy/sanction breaches. However, there is significant uncertainty as to how AI will develop in the coming years. Considering this, we propose an analytical framework based on five variables: key inputs, speed of development, AI capability, number of actors, and the nature/relationship of actors. In some of these scenarios, we argue EU competition law would struggle to address the power of the largest AI companies; but in many other scenarios it remains a powerful tool. This is a critical juncture for competition regulators. They stand at the dawn of emerging challenges presented by generative AI. With this paper, we hope to contribute to anticipatory governance at this important intersection of legal governance and technology.

Effective and future-proof competition law enforcement is crucial to ensuring this potentially transformative technology has widely distributed benefits, rather than concentrating power in a few hands.

1 INTRODUCTION

Competition law (also known as antitrust) is a key tool to govern concentration of economic power to ensure the market functions competitively for the benefit of consumers and citizens. However, competition law enforcement may be profoundly challenged by progress in developing artificial intelligence (AI) and the proliferation of generative AI systems [1], [2]. The most prominent generative AI system, ChatGPT, shows how their spread can be rapid and their potential impact could be immense. An ongoing challenge is how regulators best keep up with these developments.

The scope of this paper focuses on the European Union (EU) competition regime and how that regime may apply to different AI development and deployment scenarios. We start by providing a brief overview of EU competition law principles and why it is likely to be enforceable against entities that are most likely to develop AI in future. In the substantive part of the paper, we consider the extent to which competition law is enforceable across (2) different AI development and deployment scenarios. We define 'AI' as digital systems that can performing tasks commonly thought to require intelligence, with these tasks typically learned via data and/or experience. 'AI systems' refer to a software process (with the characteristics of AI mentioned above), running on physical

hardware, under the direction of humans operating in some institutional context [3, pp. 4 and 62]. Generative AI is a category of AI system that uses machine learning that generates a wide range of output (images, text, audio) based on data it was trained on. Their USP is their adaptability to a wide range of tasks.

We seek to contribute to the literature in three main ways. First, this paper focuses on the 'effective enforceability' of competition law to future AI development and deployment under different scenarios. Competition law is likely to be an important instrument (and perhaps the most important regulatory tool) in shaping the behaviour of 'AI actors': those that develop and deploy AI systems. However, effective enforceability is already challenging, and may become harder: in certain AI development scenarios – it may be harder for regulators to detect and sanction breaches. While we use EU competition law as our focus (looking at abuse of dominance, merger control, state aid and anti-competitive agreements), EU competition law has jurisdiction over foreign companies that are active in the EU, such as US Big Tech (indeed these companies have been the focus on EU competition law enforcement in recent years). Also, most of our analysis can apply to US antitrust [4]. Moreover, we envisage that our findings around the enforceability of competition law can also be extrapolated to the question of enforceability of law and regulation more broadly.

Second, we outline different scenarios for analysing AI development and deployment in future, based on a number of technical and strategic variables. In previous literature, scenario-mapping has focused on a more limited set of variables relating to technical model or number of developers [5, p. 170]. We envisage this will offer a nuanced framework of analysis for anticipatory governance more broadly.

Third, we intend our legal analysis of the implications of the effective enforceability of competition law to be useful for 'AI governance': the broad field that attempts to ensure systems are developed and deployed ethically, safely, securely and with broadly distributed benefits - in a word, 'responsibly' [6], [7]. Both the synergies and tensions between AI governance and competition law are potentially significant, yet currently underexplored [8], [9]. This memo builds on work at this intersection [10], [11]. We hope that this will be useful to both fields, and indeed encourage collaboration across these fields.

By identifying the areas where competition law enforcement may be less effective, we hope to contribute to anticipatory governance and help make competition law more 'future-proof'. This is essential to ensure that enforcement can keep up with complex and fast-moving technologies such as generative AI. Effective competition law enforcement, now and in future, is crucial to ensuring the benefits of this transformative technology are widely distributed.

2 FRAMEWORK OF LEGAL ANALYSIS

2.1 Effective enforceability' of Competition Law

'Effective enforceability' is a term that we introduce to refer to how effective competition law is in achieving its objectives. In relation to EU competition law, that objective as set out in the Treaty on the Functioning of the European Union (TFEU) is to prevent restrictions on and distortions of competition in the internal market [12]. The four main areas of competition law that may apply across our AI scenarios include abuse of dominance, merger regulation, collusion/cartel, and state aid.

Effective enforceability can depend on a wide variety of factors. For present purposes, we will focus on the following: (1) whether the conduct in question falls within the jurisdictional scope of competition law and is not protected by sovereign immunity rules, for example; (2) if the law is written and applied by the courts in a way that is in line with the legislators' intentions. An example of where the law is not aligned with legislator's intentions is where behaviour that a legislator would have intended to be a breach slips 'through the net' due to the presence of a lacuna, ambiguity or loophole in the rules [13], [14], or laws that fail to keep up with market developments and therefore end up being too lax/too strict in light of changes) [15], [16]; (3) regulators have the independence and the resources and expertise to effectively detect and bring a case against the breach (this may involve monitoring behaviour and assessing the market power of companies) [17, pp. 34–47], [18, p. 10]; and (4) competition law can effectively remedy and sanction the breach in a way that addresses the harm. In other words, whether competition law can restore competition in the market and change behaviour, both by punishing the company that breached the rules, and deterring others from unlawful behaviour [18].

2.2 Development Scenarios

The trajectory that AI development and deployment will take in the coming years is highly uncertain. Generative AI seems to have transformed the AI landscape in just a few months and its full impact is still difficult to predict. There is little agreement about the key input into AI development, the future speed of development, what levels of capability we will reach, the number and nature of the key 'AI actors' or the geopolitical environment they will operate in.

Nevertheless, we can draw from techniques which have been well-developed since the 1970s in futures, long-range technological forecasting, and scenario-planning and -mapping [5], [19], [20], [21, pp. 443–464], [22]. We can capture our uncertainty on particular dimensions in a set of variables. Each of these variables can have several possible values and lie on a spectrum. When we assign values to each of these variables, we can describe particular scenarios for future AI development.

Our five variables are grouped into technical variables, which relate to the technical features of the AI systems and non-technical variables, which relate to factors beyond the AI systems themselves: the number of developers, who those actors are and the geopolitical context they operate within

We expand upon each of these variables below. For each variable, we first describe the spectrum, and second consider the 'effective enforceability' of competition law across its spectrum. Our analysis depends on simplified hypothetical scenarios, where the variables change but everything else is kept constant. Of course this does not reflect complex market realities and competition analysis is very fact-specific and will depend on the particular legal and economic context in each particular case. Therefore, our analysis is necessarily based on a number of assumptions, but nevertheless draws out some informative high-level themes and 'direction of travel'. They are

Table 1: Effective enforceability of competition law across five variables

Type	Variable	Less Enforceable	More Enforceable
Technical	Key inputs	Talent and Data	Compute
Technical	Speed of development	Fast progress	Incremental progress
Technical	Capability	Higher capability	Lower capability Non-Technical
Non-Technical	Number of actors	More actors	Fewer actors
Non-Technical	Nature and relationship	States and 'shielding scenarios'	Private actors and 'weaponising scenarios'

not and should not be treated as detailed forecasts. In summary, our findings are as follows:

3 JURISDICTIONAL REACH AND ENFORCEMENT POWERS OF THE EU COMPETITION REGIME

EU competition law is a powerful tool today in shaping market behaviour, particularly in the technology sector. In a world being transformed by AI, EU competition law is also likely to be a powerful tool. There are several reasons for this.

Competition law has wide jurisdictional reach and applies to any company that has an effect within the EU, regardless of whether it is incorporated in the EU or not [23]. The European Commission (or EC, the EU-wide regulator that enforces and EU competition law) is institutionally strong, influential and well-resourced, and often seen as a world-leader in influencing competition law globally [24]. Its strong procedural and investigative powers allow it to effectively detect and evidence an infringement, as well as to impose fines and remedies to change behaviour and market structures.

Competition law also has a long history of being used for political or industrial strategy purposes. For example, in the EU, the clearest political influence on competition policy is single market integration, which is one of the aims in the TFEU. Competition law plays an essential part in breaking down internal barriers to trade within the EU and ensuring the freedom of movement of goods, services, workers and capital [25, Para. 7]. Given its prominent role in pursuing the objectives of the EU, the Commission holds significant influence within the overall EU apparatus and has real 'teeth' in enforcing competition law [26].

Importantly for looking at governance of AI companies, in November 2022 the EU passed the Digital Markets Act (DMA), an *ex ante* regulatory regime for markets dominated by large digital platforms that act as gatekeepers. The regime represents a far-reaching expansion of the EC's regulatory power in digital markets, and will significantly increase regulatory scrutiny of large gatekeeper platforms (i.e. Big Tech) from a competition perspective. The DMA seeks to drive contestability and fairness in markets and does not have an explicit focus on AI. However, given Big Tech are also the key AI companies today and for the foreseeable future, the DMA has important implications for AI governance [27, p. 7]. The DMA will potentially strengthen the effective enforceability of competition law vis-a-vis any AI company due to a broader scope of prohibited conduct and grounds for regulatory intervention, more effective monitoring and detection of breach, and quicker and wider range of sanctions.

4 TECHNICAL VARIABLES

For each variable we (1) describe the spectrum and (2) analyse how the effective enforceability of competition law might vary for different values across that spectrum.

4.1 Key inputs into AI development

Three key inputs drive advances in AI: algorithmic innovation, computational resources (hardware or 'compute'), and data [28], [29]. A company with talented experts can develop better algorithms, it can use superior compute to run a bigger model or train a model for longer, and it can use more data to train a model more effectively. This is a spectrum - these three inputs are all important, and complementary. We note that in real life, the amount of these key inputs that a company has is not the only determinant of success. Other critical factors may include, for example, good organisational management leading to wise or efficient deployment of resources or cultural fit and business practices [30], [31]. Other factors can constrain *deployment*, such as pre-existing 'internet of things' infrastructure. However, in common with other analyses, we present a simplified model based around these three inputs for the purposes of this present analysis.

All three are important, yet we can conceive of *one* of these inputs being the most constrained and therefore a bottleneck. We can envisage this as three percentages which have to sum to 100%. For example, innovation and talent could be constraining progress by 10% each while compute is 80% of the constraint, in which case compute would be the bottleneck. In such an example, many companies could be limited at the production possibility frontier by the supply and/or cost of compute, and progress in the state-of-the-art would be disproportionately attributable to running larger experiments. At the extreme, one of these inputs could be constraining development 100% - and so the others would be 0%. This can also be envisaged as the ratios of measurements of input constraint, such as: 80:10:10.

The key input driving AI advancements could be relevant as part of the assessment of market power. An assessment of market power is particularly pertinent in an abuse of dominance or merger control scenario, where market power is a key factor. A company that has unique access to a key input may be deemed to have market power as a result [32], [33]. In competition law, market power or dominance is the ability for an undertaking to 'behave independently' of market pressure from competitors and consumers, which is detrimental to consumer welfare [34, Para. 10]. If a company is deemed to have market power and to abuse that market power under Article 102, a regulator may seek to address that through

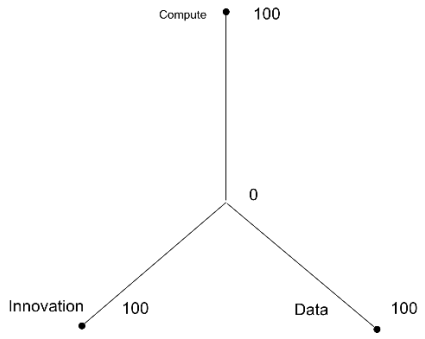

Figure 1: Spectrum showing extent to which each major input is a constraint on AI development (in % or ratio)

fines and an order to bring the infringing conduct to an end [35, Art. 7(1)]. Competition law remedies may also include access remedies, sharing that key input e.g. through granting competitors use of that key input; or structural remedies, structurally separating parts of the business that hold that key input so that the separated part of the business acts as a separate company, an independent market participant in competition with the incumbent [36].

The effective enforceability of competition law may depend on the type of key input that is the bottleneck: data, algorithmic innovations or compute. For example, if the key input is *data*, it may be challenging to assess the market power that flows from that data. As noted, this is particularly important in a merger or abuse of dominance analysis. Under competition law, data has been assessed as a source of market power in the *Microsoft/Linkedin* merger for example [37]. And under the DMA, one of the criteria for determining whether a platform is a 'gatekeeper' is whether it has 'data driven advantages' [27, Art. 3(8)(c) and (d).]. However, it may be more challenging to assess the market power from data compared to compute because it is not purely a quantitative exercise i.e. 'the more data, the more market power'. The market power that a company can derive from data will also depend on factors such as how recent the data is, the uniqueness of the data, the quality of the data, what the permitted uses of the data are (e.g. what are the scope of consents), whether it can be used to generate more synthetic data, etc. It is therefore an imprecise and highly complex exercise that may present two difficulties. First, in assessing the correct threshold for e.g. finding dominance – in other words how much is too much data? Second, in monitoring or detecting a breach – how can a regulator show that the data a company holds is enough to cross the threshold for dominance?

In addition, where a key input is the bottleneck that confers market power to a company, a competition regulator may order an access remedy in a merger or abuse of dominance context. An access remedy typically involves granting direct or indirect competitors access to an essential technology or infrastructure, or ensuring the interoperability of the access seeker's products or services with the key services, products and platforms of the defendant undertaking [38]. Access remedies are also one of the key components of the DMA, for example [27, Art. 6(10)]. However, effective enforceability may be challenged by difficulties with remedies granting data access to competitors, that are widely discussed today, such as tensions with data protection law [33]. Competition law itself may also be an obstacle, if the data contains commercially sensitive information. Competition law frowns on sharing such information between competitors.

If the key input is algorithmic innovations developed by talented staff, similar challenges to effective enforceability arise. This is because the amount of 'talent' that a company has is difficult to measure in terms of market power – rather, you would look at the product of that talent e.g. large and sustained market share, perhaps due to the superior algorithms that one's pool of computer engineers were able to design. It is therefore difficult to define the scope of the law – in other words, what would be the threshold of talent above which you have market power?

The availability of remedies may also be more limited. For example, a regulator may wish to address the dominance of a company by ordering a divestment in a merger scenario, which could either create or strengthen a competitor to the incumbent. Talent is more difficult to transfer from one entity to another via competition law remedies, relative to data or compute [36, Para. 55]. Indeed, competition law recognises that there is a talent 'flight risk' of divestment of parts of a business and takes that into account when assessing the appropriateness of a remedy. Where talent is the key input, therefore, competition law may be a less effective tool to increase competition relative to data and compute [30].

In comparison with data and talent, *compute* could be the bottleneck, and success in AI markets could rely on access to a large amount of computing power. We see this in the cloud compute capacity of Big Tech, and the 'compute partnerships' struck between OpenAI and Microsoft, and Anthropic and Google Cloud. If compute is the bottleneck, then effective enforceability of competition law may be higher, as it is likely to be easier to regulate relative to data or talent [3], [39]. This is because compute is more easily measured and quantified, and the amount of compute that is necessary to train a certain type of AI system is more easily defined relative to, for example, how much talent is required to design such a system [40]– [42]. Market power may be easier to measure. As a remedy, compute may also be more easily 'transferred' or distributed compared to talent or data: e.g., a remedy could require divesting particular data centres. By comparison, as discussed above, the transfer of talent often leads to a flight risk, and the transfer of data carries obstacles such as data privacy rules that may limit the sharing of information. This could make structural remedies easier in either a merger or abuse of dominance context. It may also be easier to order an access remedy involving compute relative to data and talent, though there have been no cases of this so far.

4.2 Speed of development

This variable refers to the speed of AI development, measured in terms of the length of time between an arbitrary set of benchmarks. For example, progress on chess-playing in the late twentieth century was slow, with progress occurring over decades [43, pp. 604–609]. However, progress in large language models over the last two years can be measured in months – with not just the state-of-the-art being rapidly replaced, but entire benchmarks having to be replaced with harder ones [44]. AI could be developed rapidly or through more

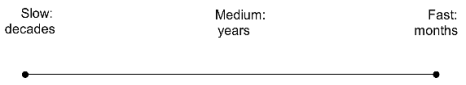

Figure 2: Speed of development spectrum

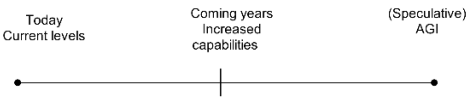

Figure 3: Spectrum of AI capabilities available to an AI actor

incremental, sequential and piecemeal development, or anywhere on the spectrum between these two extremes [45]. Speed could also vary throughout the development process: it could be slow in low capability systems and faster in higher capability systems; could have occasional shocks with large and long plateaus in between; or could slow in higher capability systems as bottlenecks or diminishing returns are encountered.

Competition law, and regulatory enforcement more generally, will likely be weaker the faster the speed of development. A key question is whether there is 'equality of arms' between the regulator and the private AI actor. When there is that equality of arms, competition law is more likely to be enforceable because the four factors that allow for effective regulatory enforcement are more likely to be met. However, this is a less likely outcome, as the private sector is generally ahead in terms of technological capability and know-how, due to differences in salaries and skills [46]. Regulators may be less able to understand the technological specifics that give rise to market power or breaches. So, for this variable we refer to the speed of development of private actors and assume that the state and regulators lag behind.

Enforceability may be more difficult in a rapid scenario for five reasons. First, new technologies may breach the law in novel ways that should be caught by existing rules but instead fall through the cracks or give rise to loopholes/lacunae in the law. Legislative changes or court jurisprudence help to evolve the substantive law to keep up, but these also take time and may be significantly outpaced by the market.

Second, in a more procedural sense, it may be harder to detect and monitor competition law breaches, because the market is moving so fast that regulators may struggle to make sense of what the developments are, and how they might be breaching competition law in potentially novel ways [47]–[49]. For example, new forms of market power may emerge that competition law struggles to characterise as market power, echoing similar discussions today with regard to how such terms have been redefined by the rise of digital platforms and data [15].

Third, the regulator may struggle to bring a case quickly enough to address the harm – a case can take a number of years, and the regulator may decide it is not worth it because the market will have moved on by that time anyway.

Fourth (and relatedly), a fine several years down the line may not be enough to restore competition because e.g. competitors have already been forced to exit the market. Alternatively, the perpetrator firm may have already made windfall profits over several years to make the conduct worthwhile. The slowness of sanctions and remedies may be an issue across mergers and antitrust enforcement. Antitrust cases can take many years to conclude and appeals extend that further [50]. A famous example is *Google Shopping*, an Article 102 case, which took over seven years to reach an EC decision, a further 4 years to reach an appeal decision in the General Court, and is currently pending appeal to the European Court of Justice [51].

Fifth, rapid development and deployment could also lead to the AI actor enjoying a monopoly-inducing effect, because it pulls ahead whilst others are further behind both technologically and financially. This could increase regulatory capture concerns, reducing the effective enforceability of competition law further.

These are already challenges that competition regulators face today in regulating the tech sector, which is complex and fast-moving. How to address these challenges is a topic that competition regulators all over the world are currently grappling with and is a key driver behind introducing the new *ex ante* regulatory regime for tech platforms.

In a more incremental scenario, these problems are still likely to exist – after all, they are present in technology markets today. However, they should be present to a lesser extent. The more incremental pace of change means that the rules and regulators are less likely to fall behind, and enforcement is more likely to be sufficiently swift to address the harm. In short, the more rapid the AI development and deployment, the greater the risks to effective competition law enforcement.

4.3 Capability levels of AI systems

Another variable is capability – what are the AI capabilities available to AI companies? By 'capability' we refer here to the state of technological capabilities: the tasks and 'work' that can be accomplished by an AI system or collection of systems [52], [53]. Capability is a broad spectrum. Currently, AI systems outperform humans in some narrow tasks. This range may increase over the coming years, if capabilities continue to improve. At the top end is the speculative possibility of artificial general intelligence (AGI): AI systems that outperform humans at most economically valuable work [54], [55]. We do not discuss this possibility, but use it instead to mark one extreme of the spectrum.

All else being equal, competition law enforcement is more likely to be effective when the AI capabilities available to AI companies are lower. In todays world, regulatory authorities are broadly able to govern the behaviour of private actors, save the usual concerns around regulatory capture and regulatory effectiveness [56]–[58]. But if the AI capabilities available to companies improve, there would likely be more scope for private actors to use them to evade competition law. Let us take a hypothetical where one private actor has developed and deployed more advanced AI systems than others including especially the competition regulator.

First, that actor may use AI systems which behave in new ways that are not yet condemned under competition law but should be, because that conduct is in fact anti-competitive [14]. The actor may hold market power or abuse that market power in a way that is sufficiently complex that it is not easily measurable or recognised by the law's prevailing analytical toolkit. For example, regulators

have struggled to characterise the harm to consumers when the service (such as search or social media) is free to the user. This might be particularly applicable in a merger or abuse of dominance scenario, such that a merger review does not find a significant impediment to competition because there is sufficient remaining competition in the market, or does not find that the actor has a dominant position for the purposes of Article 102. Two AI actors using their novel AI systems in novel ways could fall within a jurisdictional lacuna, either outside of merger review in the first place, or receiving clearance but nevertheless being harmful to competition (e.g. because of legal loopholes). Alternatively, the conduct of the AI system may technically be acting in breach of the law but does so in a way that is concealed or difficult to monitor, such that the regulator cannot detect the breach [59], [60]. This may be the case for some kinds of algorithmic collusion. More speculatively, the AI actor may be able to evade investigation or detection by using its AI capabilities to conceal its conduct from detection e.g., using large language models to produce many false documents which conceal its participation in a cartel.

Second, Big Tech are already amongst the richest companies in the world, and developing and deploying AI systems may generate yet more profits and power. If that wealth is generated in a less perceptible way, for example very quickly, or in a distributed manner across many markets, it could be harder to detect or lead to regulatory capture, therefore reducing the ability or willingness of regulators to bring a case [6, p. 9], [61, pp. 39–40]. Furthermore, the AI actor may be so well-resourced that any fines have less of a deterrent effect or ability to change its behaviour, though fines can be up to 10% of global turnover [62]. At the most extreme, a custodial sentence is possible (though rarely used) for breach of competition law, for example under UK cartel law for the most serious infringements. However, it could be difficult to attribute criminal liability to a human for decisions shaped by AI systems. Another deterrent effect for competition law enforcement is not the sanctions themselves, but the time and effort spent defending the investigations, and reputational harm. Well-resourced actors may be more willing and able to absorb that time, effort and reputational harm.

On the other hand, AI actors that develop and deploy AI systems with potentially significant market power or societal impact could attract substantial public attention, 'backlash' and focus. This could then shift the relative amount of scrutiny that competition regulatory authorities feel they should, can, or are called upon to exert over these companies.

5 NON-TECHNICAL VARIABLES

In addition to technical variables, different sociopolitical variables can also characterize different scenarios for the development and deployment of AI, with different effects on the effective enforceability of competition law.

5.1 Number of Actors

The extreme endpoints of this spectrum are monopolistic or multipolar. At the monopolistic or unipolar extreme, a single actor is the clear leading developer or deployer of AI. At the contrasting extreme, there may be a multipolar AI situation, with multiple (ten to a hundred) actors developing and deploying AI with comparable levels of capability. In between, we could consider a 'mildly multipolar' or oligopolistic scenario, with a more defined group of around five to ten actors.

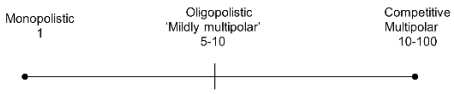

Figure 4: The spectrum of number of actors developing and deploying AI

There are several factors that may shape whether we develop towards the monopolistic or multipolar ends of the spectrum. Some commentators have argued that AI generally tends towards natural monopolies because of first-mover advantage including the ability to capture resources like data, hardware and talent; positive reputational effects; creating switching costs for consumers; and network effects [6, p. 9]. This could be reinforced by the tendency for 'winner-takes-all' in AI markets [63], [64, pp. 10–46], so that only one actor (or only a few) will develop AI. However, we do not make a claim as to where on the spectrum is most likely, except to note that current developments in generative AI seem likely to reinforce the market power of Big Tech rather than opening up competition more widely.

Note that we will use the terms 'monopolist', 'oligopolist' or 'competitor' to refer to an actor developing or deploying AI. This is neutral on the nature of that actor, that is whether it is a company or state. The considerations we analyse are relevant no matter the nature of the AI actor, which we turn to in the next section.

Effective enforceability may be higher in a monopolistic scenario relative to a multipolar scenario. In short, a multipolar scenario is likely to result in a more competitive market (to the extent that the AI actors are active on the same market), relative to a monopolist scenario where the monopolist actor likely faces little or no effective competition in the markets in which it is active. Antitrust authorities should find it easier to detect and establish that the monopolist has market power for the purposes of bringing a successful antitrust claim. Acquisitions by that monopolist may also be subject to more stringent merger control assessment compared to a multipolar scenario. This is because it is more likely to trigger the jurisdictional thresholds that allow the European Commission to review the merger in the first place, given the thresholds take into account the sizes of both buyer and target. Further, the potential lack of competition in the market compared to a multipolar scenario may make it more likely that a merger is prohibited because it is found to be anti-competitive, or only cleared subject to remedies [36, Paras 4–5], [65, Art. Article 2(3)]. The test is whether the merger can be expected significantly to impede effective competition, in particular through the creation or enhancement of a dominant position [65, Art. Article 2(3)].

However, one potential outcome of a monopolistic scenario is that AI will lead to concentration of wealth and power in the hands of the actor that develops it [6], [61, pp. 9 & 39–40]. If there is only one monopolist substantial control of AI, the implications for enforceability are similar to the previous section (Capability). In summary, a monopolist may have (1) the AI capability to act in a way

Table 2: Six scenarios for Private and State AI Actors and their Relationship

Scenario	Actor Type	Relationship
1	Private & Private	Cooperative
2	Private & Private	Competitive
3	State & State	Cooperative
4	State & State	Competitive
5	State & Private	Cooperative
6	State & Private	Competitive

to evade detection, or behave in new and novel ways that are not yet condemned under competition law (but should be, because they are in fact anti-competitive), or benefit from loopholes; (2) financial resources to implement extreme regulatory capture, allowing the monopolist to act more autonomously from any law; and/or (3) the financial resources to 'absorb' any financial sanctions, so fines have less of a deterrent effect or ability to change its behaviour.

5.2 Nature and relationship of actors

This section will consider the nature and relationship of actors developing and deploying AI, and how it affects effective enforceability. The *nature* of the actors is important. Both private actors (such as companies) and states (i.e. governments and militaries) are developing and deploying AI. An actor that is a state or linked to a state may not be subject to EU competition law if it can rely on various defences based on its sovereign status. These defences could mean the AI actor falls outside the jurisdiction of EU competition law, so that EU competition law would not apply to that AI actor. Note, however, that the lines between state and company could blur, as we discuss below. The *relationship* between a state AI actor and private AI actor is important to the question of (1) whether competition law enforcement is possible i.e. capability to enforce whether competition law enforcement is likely i.e. incentive to enforce. There are a number of permutations, but we will focus on a few that have interesting implications for competition law enforcement.

In the table below, we note six scenarios. They vary depending on whether the actor(s) are companies/private actors or states, and whether the relationship between the actors is competitive or cooperative. Where a relationship is cooperative, two actors work together to achieve a common objective, which in turn serves their mutual self-interest. In a cooperative relationship, the stronger one party is, the stronger the other party is. Where a relationship is competitive, it is a zero-sum game such that one party's gain is equivalent to another's loss, and the weaker one party is the stronger the other is.

In the first two scenarios (1 and 2), we have two private AI actors in a cooperative and competitive relationship respectively. Competition law will potentially be applicable to these private AI actors from a jurisdictional perspective as long as they affect competition in the EU (subject to other variables such as speed and capability being equal). This is because each actor is likely to constitute an 'undertaking', defined by the EC as an entity carrying out an economic activity: it offers goods or services, it bears risk and there is the potential to make profit.

The third and fourth scenarios (3 and 4) have two state actors in a cooperative and competitive relationship respectively. The important difference between scenarios 1 & 2 and scenarios 3 & 4 is that it may be more difficult to enforce competition law against a state actor because of a lack of jurisdiction. A state may seek to rely on the 'state act doctrine' under public international law, which refers to the international law principle that a foreign court should not opine on the international activities of sovereign foreign states. However, acts that are commercial in nature do not benefit from state immunity, and a practical difficulty arises in distinguishing clearly between situations where a foreign State is involved in commercial activities and where it is acting in its sovereign capability [66].

In scenario 3, the two state actors are in a cooperative relationship. In this scenario the geopolitical context is relatively stable, and there is more likely to be respect for international institutions and international law. Therefore, while competition law would likely continue to be effectively enforceable alongside international law and the two are not mutually exclusive, in practice international law would likely be the more appropriate tool to bring about a desired outcome between the two state actors. This is because competition law is not easily applied to state actors because of state immunity rules, as explained above.

On the other hand, scenario 4 involves two state actors in a competitive relationship. This represents a more fraught geopolitical situation, where there could be a breakdown in respect for the international legal order. In this scenario, competition law may be a useful alternative tool to international law, despite jurisdictional challenges, because it has stronger enforcement power (for example, large financial sanctions) compared to international law. International law is generally more difficult to enforce because the lack of a central enforcement agency means that international law depends on soft power and diplomatic pressure rather than concrete sanctions [67]. Competition law may be 'weaponised' (see below), for example, to take action against private actors that support states. However, where the geopolitical situation becomes very antagonistic, even the ability of states to enforce competition law may break down, despite its relative resilience. In an antagonistic scenario, states may prefer to take an economic hit for the sake of protecting high stakes political or security interests. States may also turn to more direct and radical action such as imposing export controls, such as those the US announced in October 2022. These new controls ban the exports of high-end semiconductors and semiconductor manufacturing technologies to China. The restrictions prevent leading US AI chip designers such as NVIDIA and AMD from selling their high-end chips for AI and supercomputing in China. Not only do the prohibitions cover exports from American firms (most notably NVIDIA and AMD), but also apply to any company worldwide that uses US semiconductor technology, which covers most of the world's leading chipmakers. However, such drastic action carries high potential risks of retaliation.. This costly 'bill of decoupling' [68] suggests that such escalation is more likely to be a last resort. Before that stage, states may prefer more nuanced and less incendiary actions such as competition law enforcement

that retain the 'business as usual' framework of the international legal order.

In the fifth scenario (5), the private actor and state are in a cooperative relationship. A cooperative scenario may tend to arise where somehow the two have mutual or aligned interests. It may be more likely to occur between a home AI actor and a domestic private actor – but it is still possible that a cooperative relationship arises with a private actor in an aligned foreign state.

In a cooperative scenario between a home state and domestic private actor, the state may seek to 'shield' the private actor from foreign states trying to 'weaponise' competition law to weaken that domestic private actor. In that scenario, we could see the home state AI actor using certain retaliatory actions such as blocking legislation to protect the domestic AI actor from foreign competition law enforcement [69]. In that case, cross-border competition law cases may not be effectively enforceable.

In a cooperative scenario with a home state and a domestic private actor, it seems possible that the state could subsume the private actor. This may be implemented through nationalisation, which refers to the process of transforming private assets into public assets by bringing them under the public ownership of a national government or state. Another possibility is that whilst not being completely nationalised, the AI companies have strong links to their state government, such as Huawei and ZTE's purported links to the Chinese government [70], [71]. In scenarios where the private actor is either formally nationalised or de facto subsumed by the state i.e. it is effectively state-controlled, it may be difficult to apply competition law given sovereign defences may apply. If the private actor is formally nationalised, it should more straightforwardly benefit from 'state act doctrine' and argue that it is acting in the exercise of public authority power, rather than acting in a commercial capability (although it can be very difficult to distinguish the two). If a private actor is de facto subsumed but not formally nationalised, it may be more difficult to argue that it is not acting in a commercial capability. However, the private actor may be able to rely on the state compulsion doctrine i.e. that a company was compelled to act in a certain way by a state. In this scenario, the private actor may be immune from EU competition law [72]. In short though, there are several ways that a private actor could be shielded from EU competition law, as long as it has the cooperation of its home state.

Finally, in scenario 6 we have one private actor and a state in a *competitive* relationship. A competitive scenario could emerge where the state feels threatened by the power, behaviour, or systemic effects of the private actor, and/or where a domestic private actor is resisting a cooperative relationship or nationalisation. A competitive relationship may be more likely to arise if the two actors are a state and a private actor in a foreign state. One might assume that a state is more likely to be in a cooperative relationship with a domestic private actor. However, this is not always the case: see for example Chinese government's crackdown on some of its most successful tech companies on Ant Group, Alibaba and Didi using competition law and a number of other legal grounds.

In a competitive relationship between a private actor and a state, the state may wish to weaken the private actor, and competition law may be one tool to do so. Competition law may be 'weaponised' against the private actor either by a home state or a foreign state. We use the term 'weaponisation' of competition law in this paper to refer to the application of competition law that are driven by policies that lie outside the classic objectives of competition law to protect the process of competition and maximise consumer welfare. In addition, weaponising of competition law may be particularly relevant in cases where there is a foreign state who does not have substantial AI capacity and who thus seeks to gain access to the technology of a foreign private AI actor who may be active in its territory, or to weaken it in favour of its home-grown AI companies. Competition law may be a particularly useful tool in this scenario because simply expropriating the assets is likely to create a significant diplomatic dispute, and likely to be far less favourable than bringing a claim under a somewhat legitimate guise.

An adversarial home state may even wish to partner with an aligned foreign state to control or weaken its own domestic private actor. In these scenarios, states may band together to counter the strength of the private actor(s). Competition law may be one way to do this: for example, see the 'copycat' antitrust action against Big Tech from the US and EU [73], [74].

6 CONCLUSION: A FRAMEWORK FOR LEGAL ANALYSIS AND ANTICIPATORY GOVERNANCE

The future of AI development and deployment over the coming years is highly uncertain. There are several dimensions of uncertainty, both technical and socio-political. Across these different possible future scenarios, it is unclear to what extent competition law (and other kinds of legal and governance tools) will be effectively enforceable. But as recent developments in generative AI demonstrate, it is crucial that regulators look forward to future scenarios in order to put anticipatory governance structures in place that can adapt and remain effective under a range of scenarios.

In this paper, we have attempted to reduce that uncertainty. We laid out five variables upon which future scenarios can be placed: key inputs, speed, capability, number of actors, and nature and relationship of actors. We examined how different values along these variables could affect the effective enforceability of the four main types of competition law (abuse of dominance, merger regulation, cartels and state aid), through the challenges they might pose to competition law enforcement through jurisdiction, exploiting loopholes, avoiding detection and being difficult to remedy. We encourge more work to be done to ensure competition law can remain future-proof across various a range of potential AI development scenarios.

ABSTRACT

Can government govern artificial intelligence (AI)? One of the central questions of AI governance surrounds *state capacity*, namely whether government has the ability to accomplish its policy goals. We study this question by assessing how well the U.S. federal government has implemented three binding laws around AI governance: two executive orders—concerning trustworthy AI in the public sector (E.O. 13,960) and AI leadership (E.O. 13,859)—and the AI in Government Act. We conduct the first systematic empirical assessment of the implementation status of these three laws, which have each been described as central to US AI innovation. First, we track, through extensive research, line-level adoption of each mandated action. Based on publicly available information, we find that fewer than 40 percent of 45 legal requirements could be verified as having been implemented. Second, we research the specific implementation of transparency requirements at up to 220 federal agencies. We find that nearly half of agencies failed to publicly issue AI use case inventories—even when these agencies have demonstrable use cases of machine learning. Even when agencies have complied with these requirements, efforts are inconsistent. Our work highlights the weakness of U.S. state capacity to carry out AI governance mandates and we discuss implications for how to address bureaucratic capacity challenges.

1 INTRODUCTION

Can government govern AI? Many commentators have discussed the *normative* question of government intervention into the market [80, 86, 93, 98, 103]. We address a distinct, but related, empirical question that highlights the bureaucratic challenge to AI governance: Is there sufficient *state capacity* to achieve the goals of AI governance when such goals have already been set in law?

Many scholars, policymakers, and commentators point to the transformative potential of AI [23, 125]. Seeking to capture the benefits of the "Fourth Industrial Revolution" or "third wave of the digital revolution," countries are prioritizing efforts to reorganize their public and private sectors, fund research and development (R&D), and establish structures and policies that unleash AI innovation [37, 73, 112, 143]. In the United States, the White House and Congress have promoted AI innovation and its trustworthy deployment by increasing R&D investments, exploring mechanisms to increase equitable access to AI-related resources through a National Artificial Intelligence Research Resource, funding National AI Research Institutes throughout the country, dedicating $280 billion—through the CHIPS and Science Act—into domestic semiconductor manufacturing and "industries of tomorrow," and coordinating AI policy in the National AI Initiative Office within the White House [10, 32, 40, 49, 53, 54, 69, 72]. While many have rightly applauded the Blueprint for an AI Bill of Rights and the associated actions across the federal government [44, 48], implementing that framework ultimately requires government agencies convert guidance and principles into practice.[1]

Federal AI initiatives raise at least three interrelated questions that are relevant to the academic literature and that implicate questions about policy effectiveness. First, as a question of *regulatory paradigm*, we might ask about the proper role of the state vis-à-vis industry and civil society actors, especially given the deep information asymmetries that plague state-based regulatory initiatives [98]. Second, conditional on the chosen paradigm, we might also ask about the proper *policy instrument*, implicating familiar debates over the specificity of rules in comparison to standards [82, 96] or the proper target of rules [90] given the policy context. Third, after policy instruments are determined, we could assess the *capacity* of bureaucracies to effectuate those actions' purpose [81, 115].

We contribute to this scholarship through a systematic assessment of the federal government's progress in implementing three important binding laws that are seen as central to U.S. leadership in trustworthy AI.[2] Through extensive research, we study (i) the AI in

[1] Similarly, the NIST AI Risk Management Framework, released in January 2023, is helpful guidance but must be voluntarily adopted [55].
[2] For discussion of U.S. federal AI policy documents from 2016-20, see [129].

Government Act of 2020 [19, 28], which aimed to provide resources and guidance to federal agencies on AI; (ii) the Executive Order on AI Leadership (E.O. 13,859) [12], which mandated government-wide efforts to promote AI R&D, AI competitiveness, and public trust; and (iii) the Executive Order on Trustworthy AI in Government (E.O. 13,960) [25], which encouraged government adoption of AI to benefit the public and promulgated trustworthy AI principles.[3] Collectively, the AI in Government Act, the AI Leadership Order, and the Trustworthy AI Order are critical pillars to the U.S. strategy on AI[4] and to envisioning an ecosystem where the U.S. government leads in AI and promotes trustworthy AI [71].

While much progress has been made, our findings—from a systematic examination conducted between late October and mid-November 2022—are sobering and highlight longstanding concerns about bureaucratic capacity. The goal of these laws to foster a responsible AI innovation ecosystem is threatened by weak and inconsistent implementation across the administrative state. First, fewer than 40 percent of all 45 requirements across the three pillars could be publicly verified as implemented at the time of our examination, including major requirements to advance AI innovation and trustworthy AI. Second, the implementation of Agency AI Plans, which are intended to provide information about the agency's approach to AI regulatory activities and to foster the agency's strategic planning around AI, has been poor. Around 88 percent of agencies that are likely subject to the requirement to submit Agency AI Plans under the AI Leadership Order failed to do so by late 2022.[5] Third, roughly half or more of agencies had not published an inventory of AI use cases, as required under the Trustworthy AI Order and in contradiction with public transparency efforts. Given Congress has since made disclosing AI use case inventories a *statutory* requirement under the 2023 National Defense Authorization Act [77], the lack of implementation is especially concerning.

These findings suggest a lack of bureaucratic capacity compounded by issues of policy ambiguity: Agencies lack the expertise, committed leadership, and sheer personnel to strategically plan for and prioritize AI, and compliance is hindered by vague mandates and reporting lines. We thus suggest three policy recommendations. First, centralized mandates must delineate (1) which agencies and sub-agencies must comply, (2) what "AI" applications are covered, and (3) how to interpret non-responses. This places agencies on notice about their obligations and facilitates public accountability. Second, if bureaucratic capacity is to blame, Congress must provide more resources for agencies to obtain adequate technical expertise. Third, senior leadership at the White House and at agencies is needed, and senior personnel at agencies should treat these requirements not as boxes to tick but as opportunities for strategic planning around AI.

Our paper proceeds as follows. Section 2 discusses related scholarship in public administration, bureaucratic politics, and transparency initiatives for public sector AI. Section 3 provides background on the three binding laws we assessed. Section 4 discusses our methodology for systematically assessing the implementation of these laws. Section 5 provides detailed findings on the implementation of the AI Leadership Order, Trustworthy AI Order, and AI in Government Act. Section 6 examines the AI Leadership Order's requirement that agencies publish Agency AI Plans in detail across 41 agencies. Section 7 assesses the Trustworthy AI Order's requirement that agencies publish AI use case inventories across 220 agencies and narrower subsets of agencies. Section 8 discusses implications and limitations and Section 9 concludes.

2 RELATED WORKS

Our study of bureaucratic implementation of AI governance speaks to four bodies of research. First, our work relates to longstanding scholarship on state and bureaucratic capacity to achieve policy goals [84, 109, 115, 121]. Prior research shows that agency performance and the realization of White House-level political goals are frustrated by organizational capacity constraints, including insufficient leadership, staff, and resources. For example, Bolton, Potter, and Thrower [81] analyzed 22,000 regulations reviewed by the Office of Information and Regulatory Affairs (OIRA) within OMB and found that organizational capacity constraints, including vacant leadership positions, insufficient staff resources, and high workloads, hindered the president's ability to advance priority rules and inhibited OIRA's ability to carry out its mission.

In the AI space, agencies' struggle to attract and retain technical talent is a hurdle to the executive branch's ability to responsibly adopt and govern AI [88, 101, 102]. One estimate is that while 60% of new machine learning PhD graduates went into industry and 24% into academia, less than 2% went into government in 2020 [144]. Embedded AI expertise, as Engstrom, Ho, Sharkey, and Cuéllar [102] detailed and as other scholars noted (e.g., [88, 101, 128]), is critical for agencies' efficacy in designing, developing, and using AI tools to achieve their mission and subjecting AI tools to meaningful accountability. These concerns about bureaucratic capacity, in turn, can inform broader normative assessments of the federal government's current ability to promote trustworthy AI.[6]

Second, our research speaks to the central debate on the role of government in AI policy, where jurisdictions have diverged between taking a more "passive" role that gives space for industry self-regulation versus an "active" role through direct regulation (e.g., [98]). These debates imagine diverse roles for the state, whether as an interlocutor with industry to help develop best practice, a research funder, an adopter of responsible and trustworthy AI technologies, a direct regulator, or some combination of the above

[3] We do not focus on the National AI Initiative Act of 2020, as the National AI Advisory Commission is statutorily tasked with tracking the Initiative's progress, nor on the Artificial Intelligence Training for the Acquisition Workforce Act, as its passage in October 2022 precludes meaningful assessment of its implementation. For more on the National AI Advisory Council, tasked with "advising the President and the National AI Initiative Office on topics related to the National AI Initiative," the creation of which was called by the National AI Initiative Act of 2020, see [56, 95].

[4] The U.S. government does currently not have a "National AI Strategy" per se, but instead has a number of documents, including the three assessed in this Paper, that collectively provide strategic guidance. The National AI Initiative Office maintains a list of related legislation, executive orders, and strategy documents. See [71].

[5] The requirement is in Section 6(c) of the AI Leadership Order, [12], and OMB's guidance was published in a memorandum known as "OMB M-21-06" [138].

[6] Cf., for example, Oxford Insight's AI Government Readiness Framework [133], which assesses government AI readiness in terms of, among other indicators, "[d]igital and data skills within government."

[86, 93, 103, 136]. Such normative debates can and should be informed by empirical evidence, including about the relative advantages and capabilities of different institutional actors. For example, Black and Murray [80] comment that a central issue about who ought to regulate concerns where "trust and legitimacy" lie—whether for a transnational standard-setting organization, a corporation engaging in self-regulation, or a state-based regulatory body. Regulation has classically been justified based on the expertise of technocratic government agencies (e.g., [123]), but AI poses extreme information asymmetries between technology developers and policymakers [88, 91, 108], in addition to concerns about public-private gaps in expertise [88, 144]. For those who believe in a robust role for the state in AI governance, our work addresses a core question: whether the government has the capacity to effectively regulate AI.

Third, our work pertains to efforts for transparency around the administrative state [89, 101, 111]. Principles of transparency and accountability are foundational to administrative law (e.g., [87, 101]). In the U.S. context, much scholarship has examined transparency initiatives such as the Freedom of Information Act, sunshine laws and hearing requirements, notice-and-comment rulemaking, and public availability of agency guidance (e.g., [87, 107, 119, 127]). Calls for greater transparency around the U.S. government's use of AI are therefore situated not only within research about the role of transparency in administrative law but also within discussions about the benefits and risks posed by agencies' use of AI (see, e.g., [88, 102]). One major question surrounds how public sector AI challenges administrative law's commitment to transparency. Coglianese and Lehr [92] argue that the opacity of AI does not pose particular barriers to administrative law. Engstrom and Ho [100], on the other hand, argue that existing administrative law doctrines may be insufficient, requiring adaptations of governance. The importance of government transparency about its use of AI necessitates a discussion about the proper lever to achieve such transparency.[7]

Last, many efforts have focused on transparency through public registries of AI use cases. Floridi [104] discusses the promise of AI registries in Helsinki and Amsterdam, noting that, the "goal is to make the use of urban AI solutions as responsible, transparent, and secure as other local government activities." Other countries, such as the United Kingdom, have adopted these AI registries [116]. At the local government level in the U.S., Bloomberg Philanthropies uses AI registries as one evaluation criterion for its "What Works Cities" Certification, which it claims is the "national standard of excellence for data-driven, well-managed local government" [68]. The City of San Jose, for instance, began an Algorithm Register in January 2023 for transparency of city services [60]. Yet the implementation of such transparency initiatives has not been straightforward. New York City's Automated Decision Systems Task Force fractured in substantial part because of a lack of consensus around what constituted algorithmic decision systems. Cath and Jansen [85] question the efficacy of the Helsinki and Amsterdam model of AI registries as a form of governance. The Administrative Conference of the United States (ACUS) commissioned a report that compiled AI use cases across federal regulatory agencies [102], requiring a large team to determine, for instance, whether the underlying use case met a definition of machine learning. This report preceded the promulgation of the AI Use Case Inventory requirement via executive order. And because requirements differ across jurisdictions, efforts like the Northwestern Computational Journalism Lab's Algorithm Tips have attempted to crowdsource information across the federal, state, and local level [62]. AI registers have been advocated in other domains as well [132], and remain one of the critical levers for transparency. Our research examines the actual implementation of such AI registries and demonstrates that substantial policy guidance may be required for faithful implementation.

[7] Calls for transparency exist not only at the federal level but also at the state level. A proposal in California (A.B. 331), for example, seeks to require AI developers to submit impact assessments annually to the California Civil Rights Department [142].

3 LEGAL SETTING

We address this core question of bureaucratic capacity for AI governance by assessing three pillars of America's strategy for AI innovation. The two executive orders and AI in Government Act all carry the force of law, and so the executive branch's ability to implement them serves as an important litmus test for the U.S. government's realization of its AI policy goals. Moreover, these laws are billed as cornerstones of America's AI policy. By enabling America "to coordinate AI strategy" and equipping federal agencies' responsible use of AI, the AI in Government Act sought to ensure America's "competitive edge against the rest of the world in the next decade" [28]. The AI Leadership Order was similarly touted as "critically important to maintaining American leadership in technology and innovation" [16], whereas the Trustworthy AI Order "signal[ed] to the world" America's commitment to "the development and use of AI underpinned by democratic values" [11, 24]. To achieve their stated goals, the AI Leadership Order sought to drive technological breakthroughs throughout all sectors of the U.S., while the two other efforts focused on the federal government's use of AI. We describe each of the laws in turn.

Executive Order 13,859 (The AI Leadership Order). The 2019 AI Leadership Order launched the American AI Initiative to "focus the resources of the Federal government to develop AI in order to increase our Nation's prosperity, enhance our national and economic security, and improve quality of life for the American people" [11]. Specifically, it sought to accelerate the federal government's efforts to build the infrastructure, policy foundations, and talent necessary for America's leadership in AI through a multipronged approach emphasizing AI R&D, AI-related data and resources, regulatory guidance and technical standards, the AI workforce, public trust in AI, and international engagement [11, 12, 117]. Noting that a "coordinated Federal Government strategy" was necessary and that AI "will affect the missions of nearly all executive departments and agencies," the AI Leadership Order further mandated that agencies pursue six related strategic objectives for "promoting and protecting American advancements in AI." These six strategic objectives were about: (1) investing in AI-related research and development; (2) making AI resources (e.g., data, models, computing resources) available to the public; (3) reducing barriers that prevent the development and use of AI technologies; (4) ensuring that domestic and international technical standards "minimize vulnerability to attacks from malicious actors and reflect Federal priorities"; (5) building the AI workforce; and (6) developing a National Security Presidential Memorandum "to protect the advantage of the United States in

AI and technology critical to United States economic and national security interests" [12].

Executive Order 13,960 (The Trustworthy AI Order). The 2020 Trustworthy AI Order directed federal agencies to harness "the potential for AI to improve government operations" [24]. Recognizing that "[t]he ongoing adoption and acceptance of AI will depend significantly on public trust," the Trustworthy AI Order articulated nine principles for federal agencies to implement—according to guidance that would be developed by the OMB—when designing, developing, acquiring, and using AI. These principles provide that AI should be (a) lawful, (b) performance-driven, (c) accurate, reliable, and effective, (d) safe, secure, and resilient, (e) understandable, (f) responsible and traceable, (g) regularly monitored, (h) transparent, and (i) accountable [25]. To support federal AI adoption, it also mandated several actions intended to increase the number of federal employees with necessary AI implementation expertise [24]. Like the AI Leadership Order, the Trustworthy AI Order required agencies to publicly disclose certain AI-related information in an attempt to cultivate trust and understanding (see Section 7). The requirement of disclosing AI use cases was also incorporated into the 2023 National Defense Authorization Act [77], meaning Congress, too, has directed federal agencies to take inventory and disclose their uses of AI, reflecting the perceived importance of this transparency measure.

AI in Government Act of 2020. The AI in Government Act sought to "ensure that the use of AI across the federal government is effective, ethical and accountable by providing resources and guidance to federal agencies" [28]. This included the establishment of an AI occupational series, a call for formal guidance for agency usage, procurement, bias assessment and mitigation of AI, and the creation of a center of excellence within the General Services Administration (GSA) to support government adoption of AI.

4 METHODOLOGY

These three laws have been in effect for sufficient time to enable us to design a study to assess the implementation status of each line-level provision. The research was based on an extensive manual search protocol—conducted between October and November of 2022—detailed in Appendices A.1, B.1, and C.1, but we provide a concise overview of our research approach here. We note at the outset that because these laws impose public transparency and reporting requirements, we rely on public materials to conduct our searches. We undertook extensive efforts to identify relevant documents or notices of actions, but these may not capture all relevant (nonpublic) actions. Our findings still remain informative about the transparency of national AI efforts, and failures to implement by statutory or regulatory deadlines are particularly informative.

To assess overall implementation, we identified all line-level actions within the three documents (e.g., instructions that a federal entity "shall budget," "shall consider," "shall review," "shall publish"). Each line-level action was categorized as a *time-boxed requirement*, where the action was required by a specified date (e.g., publishing a report within 90 days); an *open-ended requirement*, where the mandated action did not have a specific date for completion; or an *ongoing requirement*, where the mandate did not include a specific deliverable or concrete outcome and where there was no specified deadline. It was generally straightforward to assess whether the time-boxed requirements were met, whereas other mandated actions were often more ambiguous, either due to lack of a deadline, lack of express public disclosure requirements, or both. We construed ambiguity in favor of the agencies based on an assumption that the agencies were taking the necessary steps (or at least making good-faith efforts) to implement these mandates, as explained in Appendix A.

In addition, we studied the implementation status of two specific cross-agency mandates: the requirement under the AI Leadership Order for agencies to issue "Agency AI Plans," and the requirement under the Trustworthy AI Order for agencies to post AI use case inventories. In the former, the AI Leadership Order required "implementing agencies"—defined to be agencies, as determined by the National Science and Technology Council (NSTC) Select Committee on AI, with regulatory authorities and that "conduct foundational AI R&D, develop and deploy applications of AI technologies, provide educational grants, and regulate and provide guidance for applications of AI technologies"—to issue a report discussing its authorities and plans to regulate AI. The Trustworthy AI Order, by contrast, ordered all "agencies" (with exceptions only for military, intelligence, and independent regulatory agencies) to disclose their uses of AI.

Ambiguities in the scope of these executive orders—the agencies they cover and, for the AI use case inventories, the definition of "AI"—complicated assessment of their implementation. For the Agency AI Plans, we looked to agencies with regulatory authority and therefore included cabinet-level departments and agencies and the 19 agencies deemed "independent regulatory agencies" under 44 U.S.C. § 3502(5). We included the U.S. Agency for International Development (USAID), as it was the only agency represented at the National Security Council that was not already included as a Cabinet-level agency or as an independent regulatory agency. We also inquired with a member of the Select Committee and did not receive an answer on what agencies are included. The result was 41 agencies.

Because the AI Use Case Inventories requirement applied to agencies generally, we began with the Administrative Conference of the United States' *Sourcebook of U.S. Executive Agencies* ("ACUS Sourcebook"). From the 278 agencies identified in the ACUS Sourcebook's data spreadsheet, we removed agencies within the Department of Defense, agencies and sub-agencies within the intelligence community, and the 19 independent regulatory agencies defined in 44 U.S.C. § 3502(5), based on the exemptions in Section 8(a) of the Trustworthy AI Order. This left us with a total of 220 agencies.

In searching for AI Plans and Use Case Inventories, we took a systematic approach meant to optimize both the chance of finding the document while also providing clear and simple search processes. For each requirement and agency, we searched in four ways: (1) at a dedicated URL as mandated under the respective executive order; (2) a web search for certain words closely related to the requirements; (3) a search on the agency's website for those key words; and (4) a search in the publication libraries at AI.gov.

Full data generated by our research are included in the Appendices.

	Implemented	Unknown	Not Implemented
AI Leadership Order	39%	57%	4%
Trustworthy AI Order	13%	75%	13%
AI in Government Act	17%	17%	67%
Total	27%	58%	16%

Table 1: Summary of Implementation as of Nov. 2022.

5 OVERALL IMPLEMENTATION STATUS

While much progress has been made, we were unable to verify implementation of the majority of the line-level legal requirements. Across both executive orders and the AI in Government Act, we found that 11 of 45 requirements, or roughly 27 percent, were implemented (see Table 1).[8] The implemented requirements spanned a range of topics, including agencies' prioritization of AI R&D in annual budget proposals,[9] recommendations for leveraging cloud computing resources for federally funded AI R&D,[10] guidance on federal engagement in the development of AI-related technical standards,[11] and the establishment of a GSA AI Center of Excellence to facilitate the adoption of AI within the federal government.[12]

However, seven of 45 requirements (16 percent) were not implemented by the deadline, and the remaining 26 requirements (58 percent) could not be confirmed as either fully implemented or not implemented (see Appendix A.2). The requirements that remain unfulfilled—including creating an AI occupational series for federal employees, estimating the AI workforce gap in the federal government, policy guidance on federal acquisition and use of AI,[13] and a public roadmap on OMB's intended revisions or new AI policy guidance[14]—are significant for the country's AI ecosystem and the federal government's adoption of AI. Similarly, the implementation status is uncertain for major requirements, including efforts to make data and source code more accessible for AI R&D,[15] better leverage and create new AI-related education and workforce development programs,[16] and ensure agencies participate in interagency bodies that further the implementation of trustworthy AI.[17]

Requirements in the executive orders with deadlines for specific deliverables were implemented at a higher rate. Conversely, none of the AI in Government Act's four requirements with a deadline were implemented: the Office of Personnel Management (OPM) was to submit to Congress a plan to establish an AI occupational series by May 2021; OMB was required to issue a memorandum on AI procurement, mitigating discriminatory impact or bias, and promoting AI innovation by October 2021, with agencies publicly posting plans to achieve consistency with it by April 2022; and OPM was to create an AI occupational series and estimate AI-related workforce needs in each federal agency by July 2022. Of the implemented requirements across all three, many were late. For example, the NSTC Select Committee on AI produced the AI Leadership Order's mandated report to the president on better leveraging cloud computing for AI about 16 months past the deadline. Pursuant to the AI Leadership Order, OMB similarly issued a memorandum to agencies on regulatory approaches to AI about 16 months late, as well as a notice on the *Federal Register* soliciting public comments on how to improve public access to federal data for AI about two months after the AI Leadership Order's summer 2019 deadline.

We provide detailed findings in Appendix A.2 and a line-level tracker in Appendix E.1.

6 AGENCY AI PLANS

As noted above, a significant focus of the AI Leadership Order was "reduc[ing] barriers to the use of AI technologies to promote their innovative application" while also protecting "civil liberties, privacy, American values, and United States economic and national security" [12]. The AI Leadership Order therefore placed significant emphasis on examining the proper role of regulating AI, noting the desire to

[8] A requirement in Section 5(c)(ii) of the Trustworthy AI Order [25] had not been implemented when we did our systematic analysis, but we excluded this requirement from the overall implementation assessment because the deadline for its implementation had not yet passed.

[9] Section 4(a) of the AI Leadership Order [12] directed heads of AI R&D agencies to "consider AI as an agency R&D priority" and to take AI "into account when developing budget proposals and planning for the use of funds." Section 4(b) directed the same agencies to "budget an amount of AI R&D that is appropriate for this prioritization," particularly through the Networking and Information Technology Research and Development (NITRD) Program, and to identify "the programs to which the AI R&D priority will apply and estimate the total amount of such funds that will be spent on each program." This ongoing, annual requirement seems to be implemented through an annual NITRD supplement to the president's budget, progress reports on AI R&D, and a NITRD AI R&D dashboard. See [10, 13, 14, 22, 35, 64].

[10] Section 5 of the AI Leadership Order [12] directs the Secretaries of Defense, Commerce, Health and Human Services, and Energy, as well as the Administrator of NASA and the Director of the NSF, to prioritize allocation of high-performance computing resources for AI, and also directs the NSTC Select Commission on AI to work with GSA on a report to the president for leveraging cloud computing resources. The National AI Initiative Office's AI Researchers Portal includes a computer resources overview with six "Federally-supported computing infrastructure resources that are useful for AI research" identified. See [59]. The NSTC Select Committee on AI also published—16 months after the mandated deadline—*Recommendations for Leveraging Cloud Computing Resources for Federally Funded Artificial Intelligence Research and Development* as well as a complementary "lessons learned" report in July 2022. See [26, 52].

[11] Section 6(d) of the AI Leadership Order [12] directs the Secretary of Commerce through the NIST Director, with participation from relevant agencies, to "issue a plan for Federal engagement in the development of technical standards and related tools in support of reliable, robust, and trustworthy systems that use AI technologies." In August 2019, NIST published the required report. See [17].

[12] Section 103 of the AI in Government Act [19] mandates the establishment of this Center and delineates its roles; GSA has established the Center. See [139].

[13] The White House announced in May 2023 that OMB will release draft guidance on AI procurement for federal agencies in summer 2023 [114].

[14] These are respectively required by Sections 105 and 104 of the AI in Government Act [19] and Section 4(b) of the Trustworthy AI Order [25]. Note that Action 7 in the 2021 Federal Data Strategy Action Plan could arguably be construed as an implementation of the public roadmap requirement because it provides four milestones; however, it does not mention policy guidance documents (e.g., OMB Circulars) as anticipated by the Trustworthy AI Order. See [34, p. 14].

[15] Required under Section 5 of the AI Leadership Order [12].

[16] Section 7 of the AI Leadership Order [12] mandates that the NSTC Select Committee on AI "shall provide recommendations to NSTC Committee on STEM Education regarding AI-related educational and workforce development considerations" and "provide technical expertise to the National Council for the American Worker." Furthermore it directs agencies to annually communicate plans to the NSTC Select Committee on AI about AI-related fellowship and service programs. Section 7 of the Trustworthy AI Order [25] mandates that OPM "shall create an inventory of Federal Government rotational programs and determine how these programs can be used to expand the number of employees with AI expertise" and "issue a report with recommendations" for doing so that is "shared with the interagency coordination bodies…enabling agencies to better use these programs for the use of AI…"

[17] Section 6 of the Trustworthy AI Order [25] notes that agencies "are expected to participate in interagency bodies for the purpose of advancing the implementation of the Principles and the use of AI consistent with this order" and that the CIO Council "shall publish a list of recommended interagency bodies and forums in which agencies may elect to participate, as appropriate and consistent with their respective authorities and missions" to fulfill the expectation that they participate in interagency bodies to advance the AI principles.

"avoid regulatory or non-regulatory actions that needlessly hamper AI innovation and growth" [138].

Two requirements were critical to achieving this objective: (1) OMB was required to publish a memorandum providing guidance on how agencies should approach regulating AI, and (2) agencies with "regulatory authorities" were required to publicly post Agency AI Plans to "achieve consistency" with OMB's guidance. OMB's *Memorandum for the Heads of Executive Departments and Agencies on Guidance for Regulation of Artificial Intelligence Application* (OMB M-21-06 [138]), published on November 17, 2020 (about 16 months after the deadline), fulfilled the first requirement and urged a "regulatory approach that fosters innovation and growth and engenders trust, while protecting core American values." This "OMB AI Regulation Memo" described "policy considerations" to guide AI development. It (1) provided ten "principles for the stewardship of AI applications" to guide agencies,[18] (2) identified alternatives to regulation,[19] and (3) proposed actions, such as public communications and supporting voluntary consensus standards, that agencies could take to reduce barriers to the use of AI.[20]

The OMB AI Regulation Memo also provided guidance on Agency AI Plans. It required agencies to identify (a) their statutory authorities to regulate AI, (b) AI-related information that they were collecting on regulated entities, (c) statutory restrictions on their ability to collect or share such information, (d) regulatory barriers identified by stakeholder engagement, and (e) potential regulatory actions. Agencies were instructed to use an OMB-provided template, submit the plans by May 2021 (adhering to the AI Leadership Order's deadline), and publicly post their plans on their agency websites [138]. Critically, the memo did not provide guidance on which agencies were required to produce an Agency AI Plan: the AI Leadership Order's requirement applied to agencies with sufficient AI-related activities and "regulatory authorities," neither of which are self-defining or obvious.[21] We requested, but did not receive, information on the applicable agencies and have, as a result, approximated the relevant agencies as spelled out in the detailed methodology in Appendix B.1.

Out of 41 agencies assessed, only five (12 percent), posted an AI Plan using the template provided by the OMB AI Regulation Memo (see Table 2) by November 2022, even as the OMB AI Regulation Memo ordered agencies to publish them by May 2021. These agencies were the Departments of Energy (DOE), Health and Human Services (HHS), and Veteran Affairs (VA), as well as the Environmental Protection Agency (EPA) and USAID. Thirty-six agencies have not published an Agency AI Plan. The absence of plans published by the Departments of Transportation (DOT), Commerce (DOC), Homeland Security (DHS), and Housing and Urban Development (HUD) is notable, given what is commonly understood as within their regulatory and rulemaking purview and what sub-agencies fall under them. For instance, DOT includes the Federal Aviation Administration (FAA), governing civil aviation, and the National Highway Traffic Safety Administration, which administers federal motor vehicle safety standards.

	Published	Not published	Total
Number of agencies	5	36	41
Percent	12%	88%	

Table 2: Publication of Agency AI Plans as of Nov. 2022

Examination of the five Agency AI Plans also casts doubt on whether all agencies meaningfully attempted to identify relevant regulatory authorities. (We provide a detailed summary in Appendix B.2 of the substance of these five Agency AI Plans.) The DOE's AI Plan was completed with "None" written in every section. By contrast, HHS, the VA, and EPA provided more detail within their Agency AI Plan. Although the USAID plan does not identify any statutory authorities or planned regulatory actions, its publication of an Agency AI Plan demonstrates a commitment to transparency.

HHS is a particularly instructive and exemplary case. HHS identified 11 statutes that directly or indirectly authorized it to regulate AI applications, over 32 active collections of AI-related information, 12 AI use case priorities, 10 AI regulatory barriers, and four planned regulatory actions concerning AI applications [74]. The extent and depth of HHS's response likely stems from substantial efforts within the agency to formulate an AI strategic plan that considers how HHS will "[r]egulat[e] and oversee[] the use of AI in the health industry" as well as an extensive Trustworthy AI Playbook and an action plan by the Food and Drug Administration (FDA) for regulating AI-based medical devices [29, 31, 39]. In short, AI Plans reflect—and are aimed to foster—strategic planning, forethought, and coordination around AI.

7 AI USE CASE INVENTORIES

The Trustworthy AI Order mandated that agencies prepare inventories of their uses of AI, share them with the Federal Chief Information Officers Council (CIO Council) and other agencies, and then make them public [25]. The number of covered agencies is much broader than under the AI Leadership Order, exempting only independent regulatory agencies and agencies within the Department of Defense (DOD) or intelligence community.[22] Agency AI use case inventories must be prepared annually and should identify AI use cases that are inconsistent with the order, including the nine

[18]The principles were: (1) public trust in AI, (2) public participation, (3) scientific integrity and information quality, (4) risk assessment and management, (5) benefits and costs, (6) flexibility, (7) fairness and non-discrimination, (8) disclosure and transparency, (9) safety and security, and (10) interagency coordination. [138, pp. 3-7].

[19]OMB M-21-06 provided four example non-regulatory approaches: (1) providing sector-specific policy guidance, statements, and frameworks; (2) using existing authorities to promote pilot programs and experimentation (e.g., through granting waivers, regulatory exemptions); (3) engaging voluntary consensus standards-development; and (4) developing and promoting voluntary frameworks. [138, pp. 7-8].

[20]OMB M-21-06 suggested the following four "non-exhaustive" agency actions: (1) increase public "access to Federal data and models for AI R&D"; (2) public communication through requests for information (RFIs) in the *Federal Register*, increased transparency about uncertainties regarding outcomes, and making guidance documents widely available; (3) increase agency participation, including through private sector engagement, "in the development and use of voluntary consensus standards and conformity assessment activities"in order to "help agencies develop expertise in AI and identify practical standards for use in regulation"; and (4) increase international cooperation on regulation. See [138, pp. 8-11].

[21]The Agency AI Plan requirement only applied to "implementing agencies" that have regulatory authorities, including independent regulatory agencies. "Implementing agencies" were defined in Section 3 of the AI Leadership Order [12] as "agencies that conduct foundational AI R&D, develop and deploy applications of AI technologies, provide educational grants, and regulate and provide guidance for applications of AI technologies, as determined by the co-chairs of the NSTC Select Committee."

[22]The Trustworthy AI Order [25], in Section 8. For the specific language in the EO and our operationalization, see Section 4 and Appendix C.1.

implementing principles. In the case of conflict, agencies are to develop remediation plans.[23] Guidance released by the CIO Council in fall 2021 explained that AI use case inventories were to be posted by March 2022 [75].

Public disclosure of AI use case inventories has been problematic.[24] Roughly half or more of relevant agencies—a minimum of 47 percent of the agencies examined—have not published an AI use case inventory (see Table 3 and Appendices C.2 and E.3). Because of uncertainty in the relevant agencies, we report the implementation rate with different groups of agencies and at different organizational levels (see Appendix C.1 for more details on the methodology). The Trustworthy AI Order and the CIO Council's guidance for creating the inventories [25, 75], for instance, did not explain how sub-agencies and parent agencies should report their inventories (e.g., whether the DOT should include AI use cases from its sub-agency, the FAA, or let the FAA publish a separate inventory). We report use cases first with sub-agencies assessed individually and then rolled up to the parent agency.

Starting with the 220 agencies identified as potentially subject to this requirement—168 did not have an independent AI use case inventory or include their AI use cases within the inventory of their parent agency. Examining 78 parent-level agencies, only 17 posted AI use case inventories.[25] Thus, 76 percent of all 220 parent and sub-agencies, assessed separately, did not publish an inventory, and 78 percent of agencies assessed at the parent level did not publish an inventory (see Table 3).

To address the reality that executive agencies are not all similarly resourced, we also examined "large" agencies (defined as ones with over 400 employees). When focused on this subset of 125 large agencies (with parent and sub-agencies separately assessed), 47 had AI use cases published within an inventory, whereas 78 (62 percent) had not published use cases within an inventory. Assessing 37 large, parent-level agencies, 21 (57 percent) had not published an inventory.

The Trustworthy AI Order and guidance provided by the CIO Council did not specify whether an agency without AI use cases (or whose only use cases were exempted from disclosure) was required to file an inventory, or otherwise notify the public, to indicate that it had completed the requirement. It could be that 76 percent of agencies simply have no AI use cases. We hence examine the subset of agencies for which we can independently confirm the existence of AI use cases. This analysis enables us to distinguish whether the absence of inventories indicates the absence of AI use cases or an agency's failure to fulfill the Trustworthy AI Order's mandate. We rely on the extensive ACUS Report that "rigorous[ly] canvas[sed] AI use at the 142 most significant federal departments, agencies, and sub-agencies" to identify which agencies already had an AI use case as of 2019 and reported that nearly half of agencies have experimented with AI and machine learning at that time.[26] Of the 49 parent and sub-agencies with a known AI use case, 47 percent had not published an AI use case inventory (23 parent and sub-agencies). Among the narrowest group of agencies—i.e., 23 large agencies with a known AI use case assessed at the parent level—only 11 had published an AI inventory.[27] Notably HUD publicly disclosed that it does "not currently have any relevant AI use cases" [41]. We list these 23 agencies in Table 8. We also include an assessment of the implementation of the AI use case inventories of agencies enumerated in the Chief Financial Officers Act of 1990 and that are members of the CIO Council in Appendix C.2 and in Section 8.2.

Agencies	Org. Level	No inventories	Total	Perc.
All	Sub-agency	168	220	76%
	Parent	61	78	78%
Large	Sub-agency	78	125	62%
	Parent	21	37	57%
Known AI	Sub-agency	23	49	47%
	Parent	11	23	48%

Table 3: Publication of Agency AI Use Case Inventory as of Nov. 2022. "Large" agencies are those with more than 400 employees; "Known AI" are those with known AI use cases as of 2020. "Sub-agency" treats hierarchically related agencies as separate (e.g., separating the FAA and DOT); "Parent" attributes all sub-agency use cases to the parent agency.

The inventories themselves highlight serious implementation challenges with a signature transparency initiative. First, agencies are not disclosing AI use cases, even when these use cases have already been publicly documented. Customs and Border Protection (CBP), for instance, uses the Traveler Verification Service (TVS), which is a facial recognition system that "serves as CBP's backend matching service for the collection and processing of facial images in support of biometric entry and exit operations" [45, 102]. Acknowledging that "facial recognition poses a unique set of privacy issues" [9], CBP has sought to be "aggressively transparent" [45] in publishing privacy compliance documentation concerning its biometric entry-and-exit operations, including by publishing six

[23] As noted earlier, a similar AI use-case inventory requirement was adopted in the Fiscal Year 2023 National Defense Authorization Act [77].

[24] We searched for AI use case inventories starting in late October 2022, and the findings reported in the Tracker are current up to at least November 11, 2022, with some spot checks performed throughout early December 2022. Agencies may have posted inventories after our exhaustive search. But they were required to post the inventories by March 2022. Moreover, though it is possible we missed some inventories, we emphasize that they ought to be easily accessible. The CIO's guidance "encouraged" agencies to publish their inventories on a specific URL [75], and the NAIIO's repository [57] ostensibly includes all of the published inventories. Even if agencies have published inventories elsewhere, there are shortcomings to their implementation of the order if they are not published according to these methods.

[25] Three had zero use cases (HUD, NIST, and NSF), and a fourth (SSA) had only five use-cases. These are questionable, but for the purposes of the first two measures, we mark them as compliant solely from the posting of their inventories. In contrast, we count HUD as noncompliant when assessing against the identified AI use cases, i.e., the "Known AI Cases" of Table 3, because while its inventory asserts that the agency has no AI use cases, the ACUS Report identified a non-zero number of use cases. Neither NIST nor NSF were included in the "Known AI Cases" measure because the ACUS Report did not identify a use case from NIST, and NSF is not a "large" agency within the meaning of the report, and so neither is counted specially as compliant for one measure and noncompliant for another measure, unlike HUD. For further methodological discussion, see Appendix C.1.

[26] [102, p. 6]. For two reasons, the "known AI use case" estimate is potentially very conservative. First, likely have expanded their use of AI — the ACUS Report was conducted three years before our assessment. Second, the ACUS Report defined "AI" as "machine learning, which train models to learn from data"—a narrower definition than that used in the Trustworthy AI Order. For methodological considerations, including extended discussion of the definitional differences, see Appendix C.1.

[27] As HUD was identified as having a known AI use case in the ACUS AI Report, we do not include HUD's public disclosure of no AI use cases within the 11 agencies that have published an AI use case inventory. In contrast, we included HUD within the agencies that implemented the requirement in our measurement of all agencies and "large" agencies.

Privacy Impact Assessments[28] and 13 Privacy Threshold Analyses, and building a public-facing website about the technology [45, 70]. While CBP has disclosed some uses of AI under the inventory posted by DHS, TVS is not among them [43].

Second, inconsistencies in how agencies have implemented the AI use case inventories illustrate three sources of policy ambiguity.

(1) Non-response. For agencies that have not posted inventories, it is unclear whether they are asserting that they have no uses of AI or simply have not fulfilled the requirement. Of the published inventories, three—from HUD, the National Institute of Standards and Technology (NIST), and the National Science Foundation (NSF) [41, 50, 63]—state that their agencies have no AI use cases that meet the Trustworthy AI Order's requirements.

(2) Agency structure. All inventories except for NIST's were published at the parent-agency level (e.g., by DOC or DOE, rather than the NOAA or the Office of Electricity). But it is unclear whether unlisted sub-agencies within an inventory did not have relevant use cases or whether they were unresponsive to a presumed request for reporting by the parent agency. In some cases, the latter seems very likely.[29]

(3) AI definition. The definition of AI provided in the 2019 National Defense Authorization Act and incorporated into the Trustworthy AI Order is potentially quite broad, reaching among other things, any "artificial system" that "is designed to approximate a cognitive task" or that can "learn from experience and improve performance when exposed to datasets."[30] The breadth of that definition may make compliance harder for agencies when classifying particular technologies as "AI" for the purposes of an inventory.[31] For example, NOAA identified 36 AI use cases, representing the vast majority of the DOC's 49 AI use cases. The rest of Commerce's AI inventory [46] includes zero uses from the parent agency, five from the International Trade Administration, two from the National Telecommunications and Information Administration (NTIA), one from the Minority Business Development Administration, and five from the U.S. Patent and Trademark Office, with NIST publishing a separate inventory [50]. Ambiguity may result from both the breadth of the definition of covered AI—which includes uses that are new and existing, standalone and embedded, procured and developed in-house by the agency—and the carve-outs for sensitive or classified uses of AI, AI used for national security purposes, AI "embedded within common commercial products," and AI R&D, as provided in Section 9 of the Trustworthy AI Order [25].

Third, AI use case inventories often incorporate existing transparency initiatives, but with significant variation. Agencies are best positioned to know what records exist regarding each AI use case, and some have provided useful links to published documentation. For example, many use cases in the DHS inventory include links (e.g., to privacy impact assessments); some EPA, HHS, Department of the Interior (INT), DOC, and Department of Agriculture use cases include links to relevant publications; and some Department of Labor (DOL), INT, and Department of Justice (DOJ) use cases reference publicly available code.

8 DISCUSSION

We now discuss broader implications emerging from this study, as well as some limitations. First, *empirically*, our top-level finding is that implementation has been lacking, which we interpret through the lens of *bureaucratic capacity* and *policy ambiguity*. Second, *methodologically*, we discuss how social scientists can study policy implementation in a rigorous and systematic way based on our case studies.

8.1 Broader Implications

Foundational theoretical work in bureaucratic capacity has argued that lower capacity can prevent effective implementation of hierarchically imposed policy obligations. Huber [115] attributed this possibility to inhibitions on the principal's ability to punish failures on the part of the agent when the agent lacks sufficient capacity to implement the directive. Other explanations focus on the multiplicity of tasks and principals that each agency has, which implies that the agency may shirk obligations that lack enforcement mechanisms [97]. Still others might argue that policy directives understood as far from the organization's core "turf" may seem peripheral or unimportant and are thus ignored [141]. All of these different explanations can shed light on the lackluster implementation of these AI directives: Agencies, by and large, lack the technical expertise and committed leadership necessary to effectively implement and prioritize regulatory principles promulgated by the White House or Congress.

Our findings also reveal substantial policy ambiguity that places more decision-making costs on agencies seeking to comply with the directives, thereby further hampering implementation. Central questions pertaining to the scope of transparency obligations—like the AI plans and inventories—were left ambiguous by the executive orders and White House-level guidance. Our findings emphasized two sources of ambiguity—ambiguity in defining "AI" and "agency."

On the former, the definition of "AI" used in the Trustworthy AI Order left substantial discretion to the agencies to categorize their use of technology. For example, the Order's exemptions for "AI embedded in common commercial products" and for "AI research and development activities" are ambiguous.[32] We found large inconsistencies in the kinds of use cases disclosed by agencies: compare, for example, NOAA's disclosure of 36 AI use cases pertaining to scientific research with CBP's non-disclosure of facial recognition

[28] Such assessments are a legal requirement under Section 208(b) of the E-Government Act of 2002, see [134].

[29] Consider DOE: In its inventory [58], DOE reports 45 use cases from three sub-offices: Brookhaven National Laboratory (one use case); the Office of Electricity (10 use cases); and Idaho National Laboratory (34 use cases). We think these numbers are implausible as an exhaustive account of AI usage within DOE. For example, a public information sheet published in 2020 from the then-Office of Fossil Energy (now the Office of Fossil Energy and Carbon Management) boasted of having "over 60 AI-enabled projects underway" [18]. Moreover, each DOE office has listed a single individual as its point of contact for all AI use cases from that office. It seems at least plausible that those offices have designated specific employees to serve as point-individuals on AI transparency for the office but that other offices have failed to do so, which is why there are no use cases reported for other DOE sub-agencies. As another example, in the Department of the Interior's inventory [47], the United States Geological Survey (a sub-agency) disclosed 55 of the Department's 65 use cases. Some of those use cases seem to be collaborations with agencies (e.g., the U.S. Fish and Wildlife Service and the Bureau of Ocean Energy Management) that themselves did not disclose use cases. We count such agencies as failing to implement the requirement notwithstanding that other agencies reported some of their AI use cases.

[30] The full definition is provided in Section 238(g) of the FY2019 NDAA [8].

[31] The CIO's 2021 FAQs and "Example AI Use Case Inventory Scenarios" guidance documents [75] provide some details beyond the statutory definition, but much of the work of classifying technologies as "AI" still falls on the agencies.

[32] And they may not be normatively justifiable: an agency's reliance on ChatGPT may be quite important depending on how the technology is used, even if ChatGPT is a common commercial product.

systems used for biometric entry and exit operations (a system for which CBP has *published an independent website*, presumably because of the politically sensitive nature of the operation).

Additionally, both orders swept in broad terms, making it hard to know *which entities* were obligated to publish AI plans or use case inventories (see discussion in Section 4 and Appendices B.1 and C.1). Yet the problem of "agency" definition is not novel. As the authors of the ACUS Sourcebook note, "cataloging administrative agencies is difficult because so many varying definitions abound" [130, p. 11]. The point is not that there is a correct definition—rather, it is that these pillars of America's AI strategy did not even attempt to address the issue, thereby shifting costs onto lower-level executive branch entities to determine whether they ought to comply.

From the perspective of change management, a key problem with such ambiguity is that it inhibits the policymaker from effectively communicating and directing change in conditions of fast-changing technology (e.g., [137], cf. [79, 96]). Tighter rule construction itself would be helpful so that agencies better understand when and how they must comply. But discretion will inevitably vest with line-level bureaucrats implementing policies on AI (cf. [122]). Though much theoretical literature has discussed bureaucratic resistance to hierarchically imposed requirements (e.g., [118]), evidence from the perspective of "street-level" bureaucrats argues that implementation failures are more often a result of insufficient capacity than ideological opposition [83], which accords with our findings.

The poor public availability of the Agency AI Plans, AI use case inventories, and other mandated items supports existing scholarship about the consistency by which agencies make public guidance documents [87]. Coglianese found that mandated agency guidance is inconsistently published, which keeps the public in the dark about important agency actions. Agencies, Coglianese argued, need internal management practices to ensure disclosure because legal requirements without incentives or consequences for non-disclosure will be insufficient to motivate agencies to disclose [87]. Transparency requirements strengthen government accountability efforts while also enabling federal agencies to have meaningful consultations with external stakeholders. But to actualize those policies will require more careful rule construction from the top, closer attention to bureaucratic capacity down the chain, and agency adoption of management strategies to systematically track, index, and publish guidance [99].

Our systematic assessment of agency implementation of these policies provides evidence for the inference that insufficient bureaucratic capacity has hampered the implementation of U.S. AI policy. We do not rule out possible alternative explanations. For example, agencies' incentives to faithfully implement policy directives may be tied to their assessment of those policies' durability [135], where policies promulgated by a president late in her term[33] may be perceived by the agencies as less imperative or even less legitimate. Similarly, agencies may have differential incentives to comply based on how central AI initiatives are to their core functions, especially as it implicates funding. Thus, for example, NOAA's substantial disclosure of AI use cases in its inventory might be understood as a kind of "bureaucratic entrepreneurship" [124], where the agency's work helped demonstrate to the public why it needed greater funding for AI-related initiatives (funding, incidentally, which it received [106]). But while there is more room for theoretical insight from studying variation within our findings, the top-level result is still indicative of a general lack of bureaucratic capacity to implement AI policy.

Finally, our *methodological* contribution is to provide a transparent and systematic means for assessing policy implementation notwithstanding the conceptual ambiguities noted above. Our reliance on a mix of statutes, regulatory provisions, and materials by ACUS can inform subsequent efforts to assess policy that is addressed, generally, toward "agencies," as in the Trustworthy AI Order, or agencies with "regulatory authorities," as in the AI Leadership Order (see Section 4 and Appendices B.1 and C.1). Furthermore, for the AI use case inventories, we present findings with different levels of aggregation and groupings of agencies that correspond to theoretical concerns and practical realities: We considered not only the largest number of agencies to which the executive order might theoretically apply, but we also cut only to "large" agencies and to agencies that had been previously identified by ACUS as using (or considering using) AI. And we assessed each of those measures not only by disaggregating at the lowest "agency" level but also by bundling agencies into their parent departments (for example, including the IRS within the Treasury Department) to address what seems to be agencies' understandings of their obligation under the executive order (i.e., most disclosed inventories were housed at the parent-agency level) (see Section 7 and Appendix C). And while much of our work emphasized *systematic* analysis, we also considered the disclosures *qualitatively* so that our findings are sensitive not only to whether agencies ticked a box but also how meaningfully their disclosures achieved the executive orders' policy goals. While these steps involve nuance to implement, they illustrate how we can rigorously assess policy implementation. As AI governance efforts mature, these efforts will be critical to ensure that legislative and executive directives are not "lost or misdirected in the vast hallways of the federal bureaucracy" [1, p. 1111].

8.2 Limitations

We note several limitations of our assessment. First, as we have noted, our assessment is based on publicly available information. Many more implementation efforts may be underway. But the mere fact that so many deadlines have been missed—when the pace of innovation in AI is extremely fast—illustrates the severe limitations of existing governmental efforts. In addition, the difficulty in researching the implementation status is itself telling. Existing efforts have delegated to agencies the task of defining and implementing these provisions, and, as a result, efforts have been fragmented and inconsistent.

Second, some might argue that the failure to meet deadlines and implement legal requirements is no different in AI than in other domains [78]. Perhaps that is so, although there are few directly analogous studies in comparable, but non-AI, domains.[34] Regardless, our findings suggest bureaucratic capacity challenges in a highly consequential space.

[33]The AI Leadership Order was issued on February 14, 2019, and the Trustworthy AI Order on December 8, 2020, when then-President Trump was a so-called 'lame duck' president.

[34]For an exception, see the Government Accountability Office's assessment of the implementation of the Open, Public, Electronic and Necessary Government Data Act of 2018 [36].

Third, our implementation estimates may be critiqued based on the fact that they weigh provisions equally. Not all operative provisions in a bill or order matter equally. We agree and have provided the detailed, line-level tracker results to enable any assessment of implementation of specific items (Appendix E). Our qualitative assessment, however, does not suggest that all important items have been implemented. To the contrary, major items that are critical to preparing the federal government for the AI transition have not been addressed.

Fourth, while AI use case inventories are an important step toward transparency, they remain relatively limited as implemented. Some registries, for instance, include extensive data and model documentation, but the Trustworthy AI Order did not appear to require such extensive detail. As we show in Appendix C.2, numerous agencies have gone beyond the minimal requirement and documented performance benchmarks and evaluation measures, which are particularly important for assessments of trustworthiness.

Last, we released our findings in December 2022 [120] and some agencies have since posted AI use case inventories or disclosed no use cases.[35] To the extent that our research galvanized agency action, we both applaud the agencies and White House for taking initiative but also re-emphasize that formal compliance itself is not the goal. Compliance should be a *means* for strategic planning and action: Publicly verifiable steps, while important from a transparency perspective, are fundamentally proxies for assessing whether agencies are prepared for and taking concrete steps around trustworthy AI. If the tracked metrics become ends in themselves, then they are no longer reliable indicators of the underlying issue of interest. Agency responses also suggest further support for our conclusion that senior leadership is critical. All of the agencies that we know published an inventory after our white paper, except for one, are subject to the Chief Financial Officers Act (see Appendix D). This act required each agency to establish a Chief Financial Officer and provided the White House's Office of Management and Budget (OMB) greater authority over agency financial management [67]. This *could* demonstrate the important role of the White House in shepherding compliance and strategic planning.

9 CONCLUSION

Our findings have broad implications for the current ability of government to govern AI. We find that three core elements of America's collective AI strategy—the AI Leadership Order, the Trustworthy AI Order, and the AI in Government Act—have not been implemented well despite an urgent need for the U.S. government to grapple with a technology that is widely seen to have far-reaching, transformative potential.

These findings strongly suggest that there is a resource shortage, a leadership vacuum, and a capacity gap, which are exacerbated by policy ambiguity. Leadership will be required from both the White House, including the National AI Initiative Office and OMB, and agencies to coordinate and drive forward AI innovation and trustworthy adoption. Current requirements may appear to agencies like "unfunded mandates" and be treated like checklists when they should in fact be seized as opportunities for strategic planning around AI. Some agencies have recognized the urgent need and were able to respond comprehensively and meaningfully to these legal requirements (see, e.g., HHS's Artificial Intelligence Strategy, Trustworthy AI Playbook, and action plan for regulating AI-based medical devices [29, 31, 39]). If our findings are due to bureaucratic capacity, Congress should provide resources for agencies to staff and acquire technical expertise to comply in more than a perfunctory way and develop strategic AI Plans. Failure to provide proper resources and mandate senior personnel to discharge these responsibilities could otherwise undermine the goal of these laws to maintain U.S. leadership in AI innovation and trustworthy AI.

The public disclosure of AI Plans and AI use case inventories constitutes an important effort to foster transparency and accountability in public sector AI. The executive orders mandated their public disclosure and senior-level guidance instructed they be made readily available on specific websites. The fact that it has taken considerable effort for our team to track the implementation of such plans, use case inventories, and requirements (see efforts detailed in the Appendices) strongly suggests that improvements must be made on reporting and tracking of these provisions. Our assessment may miss certain use case inventories, for instance, but that is precisely the point. Disclosure must be accessible and legible to be effective.

We close by noting that on paper and in principle, America's strategy for AI innovation and responsible AI, as manifested in the Trustworthy AI Order, the AI Leadership Order, and the AI in Government Act, is highly laudable. But in practice, our assessment suggests severe challenges in the federal government's ability to navigate a rapidly changing and critically important space. Requirements have been converted into perfunctory checklists instead of triggers for strategic planning, and agencies do not appear to have effectively grappled with the opportunities and risks that AI poses.

Bureaucratic capacity is a sine qua non for turning laudable principles into reality.

[35] Agencies that have since published an explanation or use case inventory include the Departments of Education, Housing and Urban Development, the Interior, the Treasury, and Transportation; the General Services Administration; the Small Business Administration; and the U.S. Office of Personnel Management.

ACKNOWLEDGMENTS

We would like to thank Victoria Espinel, Janet Haven, Fred Oswald, Christine Tsang, Russell Wald, and Daniel Zhang for helpful comments. An earlier version of this study was released as a White Paper, "Implementation Challenges to Three Pillars of America's AI Strategy," from the Stanford Institute for Human-Centered AI (HAI) and Stanford RegLab.

A IMPLEMENTATION OF LEGAL REQUIREMENTS

A.1 Methodology

To assess the implementation status of the AI Leadership Order, the Trustworthy AI Order, and the AI in Government Act, we first identified all line-level actions that these documents mandate (e.g., instructions that a federal entity "shall budget," "shall consider," "shall review," "shall publish"). For each requirement, the following information was compiled in a tracker (see Appendix E): (1) the relevant portion of the executive order or legislation, (2) the government stakeholder responsible for its implementation, (3) a summary of the mandated outcome or deliverable, (4) the mandated deadline, if any, and (5) the "type" of requirement (see below paragraph), and (6) the status of implementation. The first four items were drawn from the text of the executive order or legislation itself, while the status of implementation was drawn from publicly available information, as of November 23, 2022. Where possible, we provide additional details about the implementation of the requirement and URL links to relevant documents. Therefore this represents the publicly verifiable status and may not capture activities executed without public disclosure (either with the intent to protect sensitive or classified information or simply because the federal entities did not prioritize or have an appropriate avenue for disclosing the activity).

As noted above, the requirements were split into three categories. This facilitated assessment of implementation by the responsible federal government entity (see tables in Appendix E.1). The categories were:

(1) ***Time-boxed requirements*** mandated a federal entity, or entities, to produce a document or achieve an outcome by a specified date (e.g., "shall develop" a report within 90 days of the date of the executive order).
(2) ***Open-ended requirements*** mandated the production of a document/deliverable or achievement of an outcome without specifying a deadline.
(3) ***Ongoing requirements*** were open-ended mandates to agencies that often did not require the production of a specific document/deliverable or achievement of a concrete outcome (e.g., agencies "shall pursue" an objective, "shall consider" actions, "shall identify opportunities," "shall provide" expertise, etc.). These ongoing requirements also did not have a deadline. This also includes outcomes that were part of an annual process without a specified date (e.g., the AI Leadership Order's requirements in Section 4(b)-(b)(1) that agencies prioritize AI R&D and "communicate plans for achieving this prioritization to the OMB Director and the OSTP Director").

Although assessing implementation of the time-boxed requirements was often straightforward, compliance with a significant percentage of mandated actions was not known or hard to determine, either because the mandate required ongoing compliance without producing a specific milestone, the mandated action did not require public disclosure of its completion or progress toward its completion, or both. Under the assumption that federal entities had taken necessary steps, or at least made good faith efforts, to meet their legal and statutory requirements, ambiguity was resolved in favor of the federal entities. Therefore, the researchers applied the following rules for determining implementation status: implemented (or indications of implementation), not implemented (or indications that the requirement was not implemented), and not known.

- ***Implemented***: Time-boxed requirements were marked as successfully implemented where the mandated outcome was achieved, even if achieved after the mandated deadline. Open-ended requirements and ongoing requirements without a defined deliverable were coded green if public information strongly supported the conclusion that federal entities were implementing the requirement.
- ***Not Implemented***: Time-boxed requirements were marked as not implemented if there was no public information, as of November 23, 2022, confirming their implementation by the mandated deadline. Requirements were coded red if public information strongly suggested that they had not been implemented by federal entities. The latter, for instance, occurred for the AI Leadership Order's requirement for a National Security Presidential Memorandum.
- ***Not Known***: Implementation of time-boxed requirements and open-ended requirements was marked as not known where public reporting was nonexistent, often because public reporting was not mandated, or did not clearly indicate the status of implementation. Similarly, the implementation of ongoing requirements was marked as not known because there was no mandated reporting and often no mandated outcome for the researchers to publicly verify.

A.2 Summary of Findings

A summary of the findings for each document is provided in Tables 1, 4, 5, and 6. The detailed methodology is provided in Appendix A.1, but it is important to highlight upfront that methodological constraints may result in our findings underestimating implementation and overestimating requirements that remain outstanding. Although best efforts were taken to properly identify all relevant documents or notices of actions, the researchers could only rely on federal entities' public disclosures, which may not capture all relevant actions taken by the federal government to achieve the mandates.

- **AI Executive Order**: Only 39 percent, or nine of the order's 23 requirements, were implemented. Given a dearth of publicly available information about many of the requirements, the implementation status for a majority of the requirements was not known (57 percent). Requirements with a specified deadline had a higher rate of implementation (45 percent) than requirements without a deadline (0 percent) or open-ended requirements without a concrete deliverable (40 percent). Critically,the requirement for agencies to publish AI Plans to achieve consistency with OMB guidance on regulating AI was not fulfilled. The implementation of these Agency AI Plans is discussed in Section 6 and Appendix B.2.
- **Trustworthy AI Order**: Implementation was even lower for the Trustworthy AI Order, with only 13 percent, or two of the

Table 4: Summary of Federal Entities' Implementation of Requirements in AI Leadership Order (EO 13,859)

	Relevant Sections	Implemented	Unknown Implementation	Not Implemented
11 Time-Boxed Requirements	5(a)(i)[a], 5(a)(ii), 5(a)(iii), 5(c), 6(a)-(b), 6(c), 6(d), 7(b), 8(a)-(b), 8(c)	45%	45%	9%
		5 (5(a)(i)[a], 5(c), 6(a)-(b), 6(d))	5 (5(a)(ii), 5(a)(iii), 7(b), 8(a)-(b), 8(c))	1 (6(c)[b].)
2 Open-Ended Requirements	5(a), 5(a)(iv)	0%	100%	0%
		—	2 (5(a), 5(a)(iv))	—
10 Ongoing Requirements	2(a)-(e), 4(a), 4(b)-(b)(i), 4(b)(ii), 4(c), 5(a)(v), 5(b), 5(d), 7(a)(i)-(ii), 7(c)	40%	60%	0%
		4 (4(a), 4(b)-(b)(i), 4(b)(ii), 5(b))	6 (2(a)-(e), 4(c), 5(a)(v), 5(d), 7(a)(i)-(ii), 7(c))	—

[a]5(a)(i) has two time-boxed requirements.
[b]See Appendix E.2

requirements, implemented.[36] Similar to the AI Leadership Order, implementation for a majority of the requirements (54 percent) could not be conclusively determined. Two of the requirements, or 13 percent, have not been implemented, including the requirement for agencies to prepare and publish AI use case inventories. The implementation of these Agency AI use case inventories is discussed in Section 7 and Appendix C.2.

- **AI in Government Act of 2020**: Compared to the executive orders, the percentage of requirements that were not implemented was much higher at 67 percent, or four of the six requirements. The only requirement implemented was to establish an AI Center of Excellence within GSA, while the progress that GSA has made on achieving the Center of Excellence's duties is unknown.

B IMPLEMENTATION OF AGENCY AI PLANS

B.1 Methodology and Background

B.1.1 Background on AI Leadership Order's "Agency AI Plan" Requirement. As discussed in Section 6, a significant focus of the AI Leadership Order was addressing concerns about regulatory gaps and hurdles to AI development and deployment. As such, the executive order mandated:

- The White's Office of Management and Budget (OMB) to issue a guidance memorandum to agencies, after publishing a draft guidance for public comment, within 180 days of the EO (approximately August 2019). Sections 6(a)-(b).
- The heads of "implementing agencies" with regulatory authorities to develop a plan to "achieve consistency" with the OMB memorandum within 180 days of OMB issuing the memorandum. Section 6(c).

[36]There were 17 requirements, but one requirement was excluded from the overall calculations because its deadline has not yet passed (i.e., the rate of implementation assumed 16 instead of 17 requirements).

OMB fulfilled its requirement over a year overdue, publishing a draft memorandum on January 1, 2020,[27] and issuing its final memorandum on November 17, 2020.[138] OMB M-21-06, Memorandum for the Heads of Executive Departments and Agencies on Guidance for Regulation of Artificial Intelligence Application (referred to as the "OMB AI Regulation Memo" for ease of understanding), provided guidance for agencies on regulatory and non-regulatory approaches to AI. Critically, it noted that "government use of AI" was outside of the scope of the memorandum.

The OMB AI Regulation Memo also provided guidance for the Agency AI Plans. Specifically, it stated:

> The agency plan must identify any statutory authorities specifically governing agency regulation of AI applications, as well as collections of AI-related information from regulated entities. For these collections, agencies should describe any statutory restrictions on the collection or sharing of information (e.g., confidential business information, personally identifiable information, protected health information, law enforcement information, and classified or other national security information). The agency plan must also report on the outcomes of stakeholder engagements that identify existing regulatory barriers to AI applications and high-priority AI applications that are within an agency's regulatory authorities. OMB also requests agencies to list and describe any planned or considered regulatory actions on AI.

Furthermore, the memorandum included specific instructions for how agencies must submit and publish their plans:

> Agency plans are due on May 17, 2021, and should be submitted to OIRA at the following email address: AIplans@omb.eop.gov. To inform the public of each agency's planned and implemented activities, agency plans must be posted on, or be accessed from (through

Table 5: Summary of Federal Entities' Implementation of Requirements in Trustworthy AI Order (EO 13,960)

	Relevant Sections	Implemented	Unknown Implementation	Not Implemented
12 Time-Boxed Requirements[a]	4(b), 5(a), 5(b), 5(c)(i), 5(c)(ii), 5(d), 5(e), 6[b], 7(a), 7(b), 7(c), 8(c)	17%	58%	17%
		2 (5(a), 7(a))	7 (5(b), 5(c)(i), 5(d), 6[b], 7(b), 7(c), 8(c))	2 (4(b), 5(e)[c])
1 Open-Ended Requirement	5(c)	0%	100%	0%
		—	1 (5(c))	—
4 Ongoing Requirements	2(b), 4(a), 4(c), 6[b]	0%	100%	0%
		—	4 (2(b), 4(a), 4(c), 6[b])	—

[a]Requirement in section 5(c)(ii) has not been implemented, but the deadline for implementation has not yet passed, so it is not classified as implemented, not implemented, or not known. Therefore the percentages for the 12 time-boxed requirements do not equal 100 percent.
[b]6 has one time-boxed requirement and one ongoing requirement. See Appendix E.1
[c]See Section 7, Table 3, and Appendix C.

a URL redirect), the following domain on the agency's website: www.[agencyname].gov/guidance.

The May 2021 deadline adhered to the AI Leadership Order's requirement that the plans be completed and submitted within 180 days of the OMB AI Regulation Memo's issuance.

The OMB AI Regulation Memo did not provide guidance on which agencies were subject to the executive order's requirements. The AI Leadership Order stated that the requirement applied to "implementing agencies that also have regulatory authorities." "Implementing agencies" were defined in Section 3 of the AI Leadership Order as "agencies that conduct foundational AI R&D, develop and deploy applications of AI technologies, provide educational grants, and regulate and provide guidance for applications of AI technologies, as determined by the co-chairs of the NSTC Select Committee." This set is potentially quite broad, especially as regulation of applications of AI would include many incumbent regulatory regimes (e.g., approval of medical devices by the Food and Drug Administration, discrimination of employment policies by the Equal Employment Opportunity Commission). However, the NSTC Select Committee on AI did not publish a list of agencies it determined were "implementing agencies," nor did the OMB AI Regulation Memo provide any additional insight. Although the OMB AI Regulation Memo directed itself to "heads of all Executive Branch departments and agencies, including independent regulatory agencies," neither the memorandum nor the executive order defined "regulatory authorities," a potentially expansive term subsuming most administrative agencies, or delineated which agencies had regulatory authorities.

B.1.2 Methodology for Assessing Implementation. To identify relevant agencies, we first searched online for a list of agencies deemed to be "implementing agencies" by the co-chairs of the NSTC Select Committee on AI. As this list was not publicly available, we instead focused on Cabinet-level departments and agencies and the 19 agencies deemed "independent regulatory agencies" under 44

U.S.C. § 3502(5).[37] We also included the U.S. Agency for International Development (USAID), as it was the only agency represented at the National Security Council[105] that was not already included as a Cabinet-level agency or as an independent regulatory agency. The reason for including each agency is identified in the full tracker in Appendix E.2. It is possible that this list is overinclusive or underinclusive of the agencies that were actually required to establish and publish an Agency AI Plan to achieve consistency with the OMB AI Regulation Memo. We also inquired with a member of the Select Committee and did not receive an answer on what agencies are included.

The intended purpose of the OMB AI Regulation Memo's requirement that the Agency AI Plans should be available on the respective agency website's page on guidance was to increase transparency and "inform the public." Therefore, identifying the plans should be intuitive to the public and should not require significant expenditure of time. To simulate how an individual might seek to access the plan, we implemented four simple approaches to finding it. For each, the researchers noted whether the approach yielded a positive identification of an Agency AI Plan in the correspondingly titled columns in E.2.

- **Dedicated Agency URL**: Visiting the link under which the OMB AI Regulation Memo expressly requires the Agency AI Plan to be posted: [agency_name].gov/guidance. We noted first if the agency had a dedicated guidance webpage. If it did, we searched "response artificial intelligence OMB M-21-06" (as "OMB" and "M-21-06" are expressly noted in the template response). If it did not, we marked "no" for this method.
- **Web Search**: We searched online (using Google) "[agency name] response artificial intelligence OMB M-21-06". If the agency's full name did not return results, we searched with the agency's acronym (e.g., HHS for the Department of Health and Human Services), where applicable.
- **Search Within Agency Website**: Searching within an agency's website: "response artificial intelligence OMB M-21-06." If (as noted above) an agency lacked its own website, we searched on its parent agency's website with its name included, e.g., "[agency name] response artificial intelligence OMB M-21-06". If the search engine returned an implausibly large number of results (e.g., on the order of 10,000), phrases would be placed in quotation marks (e.g., "artificial intelligence," "use case," and "M-21-06").
- **AI.gov**: Searching the publication library on AI.gov (the website for the National AI Initiative) for the agency's name (or acronym) and "response artificial intelligence OMB M-21-06". We also looked at all documents published by that agency and included in the publication library as there was a small number of documents per agency, if any, in the publication library.

If an Agency AI Plan was identified using any of these four methods, as of November 23, 2022, the researchers marked "yes" in the "Agency Plan" column (Appendix E.2) and provided the web link to the plan in the "URL" column. If the Agency AI Plan was not identified using any of the four methods, the researchers marked "no" for the presence of an "Agency Plan."

B.2 Summary of Findings

The agencies with an Agency AI Plan are the Departments of Energy, HHS, and VA, the EPA, and USAID (see Tables 2 and 7).

The agencies without AI Plans are the Departments of Agriculture (USDA), Commerce, Defense, Education, Homeland Security, Housing and Urban Development, Interior, Justice, Labor, State, Transportation, Treasury, and the Board of Governors of the Federal Reserve System (FED), Commodity Futures Trading Commission (CFTC), Consumer Financial Protection Bureau (CFPB), Consumer Product Safety Commission (CPSC), Federal Communications Commission (FCC), Federal Deposit Insurance Corporation (FDIC), Federal Energy Regulatory Commission (FERC), Federal Housing Finance Agency (FHFA), Federal Maritime Commission (FMC), Federal Trade Commission (FTC), Mine Enforcement Safety and Health Review Commission (FMSHRC), National Labor Relations Board (NLRB), Nuclear Regulatory Commission (NRC), Occupational Safety and Health Review Commission (OSHRC), Office of Financial Research (OFR), Office of Management and Budget (OMB), Office of Science and Technology Policy (OSTP), Office of the Comptroller of the Currency (OCC), Office of the Director of National Intelligence (ODNI), Office of the U.S. Trade Representative (USTR), Postal Regulatory Commission (PRC), Securities and Exchange Commission (SEC), Small Business Administration (SBA), and the Surface Transportation Board (STB).

Four agencies published AI-related strategic plans, including some that noted the AI Leadership Order, but these plans provided far less than the detailed required. The DHS's S&T AI and ML Strategic Plan [38], the VA's AI Strategy [30], and the Department of State's Enterprise Data Strategy [33] mention the AI Leadership Order and identify AI priorities but provide less detail on regulation than required under the AI Leadership Order. The Nuclear Regulatory Commission published an AI Strategic Plan in June 2022 [94], but it similarly does not provide enough detail to classify as an Agency AI Plan consistent with the OMB AI Regulation Memo.

C IMPLEMENTATION OF AI USE CASE INVENTORIES

C.1 Methodology

C.1.1 Background on the Trustworthy AI Order's AI Use Case Inventory Requirement. Agencies were to prepare their inventories within 180 days of the Federal Chief Information Officers Council (CIO Council) providing guidance to the agencies (which occurred in fall 2021 [75]) and annually thereafter. The CIO guidance instructed agencies to report use case inventories using a provided Excel template by March 22, 2022.

[37] The current Cabinet includes the heads of the 15 executive departments (the Secretaries of Agriculture, Commerce, Defense, Education, Energy, Health and Human Services, Homeland Security, Housing and Urban Development, Interior, Labor, State, Transportation, Treasury, and Veterans Affairs, and the Attorney General), the White House Chief of Staff, the U.S. Ambassador to the United Nations, the Director of National Intelligence, and the U.S. Trade Representative, as well as the heads of the Environmental Protection Agency, Office of Management and Budget, Council of Economic Advisers, Office of Science and Technology Policy, and Small Business Administration.[66] We excluded the White House Chief of Staff, U.S. Ambassador to the U.N., and Council of Economic Advisors because they do not have rule-making or regulatory authority.[130]

Table 7: Summary of Agencies with Agency AI Plans

Agency	Overview of the Substance in Agency's AI Plan
Department of Energy (DOE)	• Input "none" for each of the five questions
Department of Health and Human Services (HHS)	• 11 statutes that authorized HHS to regulate AI applications, even noting that two of the statutes do not directly mention AI but might provide indirect authority to regulate AI as it relates to health data or health technology • 32 active collections of AI-related information, 30 of which were approved by OMB pursuant to the Paperwork Reduction Act and two that were exempted from OMB clearance as they are "general requests" • 12 AI use case priorities, 7 were AI applications in the private sector that were under its regulatory authorities (e.g., AI algorithm for wrist fracture reduction), 4 were opportunities for HHS to "shape the development and production of AI in the private sector," such as creating and improving relevant datasets, and 1 (predicting risk of adult maltreatment) was an internal AI tool that could be adopted by the private sector • 10 AI regulatory barriers (e.g., data silos, intellectual property, concerns about HIPAA and data sharing) • 4 planned regulatory actions concerning AI applications (e.g., imposing clinical holds on medical devices)
Department of Veterans Affairs (DVA)	• No statutory authorities directing or authorizing agency regulation of AI • No active collections of AI-related information • 14 AI use case priorities (e.g., identifying risk factors for diseases or suicide risk, AI that triages incoming medical evidence like images or lab results) • 3 AI regulatory barriers, which were all specific regulations (HIPAA, Electronic Communications Privacy Act, Privacy Act of 1974 amended as 5 U.S.C. 552a) • No planned regulatory actions concerning AI
Environmental Protection Agency (EPA)	• No statutory authorities directing or authorizing agency regulation of AI • No active collections of AI-related information • No AI use cases in private sector within regulatory authority, but a handful of AI use cases identified as of interest for achieving EPA's goals • No AI regulatory barriers identified • No planned regulatory actions concerning AI, but noted EPA began working on AI strategies like technical architectures and eventually higher-level principles
U.S. Agency for International Development (USAID)	• No statutory authorities directing or authorizing agency regulation of AI • No active collections of AI-related information • No AI use cases in private sector within regulatory authority • No AI regulatory barriers identified • No planned regulatory actions concerning AI

Responsible Agencies: Agencies that must comply were defined by the Trustworthy AI Order[25] in Section 8 as "all agencies described in section 3502, subsection (1), of title 44, United States Code, except for the agencies described in section 3502, subsection (5), of title 44." The Department of Defense and "those agencies and agency components with functions that lie wholly within the Intelligence Community" were also exempted.

Scope: The Trustworthy AI Order used the definition of AI "set forth in section 238(g) of the National Defense Authorization Act

for Fiscal Year 2019 as a reference point."[38] The order further clarified in Section 9 that it applied to "both existing and new uses of AI; both standalone AI and AI embedded within other systems or applications; AI developed both by the agency or by third parties on behalf of agencies for the fulfillment of specific agency missions, including relevant data inputs used to train AI and outputs used in support of decision making; and agencies' procurement of AI applications." However, the order excluded some AI uses from the AI inventory requirement, including "AI used in defense or national security systems (as defined in 44 U.S.C. 3552(b)(6) or as determined by the agency)," "AI embedded within common commercial products, such as word processors or map navigation systems," and "AI research and development (R&D) activities." The CIO's Example AI Use Case Inventory Scenarios provides additional guidance.[75]

Submission and Publication: Given the timing of the CIO's issuance of the guidance, the CIO guidance [75] instructed:

> By March 22, 2022, Agencies shall use the provided Excel workbook, 'Agency AI Use Case Inventory,' to compile their AI use cases and upload one file per agency to the MAX site at: Agency AI Inventory Instructions and Submission - E-Government Community - MAX Federal Community.

This guidance adhered to the Trustworthy AI Order, which mandated that agencies share their inventories with other agencies within 60 days of completing them and then make their inventories publicly available within 120 days of completing their inventories.

C.1.2 Methodology for Assessing Implementation. To identify relevant agencies, we looked to the ACUS Sourcebook of U.S. Executive Agencies ("ACUS Sourcebook")[130] and included all 278 agencies and sub-agencies identified in the Sourcebook data spreadsheet.[131] Given the Trustworthy AI Order's explicit exclusions, we removed agencies within the Department of Defense, agencies and sub-agencies within the intelligence community as defined by 50 U.S.C. § 3003(4), and the 19 independent regulatory agencies defined in 44 U.S.C. § 3502(5).[39] We further made individualized adjustments for agencies that are now defunct or are administered under different names.[40] This produced a total of 220 agencies.

Similar to the Agency AI Plans, identifying AI inventories should be intuitive to the public and should not require significant expenditure of time. We implemented four approaches:

(1) **Dedicated Agency URL**: We visited the relevant website as provided by the CIO 2021 Guidance for Creating Agency Inventories of AI Use Case [75]: "[agency_name].gov/data/-AI_Inventory." If the relevant agency's webpage did not lead to an AI inventory, or if the agency did not have a URL of that form, we recorded "Dedicated Agency URL" as "No."
(2) **Web Search**: We searched online (using Google) "[agency name] artificial intelligence use case inventory." If the agency's full name did not return results, we also searched using the agency's acronym or more common name (e.g., DHS or Farmer Mac).
(3) **Search Within Agency Website**: We searched within an agency's website (i.e., using its internal search engine): "artificial intelligence use case inventory." If (as noted above) an agency lacked its own website, we searched on its parent agency's website with its name included, e.g., "[agency name] artificial intelligence use case inventory." If the search engine returned an implausibly large number of results (e.g., on the order of 10,000), phrases would be placed in quotation marks.
(4) **AI.gov**: We searched AI.gov's (website for the National AI Initiative) tracker for agency AI use case inventories.

Multiple measures were employed to measure implementation. The measurements varied along two major dimensions:

(1) **Agencies considered**: We measured implementation rates by considering different subsets of agencies—specifically, we employed three agency groupings: *all relevant agencies*, *large agencies*, and *agencies with a known AI use case*. Appendix E.3 includes the list of all 220 agencies and classifies which agencies are large and have a known AI use case.
   (a) *All relevant agencies* considers all 220 agencies identified using the methodology described above. This approach does not consider agency size or likelihood of the agency employing AI.
   (b) *Large agencies* considers 125 "large" agencies. To identify this subset, we benchmarked against the 2020 "Government by Algorithm: Artificial Intelligence in Federal Administrative Agencies" report submitted to ACUS ("ACUS AI Report").[102] The ACUS AI Report narrowed the agencies listed in the 2018 ACUS Sourcebook by (1) including only agencies with more than 400 employees; and (2) removing active military and intelligence-related agencies. The ACUS AI Report therefore identifies 142 "large" agencies. For this tracker, the 142 agencies had to be further narrowed by removing the independent regulatory agencies within the meaning of 44 U.S.C. § 3502(5) and the now-defunct agencies.[41] The result is a total of 125 agencies.[42]

[38] The order noted in Section 9(a) that the evolution of AI use in the federal government necessitates that "OMB guidance developed or revised pursuant to section 4 of this order shall include such definitions as are necessary to ensure the application of the Principles in this order to appropriate use cases."

[39] One of the named independent regulatory agencies within 44 U.S.C. § 3502(5) is the Interstate Commerce Commission, which is now defunct. We excluded its successor, the Surface Transportation Board.

[40] Specifically, we excluded: (1) the National Association of Registered Agents and Brokers (NARAB), which was statutorily created in 2015 but not implemented; (2) the Federal Supplementary Medical Insurance Trust Fund and the Federal Hospital Insurance Trust Fund, both of which are administered by the Medicare Board of Trustees, which is what we have included in the Tracker; (3) the Office of Healthy Homes and Lead Hazard Control, which is currently known as the Office of Lead Hazard Control and Healthy Homes (included in the Tracker); (4) the Grain Inspection, Packers, and Stockyards Administration, whose functions are now housed in the Agricultural Marketing Service; (5) the Northern Great Plains Regional Authority, which is now defunct; (6) the Economic and Statistics Administration, which no longer exists; and (7) the Internal Revenue Service Oversight Board, which has been suspended. We further added the Executive Office of the President as a parent agency. Though it is probably best regarded as not an "agency" ([130, p. 19]). Notably, we did not exclude three agencies in the Department of Agriculture listed by the ACUS Sourcebook—the Rural Business-Cooperative Service, the Rural Housing Service, and the Rural Utilities Service—that seem to be child-agencies of a USDA sub-agency known as "Rural Development." To our knowledge, these three are the only examples of sub-sub-agencies featured in our analysis.

[41] One agency that the ACUS AI Report analyzed that we did not include was the Office of Medicare Hearings and Appeals, because it is not listed in the ACUS Sourcebook.

[42] These agencies are marked in the second column of the Full Tracker (see Appendix E.3, where the 125 agencies considered by the ACUS AI Report and relevant to the order were marked as "Yes" and agencies not considered in the ACUS AI Report were marked as "No."

(c) *Agencies with a known AI use case* considers 49 agencies with a non-zero number of AI use cases identified by the ACUS AI Report team.[43] The ACUS AI Report identified through "an agency-by-agency, web-based search protocol, augmented by a range of third-party sources" any use case where an agency "had *considered using* or had *already deployed* AI/ML technology to carry out a core function," discounting instances "where agencies demonstrated no intent to operationalize a given tool," such as "a pure research paper using AI/ML." Because the ACUS team focused on whether the agency was deploying AI for a "core function," identifying an AI use case is a decent proxy for presuming that that agency ought to report some inventory pursuant to the Trustworthy AI Order. If the agency did not have an inventory but it did have a non-zero number of use cases, we classify that agency as not having implemented the requirement.[44]

(2) **Organizational level**: We calculate the compliance and noncompliance rate at both the *individual/sub-agency* and *parent* level. Appendix E.3 identifies the parent agency and its sub-agencies.

(a) At the *individual/sub-agency level*, we disaggregate all sub-agencies from their parent agency. Because nearly all inventories were published by the parent-level agency,[45] we denoted a sub-agency as having published an inventory if its use cases are described and assigned to that sub-agency within the parent agency's inventory.[46] We calculated the implementation rate by dividing the number of sub-agencies and parent-level agencies with a use case inventory by the total number of agencies for that measure (i.e., 220 for "all relevant agencies," 125 for "large agencies," and 49 for "large agencies with known AI uses").

(i) For example, the Department of Justice, which has 14 sub-agencies, published an AI use case inventory that included use cases from two of its sub-agencies that were in our set of agencies (Drug Enforcement Administration and Federal Bureau of Investigation).[47] Because DOJ, DEA, and FBI have or are listed in a use case inventory, they are marked as having implemented an inventory, while the remaining 12 sub-agencies not included in DOJ's AI use case inventory are marked otherwise; the non-implementation rate is thus 80% (12/15).

(b) At the *parent* level, we bundle all sub-agencies' use cases into the parent-level agency. There are 78 parent-level agencies.

(i) For example, instead of counting the Department of Commerce and all of its sub-agencies, we count all of the sub-agencies as part of the Department of Commerce. Whether a DOC sub-agency has an AI use case inventory, therefore, does not impact whether DOC is marked as having implemented an inventory. However, for the assessment among "large agencies with known AI uses," child-agency identified use cases were imputed to the parent agency: for example, while the ACUS Report did not identify any AI use cases by DOC at the department level, DOC was marked as having known AI use cases in the parent-level assessment because its sub-agencies had known AI use cases.

(ii) A parent-level measure is generally a more conservative measurement because it significantly reduces the number of small agencies assessed for compliance.

C.2 Summary of Findings

Table 8 provides results on the filing of AI use case inventories for large, parent-level agencies that had a known use case as of 2019. The ACUS AI Report is the best available public resource for comparing the likely agencies with AI use cases. We emphasize that the difficulty of searching for and verifying agency uses of AI against the Trustworthy AI Order's requirements is precisely why disclosure is important—and, indeed, why it would be valuable even for agencies to post empty inventories so the public is made aware that the agency believes it does not have any use cases that require disclosure.

Use of the ACUS AI Report involves several nuances. First, some of the 142 agencies examined in the Report were not relevant for the use case inventory requirement given that many were either independent regulatory agencies (exempted by the terms of the Trustworthy AI Order) or no longer functional. Second, the ACUS AI Report's definition of AI deviates in small ways from the Trustworthy AI Order's definition, although the latter appears to be broader.[48]

[43] The ACUS AI Report team identified 157 use cases across 64 agencies, representing around 45% of the agencies that the team canvassed.See [102, pp. 15-16]. However, some of these agencies were not included in our original 220 agencies assessed. For example, the ACUS AI Report identifies multiple AI use cases at the Securities and Exchange Commission, however the SEC is excluded from the Trustworthy AI Order as it is an independent regulatory agency under 35 U.S.C. § 3502(5). Therefore our final number of agencies with AI use cases is 49 instead of 64.

[44] The third column of the Full Tracker, presented in Appendix E.3 marks as "Yes" only agencies for which the ACUS AI Report Team found an AI use case within the scope of the report. Agencies marked as "No" did not have a use case that the ACUS AI Report identified. Agencies marked "N/A" were excluded from this subset because they were not "large" agencies as defined by the ACUS AI Report.

[45] The only exception was NIST's inventory, which was published separately from that of its parent agency (the Department of Commerce).

[46] For example, the Department of the Interior's AI use case inventory discloses a U.S. Geological Survey (USGS) AI use case that was "[f]unded by the Federal Highway Administration"' (FHWA), a sub-agency of the Department of Transportation, not the Department of the Interior. Despite this mention in INT's inventory, we did not mark FHWA as having an inventory because there were no FHWA use cases disclosed in DOT's inventory. The mention of FHWA in the INT inventory is an indicator of the thoroughness of USGS but cannot be assumed to indicate FHWA prepared an AI use case inventory. Similarly, that USGS disclosed in the INT inventory use cases that are a collaboration with other INT sub-agencies (namely, Fish and Wildlife Services and the Bureau of Ocean Energy Management) does not necessarily indicate that those other agencies participated in the preparation of an inventory. In contrast, because the INT inventory disclosed a non-zero number of use cases by USGS (55), we mark USGS as having an inventory.

[47] DOJ's other two use cases were by the Justice Management Division and the Tax Division, which were not sub-agencies within our search criteria.

[48] As noted above, the Trustworthy AI Order incorporates the FY2019 NDAA's definition of AI "as a reference point," but it anticipates that definition will be updated by subsequent OMB guidance. See [25], Section 9(a). The CIO's 2021 guidance did not displace the NDAA's definition; instead, it stated that agencies "shall assess their use of AI and include criteria that aligns with the definition of AI as described in section 238(g) of the National Defense Authorization Act" [75]. That definition, in full, explains that AI means:[8]

(1) Any artificial system that performs tasks under varying and unpredictable circumstances without significant human oversight, or that can learn from experience and improve performance when exposed to datasets.

(2) An artificial system developed in computer software, physical hardware, or other context that solves tasks requiring human-like perception, cognition, planning, learning, communication, or physical action.

Third, the Report included anticipated uses of AI, whereas these have a more ambiguous treatment under the order: The order indicated that AI inventories should include "current and planned uses" in Section 5(b), but it also stated in Section 9(d)(iii) that it only applied to "existing and new uses of AI" and excluded "AI research and development (R&D) activities." That said, agencies that have filed AI use case inventories have commonly included use cases of AI that are under development. Fourth, the Report team searched for AI use from January to August 2019 (see [102, pp. 15-16]), and such use cases may not be operational today. If anything, however, we would expect machine learning to have been more widely adopted over the past three years.

To address these concerns, we double-checked the 23 parent agencies' identified use cases against the Trustworthy AI Order's definition and assessed whether those use cases were still plausibly in use today. When unclear, we identify additional and current use cases that would fall under the Trustworthy AI Order's inventory obligation.[49] In two instances, it is less clear whether agencies have active use cases.[50] Regardless of specific agency use cases, what this demonstrates is substantial inconsistency in how agencies have implemented the requirement.

Some of these use cases both touch on core agency functionalities and have been the subject of public disclosure. Beyond CBP's TVS discussed above, we describe two further examples. First, the Internal Revenue Service's Return Review Program (RRP) uses "cutting-edge machine-learning technologies to detect, resolve, and prevent criminal and civil tax refund fraud and noncompliance" [51, 113]. While the IRS has published a privacy impact assessment stating the general purpose and data used by RRP [15], and the system has been critiqued by oversight agencies [2–4, 21], the IRS did not disclose this use case because neither it nor its parent agency published an AI use case inventory. Second, the Social Security Administration (SSA) uses an Anti-Fraud Enterprise System (AFES), an "industry-proven predictive analytics software to identify high-risk transactions for further review" [5, 42]. While SSA does not seem to have fully implemented AFES, it has published a privacy impact assessment for the initiative [6] but did not include it in its AI use case inventory [76].

Use case inventories also vary in terms of the information they provide for each listed AI use case. We highlight here examples of when inventories report performance benchmarks or other methodological details that would bear on the trustworthiness of their AI use cases. For example, one of the use cases by the U.S. Citizenship and Immigration Services (USCIS)—labeled "BET/FBI Fingerprint Success Maximization"—includes a statement estimating its efficacy but also its costs, noting a model could "catch 98% of rejected submissions" and potentially have saved "42,763 additional appointments in 2020" at cost of "forcing recapture during 11% of encounters" [43]. More attention needs to be paid to evaluation and performance assessments to enable the public, Congress, and other oversight bodies to assess the benefits and drawbacks of the use of AI.

The Department of Labor's use case with narratives about work-related injuries and illnesses from the Survey of Occupational Injuries and Illnesses also illustrates the value of transparency regarding model development. There, employees manually classified qualitative answers to the survey into six categories, and then machine-learning algorithms were adopted to code the surveys using those labeled data as a training set. As detailed in its use case inventory, "[u]se of these autocoders subsequently expanded and coded 85% of all SOII elements for reference year (RY) 2019. This gradual increase occurred by adapting the selection criterion based on careful monitoring of the processes. This monitoring allowed the coding to expand to all six elements coded (occupation, nature, part, event, source, secondary source)" [65]. While the agency has not provided measures of time saved or accuracy, it has provided laudable details about the development process.

By contrast, the FBI's Threat Intake Processing System (TIPS), which is described as using "artificial intelligence (AI) algorithms to accurately identify, prioritize, and process actionable tips,"[61] provides less insight on evaluation. The FBI noted that it can "conduct ongoing testing on the code" and "monitor and/or audit performance," but it provides no other detail on development of performance measures.[51]

Finally, we note that the implementation rate of the AI use case inventories is higher when focusing on the agencies enumerated in the CFO Act of 1990[52] or that are members of the CIO Council.[53]

(3) An artificial system designed to think or act like a human, including cognitive architectures and neural networks.
(4) A set of techniques, including machine learning, that is designed to approximate a cognitive task.
(5) An artificial system designed to act rationally, including an intelligent software agent or embodied robot that achieves goals using perception, planning, reasoning, learning, communicating, decision-making, and acting.

In contrast, the ACUS AI Report provides the following discussion of its scope:([102, p. 12])

> By "artificial intelligence," we limit our scope to the most recent forms of machine learning, which train models to learn from data. These include a range of methods (e.g., neural networks, random forests) capable of recognizing patterns in a range of types of data (e.g., numbers, text, image)—feats of recognition that, if undertaken by humans, would be generally understood to require intelligence. . . . Conceptually, AI includes a range of analytical techniques, such as rule-based or 'expert' symbolic systems, but we limit our focus to forms of machine learning. Our scope also excludes conventional forms of statistical inference (e.g., focused on causal, as opposed to predictive, inference) and forms of process automation that do not involve machine learning (e.g., an online case management system).

[49] For DOED, see [126]; for HUD, see [110]; and for SBA, see [140].

[50] EEOC's use of AI was only obliquely mentioned in public documentation, preventing a thorough assessment of whether the AI use should be disclosed under the executive order. The original use case cited in the ACUS AI Report was derived from a recommendation about potential improvements to EEOC's "data analysis and predictive analytics activities," including "text analytics." See [102, pp. 30–31]. Other documentation suggests that EEOC's staff should be trained in the use of AI [7]. And USITC's use case posed boundary questions about whether the AI use was merely for R&D versus for future operations.

[51] By the terms of the Trustworthy AI Order, agencies must report only "non-classified and non-sensitive use cases of AI" in their inventories, and publication should be "to the extent practicable" in light of, among other things, potential "sensitive law enforcement" information. See [25], Section 5(a), (e). Although providing information about TIPS presumably raises concerns about sensitive law enforcement decisions, we emphasize each agency's obligation to balance these concerns with the imperative of transparency, especially given that prioritization of law enforcement resources is shaped by the AI use case.

[52] The 24 agencies listed in the CFO Act include USDA, DOC, DOED, DOE, HHS, DHS, HUD, DOJ, DOL, STAT, INT, TRS, DOT, DVA, EPA, GSA, NASA, NSF, OPM, SBA, SSA, and USAID. DOD and the NRC were excluded based on the scope of the Trustworthy AI Order, such that 22 agencies were relevant.

[53] These agencies include USDA, DOC, DOED, DOE, HHS, DHS, HUD, DOJ, DOL, STAT, INT, TRS, DOT, DVA, EPA, GSA, NASA, NARA, NSF, OMB, OPM, SBA, SSA, and USAID.[20] Based on the scope of the Trustworthy AI Order, we excluded the Intelligence Community, NRC, and various defense-related agencies.

Table 8: Inventory Implementation of Large, Parent-level Agencies with Known AI Use Cases

Parent-level Executive Agency	Inventory
Department of Commerce (DOC)	Yes
Department of Education (DOED)	No
Department of Health and Human Services (HHS)	Yes
Department of Homeland Security (DHS)	Yes
Department of Housing and Urban Development (HUD)	No (public disclosure of no use cases[a])
Department of Justice (DOJ)	Yes
Department of Labor (DOL)	Yes
Department of the Interior (INT)	Yes
Department of the Treasury (TRS)	No
Department of Transportation (DOT)	Yes
Department of Veterans Affairs (DVA)	Yes
Environmental Protection Agency (EPA)	Yes
Equal Employment Opportunity Commission (EEOC)	No
General Services Administration (GSA)	No
Legal Services Corporation (LSC)	No
National Aeronautics and Space Administration (NASA)	Yes
National Archives and Records Administration (NARA)	No
Railroad Retirement Board (RRB)	No
Small Business Administration (SBA)	No
Social Security Administration (SSA)	Yes[b]
United States Department of Agriculture (USDA)	Yes
United States International Trade Commission (USITC)	No
United States Postal Service (USPS)	No

[a]Agencies that disclosed no use cases in their inventories were generally marked as "compliant." However, we have marked HUD as non-compliant only for the "known AI use cases" measure, given strong evidence that it has AI use cases.
[b]SSA only identified five AI use cases.[76]

The number of CFO Act agencies that have published an inventory or a public disclosure of no relevant AI use cases is 17 (77%). The number of CIO Council member agencies that published an inventory or disclosed no use cases is 71%. Although the ACUS AI Report casts doubt on HUD's public disclosure that it has no AI use cases, we mark it as having implemented an inventory for these calculations. The relatively higher implementation rate for these agencies may illustrate that the CIO Council faces challenges in ensuring agencies not directly involved with the Council prepare and publish an AI use case inventory. Regardless, neither the Trustworthy AI Order nor the CIO's implementing guidance limited the scope of relevant agencies to those enumerated by the CFO Act or involved with the CIO Council.

D PRE- AND POST-WHITE PAPER AI USE CASE INVENTORY TRACKER

Figure 1 details the differences in compliance with the AI use case inventory requirement before and after the publication of our white paper (see [120]) for large, parent-level agencies with known AI use cases. The right-most column is updated through July 3, 2023. The grey row includes the total number of agencies that meet the criteria for each column. The figure excludes some agencies subject to the Chief Financial Officers Act because they are independent regulatory agencies exempted from the requirement for an AI use case inventory. Compare this figure to Table 8. HUD, SBA, and USITC are marked as non-compliant because there is strong evidence that these agencies have AI use cases.

Large, Parent-level Agency	CFO Act Agency	Known AI Use Cases (Table 1, White Paper)	Agency Inventory (White Paper)	Agency Inventory (after publication)
	22	22	15	23
Department of Agriculture	✓		Yes	Yes
Department of Commerce (DOC)	✓	✓	Yes	Yes
Department of Education (DOED)	✓	✓	No	Yes
Department of Energy (DOE)	✓		Yes	Yes
Department of Health and Human Services (HHS)	✓	✓	Yes	Yes
Department of Homeland Security (DHS)	✓	✓	Yes	Yes
Department of Housing and Urban Development (HUD)	✓	✓	Yes (but disclosed no use cases)	Yes (but disclosed no use cases)
Department of Interior (INT)	✓	✓	No	Yes
Department of Justice (DOJ)	✓	✓	Yes	Yes
Department of Labor (DOL)	✓	✓	Yes	Yes
Department of State (STAT)	✓		Yes	Yes
Department of Transportation (DOT)	✓	✓	No	Yes
Department of the Treasury (TRS)	✓	✓	No	Yes
Department of Veterans Affairs (DVA)	✓	✓	Yes	Yes
Environmental Protection Agency (EPA)	✓	✓	Yes	Yes
Equal Employment Opportunity Commission (EEOC)		✓	No	No
General Services Administration (GSA)	✓	✓	No	Yes
Legal Services Corporation (LSC)		✓	No	No
National Archives and Records Administration (NARA)		✓	No	No
National Aeronautics and Space Administration (NASA)	✓	✓	Yes	Yes
National Science Foundation (NSF)	✓		Yes (but disclosed no use cases)	Yes (but disclosed no use cases)
Office of Personnel Management (OPM)	✓		No	Yes
Railroad Retirement Board (RRB)		✓	No	No
Small Business Administration (SBA)	✓	✓	No	Yes (but disclosed no use cases)
Social Security Administration (SSA)	✓	✓	Yes	Yes
United States Agency for International Development (USAID)	✓		Yes	Yes
U.S. International Trade Commission (USITC)		✓	No	Yes (but disclosed no use cases)
U.S. Postal Service (USPS)		✓	No	No

Figure 1: Inventory Implementation of Large, Parent-level Agencies with Known AI Use Cases Before White Paper Publication versus After (as of July 3, 2023)

E FULL TRACKER

E.1 Line-Level Requirements Tracker

Section	Responsible Stakeholder	Summary of Requirement	Deadline	Type of Requirement	Status of Implementation
EO 13859 - Maintaining American Leadership in Artificial Intelligence 84 Federal Register 3967, February 11, 2019, https://www.federalregister.gov/documents/2019/02/14/2019-02544/maintaining-american-leadership-in-artificial-intelligence					
Sect. 2(a)-(e)	Implementing Agencies (see "Key Information" box)	"[S]hall pursue six strategic objectives in furtherance of both promoting and protecting American advancements in AI: (a) Promote sustained investment in AI R&D in collaboration with industry, academia, international partners and allies, and other non-Federal entities to generate technological breakthroughs in AI and related technologies and to rapidly transition those breakthroughs into capabilities that contribute to our economic and national security. (b) Enhance access to high quality and fully traceable Federal data, models, and computing resources, while maintaining safety, security, privacy, and confidentiality protections consistent with applicable laws and policies. (c) Reduce barriers to the use of AI technologies to promote their innovative application while protecting American technology, economic and national security, civil liberties, privacy, and values. (d) Ensure that technical standards minimize vulnerability to attacks from malicious actors and reflect Federal priorites for innovation, public trust, and public confidence in systems that use AI technologies; and develop international standards to promote and protect these priorities. (e) Train the next generation of American AI researchers and users through apprenticeships; skills programs; and education in science, technology, engineering, and mathematics (STEM), with an emphasis on computer science, to ensure that American workers, including Federal workers, are capable of taking full advantage of the opportunities of AI."	None	Ongoing requirement	Not known because this is ongoing requirement without mandated outcomes to assess and therefore requires continued implementation
Sect. 2(f)	Implementing Agencies	"Develop and implement an action plan, in accordance with the National Security Presidential Memorandum of February 11, 2019 (Protecting the United States Advantage in Artificial Intelligence and Related Critical Technologies) (the NSPM) to protect the advantage of the United States in AI and technology critical to United States economic and national security interests against strategic competitors and foreign adversaries."	None	Open-ended requirement	This requirement is expanded upon in section 8 of the executive order. See requirement for section 8(c) below.

Figure 2: Line-Level Implementation Tracker, AI Leadership Order (E.O. 13859) (1 of 7)

Sect. 4(a)	Heads of AI R&D agencies (see "Key Information" box)	"[S]hall consider AI as an agency R&D priority" and "take this priority into account when developing budget proposals and planning for the use of funds in Fiscal Year 2020 and in future years." "[S]hall also consider appropriate administrative actions to increase focus on AI for 2019."	None	Ongoing requirement	Indications of sustained implementation on this ongoing requirement The National Artificial Intelligence Research and Development Strategic Plan: 2019 Update, published by the NSTC Select Committee on AI in June 2019, "highlights the key priorities for Federal investment in AI R&D" as a response to EO 13859's directive and to support the American AI initiative. The 2016 - 2019 Progress Report: Advancing Artificial Intelligence R&D, published in November 2019 by NITRD and the Select Committee, "document[s] the Nation's progress in meeting the aims of the *National Artificial Intelligence Research and Development Strategic Plan: 2019 Update*."
Sect. 4(b)-(b)(i)	Heads of AI R&D agencies	"[S]hall budget an amount of AI R&D that is appropriate for this prioritization" and after the submission of President's Budget request for Congress, "shall communicate plans for achieving this prioritization to the OMB Director and the OSTP Director each fiscal year through the Networking and Information Technology Research and Development (NITRD) Program."	None	Ongoing requirement	Indications of sustained implementation for this ongoing requirement (see below status for Sect. 4(b)(ii))
Sect. 4(b)(ii)	Heads of AI R&D agencies	"[S]hall identify each year, consistent with applicable law, the programs to which the AI R&D priority will apply and estimate the total amount of such funds that will be spent on each program. This information shall be communicated to the OMB Director and OSTP Director each fiscal year through the NITRD Program."	Annually within 90 days of enactment of appropriations for an agency	Ongoing requirement	Indications of sustained implementation for this ongoing requirement The Networking & Information Technology Research & Development (NITRD) Program's Supplement to the President's FY2020 Budget reported, for the first time, the federal investments in AI for FYs 2018-2020. It also described "key programs and coordination activities" for FY2020. The 2016 - 2019 Progress Report: Advancing Artificial Intelligence R&D, although not exhaustive, also details agency AI R&D activities and how they fit within the national AI R&D priorities. Launched on August 14, 2020, and as required by the National AI Initiative Act of 2020, NITRD's AI R&D dashboard tracks nondefense AI R&D investments by agency, by program component areas, and overall. Agencies AI R&D budgets, estimates, and activities were also published in the NITRD Supplement to the President's FY2021 Budget and the NITRD and the National AI Initiative Office Supplement to the President's FY2022 Budget.
Sect. 4(c)	Heads of AI R&D agencies	"[S]hall explore opportunities for collaboration with non-Federal entities, including: the private sector; academia; non-profit organizations; State, local, tribal, and territorial governments; and foreign partners and allies, so all collaborators can benefit from each other's investment and expertise in AI R&D."	None	Ongoing requirement	Not known as this is an ongoing requirement without mandated outcomes to assess

Figure 3: Line-Level Implementation Tracker, AI Leadership Order (E.O. 13859) (2 of 7)

Sect. 5(a)	Head of all agencies	"[R]eview their Federal data and models to identify opportunities to increase access and use by the greater non-Federal AI research community in a manner that benefits that community, while protecting safety, security, privacy, and confidentiality. Specifically, agencies shall improve data and model inventory documentation to enable discovery and usability, and shall prioritize improvements to access and quality of AI data and models based on the AI research community's user feedback."	None	Open-ended requirement	Not known as no mandated public reporting on status The National AI Initiative Office has a page on Data Resources in its AI Researchers Portal that provides links to seven "quality Federal datasets that are useful for AI research." Completion of requirement likely hindered by the OMB's lack of compliance with its statutory requirements under the OPEN Government Data Act to issue guidance on making data open and establishing data inventories (see below status for Sect. 5(a)(i) on investigating barriers to access or quality limitations of Federal data).**
Sect. 5(a)(i)	OMB Director	To "help identify datasets that will facilitate non-Federal AI R&D and testing, "the OMB Director shall publish a notice in the Federal Register inviting the public to identify additional requests for access or quality improvements for Federal data and models that would improve AI R&D and testing."	Within 90 days of EO	Time-boxed requirement	Implemented - Notice of request for information: Identifying Priority Access or Quality Improvements for Federal data and models for Artificial Intelligence Research and Development (R&D), and Testing (July 10, 2019 - about two months after deadline)
Sect. 5(a)(i)	OMB Director with Select Committee on AI	To "help identify datasets that will facilitate non-Federal AI R&D and testing"... "shall investigate barriers to access or quality limitations of Federal data and models that impede AI R&D and testing."	Within 90 days of EO	Time-boxed requirement	Implemented - The Federal Data Strategy 2020 Action Plan, in Action 8: Improve Data and Model Resources for AI Research and Development, details the Federal Government's plan to achieve this directive, noting that that this dirctive will be completed once the OMB publishes an RFI (which was completed, see above status update). The 2020 Action Plan tracker marks this milestone as complete on August 2019, when OMB published and required comments for its RFI (see above status update). It further notes: "The RFI received 28 comments. The ability to preserve a respondent's privacy was the largest barrier identified and there were also many comments requesting more high quality and curated open data, including requests for data cleaning, normalized fields, and metadata improvements that would facilitate fitness for use and provenance tracking." However, the Federal Data Strategy 2020 Action Plan also notes that the Federal government will "address[] identified barriers by updating Federal data and source code inventory guidance for agencies to utilize in enhancing the discovery and usability of Federal data and models in AI R&D." (see below status update on Sect. 5(a)(ii)).

**Despite the lack of guidance for Phase II: Open Data Access and Management, some agencies (e.g., the Department of Justice, AmeriCorp) had begun publishing their data inventories. *See* GAO-22-104574, OPEN DATA: Additional Action Required for Full Public Access (December 2021). OMB M-21-06 also refers agencies, pursuant to section 5 of the EO, to follow additional OMB guidance "regarding discovery and usability of Federal data and models for non-Federal use."

Figure 4: Line-Level Implementation Tracker, AI Leadership Order (E.O. 13859) (3 of 7)

Sect. 5(a)(ii)	OMB with its interagency councils and NSTC Select Committee on AI	"[S]hall update implementation guidance for Enterprise Data inventories and Source Code Inventories to support discovery and usability in AI R&D."	Within 120 days of EO	Time-boxed requirement	Not known as no mandated public reporting on status (expected completion ~June 2019) A document entitled Implementation Guidance to Federal Agencies Regarding Enterprise Data and Source Code Inventories (although the document cannot be identified through a search of code.gov). However, an official statements about this document or its release is not readily available through an online search, nor is the document explicitly linked to the OMB. Similarly, an overview of OMB Guidance on IT authorities that is maintained by the Federal Chief Information Officiers Council (CIO Council) does not mention any guidance published in 2019 or 2020 that would fit this description (only notes a 2016 OMB Memorandum on source code guidance (OMB M-16-21)). (see https://www.cio.gov/handbook/cio-responsibilities/it-leadership-and-accountability/agency-it-authorities-omb-guidance/). Given these facts and the language in the document ("While feedback from the public is pending, an initial report has been completed with the input from various agencies to identify known barriers."), this Guidance does not appear to be final. Additionally, the Federal Data Strategy 2020 Action Plan, in Action 8: Improve Data and Model Resources for AI Research and Development, notes that OMB would "provide technical schema formats on inventories" to agencies by December 31, 2020. However the 2020 Action Plan tracker marks this milestone as still pending OMB Open Data Plan Guidance, which the GAO's tracker associated with its December 2021 report (GAO-22-104574, OPEN DATA: Additional Action Required for Full Public Access) notes that "[i]n March 2022, OMB staff told us that action to implement this recommendation is in progress, but they have not determined a time frame for issuing the guidance." This guidance has still not been published, with the CDO Council's April 2022 Enterprise Data Inventories report noting that the guidance was forthcoming. See 1.1.4 Agency IT Authorities – OMB Guidance, also, GAO's October report GAO-21-29, Open Data - Agencies Need Guidance to Establish Comprehensive Data Inventories; Information on Their Progress is Limited.

Figure 5: Line-Level Implementation Tracker, AI Leadership Order (E.O. 13859) (4 of 7)

Sect. 5(a)(iii)	Agencies	"[I]n accordance with the implementation of the Cross-Agency Priority Goal: Leveraging Federal Data as a Strategic Asset, from the March 2018 President's Management Agenda," "shall consider methods to improve the quality, usability, and appropriate access to priority data by the AI research community" and "identify associated resource implications."	Within 180 days of EO	Time-boxed requirement	Not known as no mandated public reporting on status (expected completion ~August 2019) The document entitled Implementation Guidance to Federal Agencies Regarding Enterprise Data and Source Code Inventories recommends practices for agencies to improve the quality, usability, and access to priority data for AI R&D, noting that doins so "is also consistent with the Cross Agency Priority Goal #2 of the President's Management Agenda which is leveraging data as a strategic asset." However, it is not known if this is final guidance (see above status update on Sect. 5(a)(ii)). Compliance by individual agencies is not known. The Federal Data Stratgy 2021 Action Plan, in Action 5. Public Agency Open Data Plans, also marks as a milestone that each agency will "Publish an Open Data Plan that identifies specific priority data assets, including assets that support COVID-19 response and AI R&D." These plans will be reported through agency Information Resource Management (IRM) Strategic Plans. Compliance across agencies is not known.
Sect. 5(a)(iv)	Agencies in coordination with the Senior Agency Officials for Privacy (EO 13719), heads of Federal statistical entities, Federal program managers and other relevant personnel	"In identifying data and models for consideration for increased public access,"..."shall identify any barriers to, or requirements associated with, increased access to and use of such data and models, including: privacy and civil liberty protections for individuals who may be affected by increased access and use. . . ;" "safety and security concerns. . .;" "data documentation and formatting. . . ;" "changes necessary to ensure appropriate data and system governance;" and "any other relevant considerations."	None	Open-ended requirement	Not known because no mandated public reporting on status
Sect. 5(a)(v)	Agencies	"In accordance with the President's Management Agenda and the Cross-Agency Priority Goal: Leveraging Data as a Strategic Asset. . . shall identify opportunities to use new technologies and best practices to increase access to and usability of open data and models, and explore appropriate controls on access to sensitive or restricted data and models, consistent with applicable laws and policies, privacy and confidentiality protections, and civil liberty protections."	None	Ongoing requirement	Not known because no mandated public reporting on status of ongoing requirement without mandated outcome
Sect. 5(b)	Secretaries of Defense, Commerce, Health and Human Services, and Energy; Administrator of NASA; Director of NSF	"[S]hall, to the extent appropriate and consistent with applicable law, prioritize the allocation of high-performance computing resources for AI-related applications through: (i) increased assignment of discretionary allocation of resources and resource reserves; or (ii) any other appropriate mechanisms."	None	Ongoing requirement	Indications of implementation of ongoing requirement (note: no mandated outcomes to assess or mandated public reporting on status) The National AI Initiative Office's AI Researchers Portal includes Computer Resources overview. There are six "Federally-supported computing infrastructure resources that are useful for AI research."

Figure 6: Line-Level Implementation Tracker, AI Leadership Order (E.O. 13859) (5 of 7)

Sect. 5(c)	NSTC Select Committee on AI, in coordination with the GSA	"[S]hall submit a report to the President making recommendations on better enabling the use of cloud computing resources for federally funded AI R&D"	Within 180 days of EO	Time-boxed requirement	Implemented - The NSTC Select Committee on AI published Recommendations for Leveraging Cloud Computing Resources for Federally Funded Artificial Intelligence Research and Development (November 17, 2020 - about sixteen months after expected completion). In July 2022, the NSTC Select Committee published Lessons Learned from Federal Use of Cloud Computing to Support Artificial Intelligence Research and Development.
Sect. 5(d)	NSTC Select Committee on AI	"[S]hall provide technical expertise to the American Technology Council on matters regarding AI and the modernization of Federal technology, data, and the delivery of digital services, as appropriate."	None	Ongoing requirement	Not known because no mandated public reporting on status of ongoing requirement without mandated outcome
Sect. 6(a)-(b)	OMB Director in coordination with OSTP Director, Director of Domestic Policy Council, and Director of NEC, and in consultation with other relevant agencies and stakeholders	"[S]hall issue a memorandum to the heads of all agencies that shall: (i) inform the development of regulatory and non-regulatory approaches by such agencies regarding technologies and industrial sectors that are either empowered or enabled by AI, and that advance American innovation while upholding civil liberties, privacy, and American values; and (ii) consider ways to reduce barriers to the use of AI technologies in order to promote their innovative application while protecting civil liberties, privacy, American values, and United States economic and national security." OMB shall issue a draft version for public comment before memorandum is finalized.	Within 180 days of EO	Time-boxed requirement	Implemented - Request for Comments on a Draft Memorandum to the Heads of Executive Departments and Agencies, "Guidance for Regulation of Artificial Intelligence Applications" was published Janaury 1, 2020 on the Federal Register for public comment - OMB M-21-06, Guidance for Regulation of Artificial Intelligence Applications was published November 17, 2020 (memorandum was supposed to be published around August 2019)
Sect. 6(c)	Heads of implementing agencies "that also have regulatory authorities"	"[S]hall review authorities and submit to OMB plans to achieve consistency with OMB memorandum described in subsection 6(a)," which became OMB M-21-06	Within 180 days of OMB memoran-dum	Time-boxed requirement	Not Implemented (expected ~May 2021) See Section III and Appendix B
Sect. 6(d)	Secretary of Commerce through the NIST Director, with participation from relevant agencies (determined by the Secretary of Commerce)	"[S]hall issue a plan for Federal engagement in the development of technical standards and related tools in support of reliable, robust, and trustworthy systems that use AI technologies." Plan should be consistent with OMB Circular A-119 and include "(A) Federal priority needs for standardization...; (B) identification of standards development entities in which Federal agencies should seek membership with the goal of establishing or supporting United States technical leadership roles; and (C) opportunities for and challenges to United States leadership in standardization related to AI technologies." The NSTC Select Committee on AI, private sector, academia, non-governmental entities, and other stakeholders shoudl also be consulted, as needed.	Within 180 days of EO	Time-boxed requirement	Implemented - NIST published A Plan for Federal Engagement in Developing AI Technical Standards and Related Tools in August 2019 (on time). To develop the report, NIST also consulted the public and private sector, including through a May 2019 workshop and opportunities for public comment.

Figure 7: Line-Level Implementation Tracker, AI Leadership Order (E.O. 13859) (6 of 7)

Sect. 7(a)(i)-(ii)	Heads of implementing agencies "that also provide educational grants"	"[S]hall, to the extent consistent with applicable law, consider AI as a priority area within existing Federal fellowship and service programs," including programs focused on high school, undergraduate, and graduate fellowships, alternative education and training, that support early-career university faculty who conduct AI R&D, "scholarship for service programs," "direct commissioning programs of the United States Armed Forces," and "programs that support the development of instructional programs and curricula that encourage the integration of AI technologies into courses. . ." These agencies "shall annually communicate plans for achieving this prioritization to the co-chairs of the [NSTC] Select Committee [on AI]."	Annually	Ongoing requirement	Not known because no mandated public reporting on status
Sect. 7(b)	NSTC Select Committee on AI	"[S]hall provide recommendations to NSTC Committee on STEM Education regarding AI-related educational and workforce development considerations that focus on American citizens."	Within 90 days of EO	Time-boxed requirement	Not known because no mandated public reporting on statuts (expected completion ~May 2019)
Sect. 7(c)	NSTC Select Committee on AI	"[S]hall provide technical expertise to the National Council for the American Worker on matters regarding AI and the American workforce, as appropriate."	None	Ongoing requirement	Not known because no mandated public reporting on status of ongoing requirement without mandated outcome
Sect. 8(a)-(b)	Assistant to the President for National Security Affairs, in coordination with OSTP Director and recipients of the NSPM (Sect. 2(f))	"[S]hall organize the development of," and submit to the President for approval, "an action plan to protect the United States advantage in AI and AI technology critical to United States economic and national security interests against strategic competitors and adversarial nations." Note: The action plan "may be classified in full or in part, as appropriate."	Within 120 days of EO	Time-boxed requirement	Not known because no mandated public reporting on status (expected completion ~June 2019); however, there are indications that the National Security Presidential Memorandum may not itself have been issued. The Federation of American Scientists (FAS) tracks National Security Presidential Memorandums (NSPMs), Presidential Policy Directives (PPDs), and Presidential Study Directives (PSDs). It's tracking of the Trump Administration (https://irp.fas.org/offdocs/nspm/index.html) notes that this directive was not fulfilled. Similarly, the Biden Aministration has not issues a related National Security Memoranda (NSM), to the public's knowledge (https://irp.fas.org/offdocs/nsm/index.html).
Sect. 8(c)	Agencies who are recipients of the Action Plan (Sect. 8(a))	Implement the action plan as described in subsection 8(a)-(b)	Within 120 days of EO	Time-boxed requirement	Not known because no mandated public reporting on status (expected completion ~June 2019)

Figure 8: Line-Level Implementation Tracker, AI Leadership Order (E.O. 13859) (7 of 7)

EO 13960 - Promoting the Use of Trustworthy Artificial Intelligence in the Federal Government 5 Federal Register 78939, December 8, 2020, https://www.federalregister.gov/documents/2020/12/08/2020-27065/promoting-the-use-of-trustworthy-artificial-intelligence-in-the-federal-government					
Sect. 2(b)	Agencies (defined by 44 U.S.C. 3502(1), excluding independent regulatory agencies as defined by 3502(5)); excluding the Department of Defense and agencies wholly within the Intelligence Community (see Sect. 8)	"It is the policy of the United States that responsible agencies, as defined in section 8 of this order, shall, when considering the design, development, acquisition, and use of AI in Government, be guided by the common set of Principles set forth in section 3 of this order, which are designed to foster public trust and confidence in the use of AI, protect our Nation's values, and ensure that the use of AI remains consistent with all applicable laws, including those related to privacy, civil rights, and civil liberties."	None	Ongoing requirement	Not known because no mandated public reporting on status of ongoing requirement Example agency documents that indicate implementation: - NASA's Responsible AI Plan (2022) - USAID Artificial Intelligence Action Plan (2022) - HHS Artificial Intelligence (AI) Strategy (2021) - DHS S&T Artificial Intelligence & Machine Learning Strategic Plan (2021)
Sect. 4(a)	OMB; agencies	"To the extent" existing OMB policies that "currently address many aspect of information and information technology design, development, acquisition, and use. . . are consistent with the Principles set forth in this order and applicable law, these existing policies shall continue to apply to relevant aspects of AI use in Government."	None	Ongoing requirement	Not known because no mandated public reporting on status of ongoing requirement without mandated outcome
Sect. 4(b)	OMB Director, in coordination with key stakeholders (defined by Director)	"[S]hall publicly post a roadmap for the policy guidance that OMB intends to create or revise to better support the use of AI, consistent with this order. This roadmap shall include, where appropriate, a schedule for engaging with the public and timelines for finalizing relevant policy guidance. In addressing novel aspects of the use of AI in Government, OMB shall consider updates to the breadth of its policy guidance, including OMB Circulars and Management Memoranda."	Within 180 days of EO	Time-boxed requirement	Not Implemented (expected ~June 2021) The 2021 Federal Data Strategy Action Plan, in Action 7. Artificial Intelligence and Automation, does indicate four milestones, such as making an Algorithmic Assessment Tool publicly available for agency use and coordinating the AI use case inventories, with associated target dates. However, it does not mention policy guidance documents like Management Memorandum or OMB Circulars.
Sect. 4(c)	Agencies; OMB	"[S]hall continue to use voluntary consensus standards developed with industry participation, where available, when such use would not be inconsistent with applicable law or otherwise impracticable. Such standards shall also be taken into consideration by OMB when revising or developing AI guidance."	None	Ongoing requirement	Not known because no mandated public reporting on status of ongoing requirement without mandated outcome

Figure 9: Line-Level Implementation Tracker, Trustworthy AI Order (E.O. 13960) (1 of 3)

Sect. 5(a)	Federal Chief Information Officers Council (CIO Council) in coordination with other interagency bodies (as determined by CIO Council)	"[S]hall identify, provide guidance on, and make publicly available the criteria, format, and mechanisms for agency inventories of non-classified and non-sensitive use cases of AI by agencies"	Within 60 days of EO	Time-boxed requirement	Implemented - CIO Council maintains an overview of this directive and the implementation guidance on its website. In fall 2021, the CIO Council published 2021 Guidance for Creating Agency Inventories for AI Use Case, in addition to a FAQ document, Example AI Use Case Inventory Scenarios, and a template for agencies to use for creating their inventory.
Sect. 5(b)	Agencies (see Sect. 2(b) Responsible Stakeholder)	"[S]hall prepare an inventory of its non-classified and non-sensitive use cases of AI, within the scope defined by section 9 of this order, including current and planned uses, consistent with the agency's mission."	Within 180 days of CIO Council's issuance of guidance (see Sect. 5(a)); annually thereafter	Time-boxed requirement	Not known because no mandated reporting on status separate from Sect. 5(e) / see below status on Sect. 5(c)-(e)
Sect. 5(c)	Agencies (see Sect. 2(b) Responsible Stakeholder)	"As part of their respective inventories of AI use cases, agencies shall identify, review, and assess existing AI deployed and operating in support of agency missions for any inconsistencies with this order."	None	Open-ended requirement	Not known because no mandated public reporting on status separate from Sect. 5(e) / See below status on Sect. 5(c)(i) and 5(c)(ii)
Sect. 5(c)(i)	Agencies (see Sect. 2(b) Responsible Stakeholder)	"[S]hall develop plans either to achieve consistency with this order for each AI application or to retire AI applications found to be developed or used in a manner that is not consistent with this order." "These plans must be approved by the agency-designated responsible official(s), as described in section 8 of this order, within this same 120-day time period."	Within 120 days of completing AI inventory	Time-boxed requirement	Not known because no mandated public reporting (expected completion ~July 2022)
Sect. 5(c)(ii)	Agencies (see Sect. 2(b) Responsible Stakeholder)	"[S]trive to implement the approved plans. . . subject to existing resource levels" and "in coordiantion with the Agency Data Governance Body and relevant officials from agencies"	Within 180 days of plan approval	Time-boxed requirement	Not implemented, but not past deadline
Sect. 5(d)	Agencies (see Sect. 2(b) Responsible Stakeholder); CIO and CDO Councils	"[S]hall share their inventories with other agencies, to the extent practicable and consistent with applicable law and policy, including those concerning protection of privacy and of sensitive law enforcement, national security, and other protected information. This sharing shall be coordinated through the CIO and Chief Data Officer Councils. . . ."	Within 60 days of completing AI inventory	Time-boxed requirement	Not known because no mandated public reporting on status (expected completion ~May/June 2022)
Sect. 5(e)	Agencies (see Sect. 2(b) Responsible Stakeholder)	"[S]hall make their inventories available to the public, to the extent practicable and in accordance with applicable law and policy, including those concerning the protection of privacy and of sensitive law enforcement, national security, and other protected information."	Within 120 days of completing AI inventory	Time-boxed requirement	Not Implemented (expected ~July 2022) See Section IV and Appendix C NAIIO published 12 agencies' inventories to date

Figure 10: Line-Level Implementation Tracker, Trustworthy AI Order (E.O. 13960) (2 of 3)

Sect. 6	Agencies (see Sect. 2(b) Responsible Stakeholder)	"[A]re expected to participate in interagency bodies for the purpose of advancing the implementation of the Principles and the use of AI consistent with this order."	None	Ongoing requirement	Not known because no mandated outcome to assess for ongoing requirement
Sect. 6	CIO Council	"[S]hall publish a list of recommended interagency bodies and forums in which agencies may elect to participate, as appropriate and consistent with their respective authorities and missions" to fulfill the expectation that they participate in interagency bodies to advance the AI principles (see above requirement).	Within 45 days of EO	Time-boxed requirement	Not known because no mandated public reporting on status (expected completion ~February 2021)
Sect. 7(a)	Presidential Innovation Fellows (PIF) program (administed by GSA) in collaboration with other agencies	"[S]hall identify priority areas of expertise and establish an AI track to attract experts from industry and academia to undertake a period of work at an agency. These PIF experts will work within agencies to further the design, development, acquisition, and use of AI in Government, consistent with this order."	Within 90 days of EO	Time-boxed requirement	Implemented - Although the EO had not mandated public reporting on status, the 2022 PIF Application did have a "Data Strategy and AI" track. However, this ia an ongoing requirement for PIF Fellows.
Sect. 7(b)	OPM, in coordination with GSA and other relevant agencies	"[S]hall create inventory of Federal Government rotational programs and determine how these programs can be used to expand the number of employees with AI expertise."	Within 45 days of EO	Time-boxed requirement	Not known becuase no mandated public reporting on status (expected completion ~February 2021)
Sect. 7(c)	OPM	"[S]hall issue a report with recommendations for how the programs in the inventory can be best used to expand the number of employees with AI expertise at the agencies. This report shall be shared with the interagency coordination bodies identified pursuant to section 6 of this order, enabling agencies to better use these programs for the use of AI, consistent with this order."	Within 180 days of creating inventory pursuant to Sect. 7(b)	Time-boxed requirement	Not known because no mandated public reporting on status (expected completion ~August/September 2021), but 2022 Federal Workforce Priorities Report, published on May 10, 2022, does not include recommendations pursuant to this EO
Sect. 8(c)	Agencies (see Sect. 2(b) Responsible Stakeholder)	"[S]hall specify the responsible official(s) at that agency who will coordinate implementation of the Principles set forth in section 3 of this order with the Agency Data Governance Body and other relevant officials and will collaborate with the interagency coordination bodies identified pursuant to section 6 of this order."	Within 30 days of EO	Time-boxed requirement	Not known because no mandated public reporting on status (expected completion ~January 2021)

Figure 11: Line-Level Implementation Tracker, Trustworthy AI Order (E.O. 13960) (3 of 3)

AI in Government Act of 2020 In the Consolidated Appropriations Act, 2021 (P.L. 116-260) as Division U, Title I, December 27, 2020, https://www.congress.gov/116/plaws/publ260/PLAW-116publ260.pdf					
Sect. 103	GSA	Create an "AI Center of Excellence" within the GSA that shall "(1) facilitate the adoption of artificial intelligence technologies in the Federal Government; (2) improve cohesion and competency in the adoption and use of artificial intelligence within the Federal Government; and (3) carry out paragraphs (1) and (2) for the purposes of benefitting the public and enhancing the productivity and efficiency of Federal Government operations."	None	Open-ended requirement	Implemented - The Aritificial Intelligence Center of Excellence (CoE) provides a number of services (*see* AI Services Catalog) and published an "AI Guide for Government" that is "A living and evolving guide to the application of artificial intelligence for the U.S. federal government."
Sect. 103	GSA AI Center of Excellence	"The duties of the AI CoE shall include -- (1) regularly convening individuals from agencies, industry, Federal laboratories, nonprofit organizations, institutions of higher education, and other entities to discuss recent developments in artificial intelligence, including the dissemination of information regarding programs, pilots, and other initiatives at agencies, as well as recent trends and relevant information on the understanding, adoption, and use of artificial intelligence; (2) collecting, aggregating, and publishing on a publicly available website information regarding programs, pilots, and other initiatives led by other agencies and any other information determined appropriate by the Administrator; (3) advising the Administrator, the Director, and agencies on the acquisition and use of artificial intelligence through technical insight and expertise, as needed; (4) assist agencies in applying Federal policies regarding the management and use of data in applications of artificial intelligence; (5) consulting with agencies, including the Department of Defense, the Department of Commerce, the Department of Energy, the Department of Homeland Security, the Office of Management and Budget, the Office of the Director of National Intelligence, and the National Science Foundation, that operate programs, create standards and guidelines, or otherwise fund internal projects or coordinate between the public and private sectors relating to artificial intelligence; (6) advising the Director on developing policy related to the use of artificial intelligence by agencies; and (7) advising the Director of the Office of Science and Technology Policy on developing policy related to research and national investment in artificial intelligence."	None	Ongoing requirement	Not known because (1), (3), (4), (5), (6), and (7) are ongoing requirements without mandated outcomes to assess However, on (1), (3), (4), and (5), GSA has established a Community of Practice for AI that any federal employee can join to support "the practical implementation of responsible AI in the federal government" through a "monthly newsletter, events, and working groups." GSA also published in January 2022 an Artificial Intelligence Governance Toolkit that is intended to provide "agency leaders, privacy practitioners and others" with "a framework that addresses privacy and governance at both the organizational and system levels." On (2), GSA's Center of Excellence does publish "latest updates" but has only published three articles as of November 8, 2022 (see here)

Figure 12: Line-Level Implementation Tracker, AI in Government Act (1 of 3)

Sect. 104(a)-(b), (d)	OMB, in coordination with OSTP Director. GSA Adminstrator, and other relevant agencies or stakeholders (determined by OMB Director)	"[S]hall issue a memorandum to the head of each agency that shall-- (1) inform the development of policies regarding Federal acquisition and use by agencies regarding technologies that are empowered or enabled by artificial intelligence, including an identification of the responsibilities of agency officials managing the use of such technology; (2) recommend approaches to remove barriers for use by agencies of artificial intelligence technologies in order to promote the innovative application of those technologies while protecting civil liberties, civil rights, and economic and national security; (3) identify best practices for identifying, assessing, and mitigating any discriminatory impact or bias on the basis of any classification protected under Federal nondiscrimination laws, or any unintended consequence of the use of artificial intelligence, including policies to identify data used to train artificial intelligence algorithms as well as the data analyzed by artificial intelligence used by the agencies; and (4) provide a template of the required contents of the agency plans. . ." to comply with this memorandum. Sect. 104(b) requires a draft version for public comment and Sect. 104(d) requires the OMB Director issue a memorandum "every 2 years thereafter for 10 years".	Draft version for public comment not later than 180 days after enactment of Act (enacted Jan. 2021) Not later than 270 days after Act enacted	Time-boxed requirement	Not Implemented (expected draft ~July 2021 and final ~October 2021)
Sect. 104(c)	Head of agencies	"[S]hall submit to [OMB] Director and post on a publicly available page on the wesbite of the agency-- (1) a plan to achieve consistency with the memorandum; or (2) a written determination that the agency does not use and does not anticipate using artificial intelligence." Requires agencies submit same plan or written determination after every update the OMB Director publishes (sect. 104(d)).	No later than 180 days after OMB issues memorandum	Time-boxed requirement	Not Implemented (expected ~April 2022)

Figure 13: Line-Level Implementation Tracker, AI in Government Act (2 of 3)

Sect. 105(a)	OPM Director	"[I]n accordance with chapter 51 of title 5, United States Code, the Director of the Office of Personnel Management shall— (1) identify key skills and competencies needed for positions related to artificial intelligence; (2) establish an occupational series, or update and improve an existing occupational job series, to include positions the primary duties of which relate to artificial intelligence; (3) to the extent appropriate, establish an estimate of the number of Federal employees in positions related to artificial intelligence, by each agency; and (4) using the estimate established in paragraph (3), prepare a 2-year and 5-year forecast of the number of Federal employees in positions related to artificial intelligence that each agency will need to employ."	Not later than 18 months after Act enacted	Time-boxed requirement	Not Implemented (expected ~July 2022)
Sect. 105(b)	OPM Director	"[S]hall submit to the Committee on Homeland Security and Governmental Affairs of the Senate and the Committee on Oversight and Reform of the House of Representatives a comprehensive plan with a timeline to complete requirements described in subsection (a)."	Not later than 120 days after Act enacted	Time-boxed requirement	Not Implemented (expected ~May 2021)

Self-determination through explanation: an ethical perspective on the implementation of the transparency requirements for recommender systems set by the Digital Services Act of the European Union

Matteo Fabbri

Lucca, Italy

ABSTRACT

In the contemporary information age, recommender systems (RSs) play a critical role in influencing online behaviour: from social media to e-commerce, from music streaming to news aggregators, individuals are constantly targeted by personalized recommendations suggesting contents that may interest them. Despite such diffusion, the extent to which recommendations influence users' decisions is still underexplored, given that independent audits on the structure and functioning of RSs deployed on online platforms are usually prevented by proprietary constraints. The nudging potential of RSs can represent a risk for vulnerable people: indeed, judicial cases involving platforms' responsibility for displaying recommendations that may lead to political radicalization or endangerment of minors have recently caught public attention. The Digital Services Act of the European Union (DSA) is the first supranational regulation that sets specific transparency and auditing requirements for RSs implemented by online platforms with the aim of enhancing users' self-determination: in particular, it allows users to modify the parameters on which recommendations rely so to let them choose autonomously which kind of content they want to see. This research focuses on whether and how the enforcement of this regulation can mitigate the unfair consequences of the power imbalance between online platforms and users. To this aim, I discuss the harms arising from digital nudging based on RSs and propose explanations as a tool that can reduce the impact of those harms by increasing users' awareness. Through a comparative analysis of relevant articles of the DSA, the General Data Protection Regulation (GDPR) and the AI Act, I outline how the provisions of the DSA fill some of the gaps left by other relevant European regulations, while leaving the so-called right to explanation substantially unaddressed. As a result of this analysis, I argue that, in order for the implementation of the DSA provisions on recommender systems to be effective, policy-makers should: 1) enhance users' awareness through clear and easily accessible explanations on how the recommendation process works and how they can be influenced by it; 2) grant users the possibility of intervening directly on the strategies through which RSs target them on the platform's interface.

1 INTRODUCTION

In the contemporary information age, recommender systems (RSs) play a crucial role in determining the way in which people interact and obtain information online: from social media feeds to news aggregators and e-commerce websites, users are constantly targeted by personalized recommendations about contents or products they may like. From a technical perspective, RSs can be defined as algorithms aimed at estimating predictive ratings for some items which a user has not seen yet (Adomavicius and Tuzhilin, 2005) [6] in order to generate recommendations about content which may interest them. The Digital Services Act of the European Union (DSA) [1] [5], which is the first supranational regulation addressing automated recommendations specifically, defines RS as "a fully or partially automated system used by an online platform to suggest in its online interface specific information to recipients of the service or prioritize that information, including as a result of a search initiated by the recipient of the service or otherwise determining the relative order or prominence of information displayed" (DSA, art. 3 (s)). This definition highlights the method ("fully or partially automated"), aim ("to suggest"), content ("specific information"), target ("recipients of the service"), input ("as a result of a search initiated by the recipient") and output ("determining the relative order or prominence of information displayed") of a recommendation process. As it can be observed, RSs concern the main aspects

[1] REGULATION (EU) 2022/2065 OF THE EUROPEAN PARLIAMENT AND OF THE COUNCIL of 19 October 2022 on a Single Market For Digital Services and amending Directive 2000/31/EC (Digital Services Act).

of the user's experience: this is why their influencing potential should not be underestimated. In fact, whilst RSs should be aimed at improving user experience, they can give rise to a variety of ethical concerns related to privacy, autonomy and fairness [21], to name but a few. Indeed, the political economy of platforms based on profiling and recommendations has been notably addressed by [34] with the concept of "surveillance capitalism". However, independent research and ethical auditing on the design and functioning of the RSs implemented on online platforms is usually prevented by proprietary constraints.

For these reasons, there is a normative discrepancy between the widespread use of RSs in various domains and the methods through which their ethical and societal impact can be evaluated. Issues related to transparency and explainability have become increasingly pressing, as the implementation of opaque models may have problematic consequences on the users' ability to retrieve relevant information and define their online identity. As algorithmic recommendations often rely on implicit personal data, such as browsing and click-through history, and their functioning is not explained to users, their influence is not accountable. Although explanations for RSs have been addressed by research in Explainable AI [31], their effects on the design of algorithms and on the different stakeholders within the recommendation process have not been assessed extensively. Moreover, even when explanations are provided in real-world platforms, users are not able to interact explicitly with them, apart from providing limited feedback. The limitations regarding the transparency and accountability of automated recommendations are supposed to be addressed by the provisions of the DSA, which would require very large online platforms, including marketplaces and social media, to let users shape the design of the RSs managing their online experience. However, the effectiveness of the application of the regulatory provisions will depend on the extent to which people understand how RSs work and how they can shape their functioning: therefore, explanations should have a prominent role in this context.

In this paper, I focus on whether and how the new European regulatory context around RSs can address the risks and opportunities stemming from this pervasive digital technology, especially from the perspective of mitigating the unfair consequences of the power imbalance between platforms and users. Firstly, I discuss the possible harms arising from RSs as instances of digital nudging and introduce explanations as a tool that can reduce the impact of those harms by increasing users' awareness. Secondly, I consider the impact of the DSA provisions about RSs and online targeted advertising within the regulatory context set by relevant articles of the AI Act (AIA) and the General Data Protection Regulation (GDPR) of the European Union. This comparative analysis outlines how the provisions of the DSA fill some of the gaps left by other European regulations, while substantially lacking measures to effectively enhance users' autonomy. As a result of this analysis, I argue that, in order for the aims of the DSA provisions about RSs to be fulfilled, the principle of users' self-determination needs to be substantiated by: 1) easy accessibility of explanations on how the recommendation process works and how users can be influenced by it; 2) an extended possibility for users to intervene directly on the strategies through which RSs target them on the platform's interface.

2 CONTEXT

2.1 From personalization to epistemic fragmentation

[21] propose an initial taxonomy of the ethical challenges posed by automated recommendations: among the social effects of RSs, they identify a "lack of exposure to contrastive views", giving rise to the so-called filter-bubbles, which can be exploited by manipulative agents in order to increase the frequency with which a content is recommended within specific online communities. [8] put in evidence, phenomena such as polarization on social media arise because of a subtle manipulation of the contents delivered individually but spread collectively by RSs: through strategic content tagging and by exploiting the networked structure of platforms, political campaigners may be able to redirect public attention on controversial contents which appear on the social media feeds of users. In this regard, [29] has famously pointed out the widespread political implications of digital technologies, including RSs, which have allowed people to "filter what they want to read, see, and hear", not coming "across topics and views that you have not sought out".

In fact, the concept of recommendation is inherently related to that of personalization, although the corresponding phenomena are distinct. In fact, the latter represents the pre-condition for the former. On the one hand, recommendations make sense only if they can be personalized, because, if they were not personalized, they would not be able to reduce the information overload on platforms, which is their main utility for users and providers [14]. On the other hand, personalization can be applied mainly through algorithmic recommendations (in the form of targeted advertisements, suggested contents, etc.): therefore, even if personalization as a design concept makes sense independently of recommendations, its application within the infosphere often relies on them. Therefore, automated recommendations depend on personalization, whilst personalization is embedded within recommendations from the perspective of its application.

This distinction is required in order to understand how the sociotechnical structure of RSs is related to the epistemic fragmentation of users [20], a prominent problem in online platforms. Epistemic fragmentation can be defined as the phenomenon by which individual users lose contact with their peers through online targeted advertising. In particular, as each user is targeted individually by automated recommendations, one cannot know which content another person sees: in this sense, users' knowledge about their common experience on the platform is fragmented, because what they see is the result of personalization and cannot be shared among different individuals. This aspect is even more relevant considering that the effects of personalization do not necessarily imply that each user sees a different array of contents. In fact, an analysis of news recommendations on Google News by [23] found that "users with different political leanings from different states were recommended very similar news".

Epistemic fragmentation is not only a result of the individualization of recommended contents, but it also derives from the opaqueness of the recommendation process, which prevents users from becoming aware of the platform dynamics. This situation can give rise to ethical concerns especially when personalisation

is based on implicit user profiling, through which "the system determines what the user is interested in" thanks to implicit data, which include "web usage mining [...], IP address, cookies" and other metadata [7]. Indeed, if a user is profiled through implicit data, the recommendations will be less transparent and explainable compared to a situation in which "the user customizes the information source himself" (ibidem) by providing explicitly data such as personal interests, demographic information and ratings. In the context of an epistemically fragmented user experience, the influence of RSs relying on implicit profiling may hold negative aggregate social implications. In fact, when users do not have control over which kind of data is used for their profiling, the recommendations are more likely to bring unwanted contents to their attention.

As a result, users may suffer, on a first dimension, from absolute harms of inclusion or exclusion, which "originate in the nature of the content that is either included or excluded from what is shown to an individual consumer" [20]: the former occur when genuinely bad and offensive contents (i.e. false claims or racist stereotypes used for promotional purposes) are displayed on the users' profile, whilst the latter occur when essential contents (i.e. important public heath announcements) are omitted, without the user's consent or control on the process. On a second dimension, users can be affected by contextual harms of inclusion or exclusion, which "do not stem from the nature of the content per se, but depend on the context in which the content is delivered" (ibidem): for example, a contextual harm of inclusion may occur when unhealthy food is suggested to obese people or children, who may be more likely to buy them; conversely, a contextual harm of exclusion can be recognised when a job-seeker does not encounter advertisements for positions in their area. The categories of harms produced by RSs do not arise only from implicit profiling but may also be a consequence of the data that users choose to provide explicitly. For example, a user may want to provide explicit data about personal unhealthy habits, such as gambling, because they are interested in finding products or offers in the related domain, regardless of their impact on wellbeing. In the same way, some users may give a high rating to recommendations about contents featuring stereotypes that other people may find offensive or unethical: if the latter share interests with the former, they may see such unwanted recommendations due to collaborative filtering algorithms. These cases show that even personalization based on explicit profiling may originate unexpected harms, which cannot be evaluated just from the point of view of the single user but need to be interpreted within the context of both the platform environment and the socio-technical structure of RSs. Therefore, the harms generated by personalized recommendations do not depend only on the individual case of application, but also on the policy informing the system.

2.2 Digital nudging and recommendation policies

The origin of harms caused by RSs lies in their potential to influence users' choices. In particular, since algorithmic recommendations "influence which information is easily accessible to us and thus affect our decision-making processes though the automated selection and ranking of the presented content", they can be interpreted "as digital nudges, because they determine different aspects of the choice architecture for users" [17]. According to the original definition in behavioural economics proposed by [30], nudges are the features of a choice architecture "that have an influence on which decisions people make" [17]. Nudging "should be aimed at helping people make better decisions than they probably would if the nudge would not be there" (ibidem) without forcing them to adopt a specific choice. The nudging potential of RSs depends on the effectiveness of the recommendation policies implemented in the algorithmic design, which usually rely on the exploitation or exploration of the space of choices.

An exploitative policy aims "to recommend an item that has the highest expected probability of satisfying the user's preferences" [22], whilst an explorative policy is focused on recommending "content with uncertain predicted user engagement for the purpose of gathering more information" about users' interests [19]. When RSs rely exclusively on exploitative policies, users can be led into feedback loops that may reinforce their current preferences, resulting in bad consumer choices in the long run. For example, a user that usually buys unhealthy food through a delivery app based on exploitative RSs may receive recommendations about the same kind of food every time they want to make an order and therefore their health could be impacted negatively. In this case, an explorative policy could instead propose different kinds of products that do not correspond to the preferences previously expressed by the user, eventually inducing them to find healthier food they like.

Since the aim of RSs is to recommend items which users may purchase or consume, it is relevant to know whether and how explanations, which stem mainly from explicit profiling, can impact on the users' perception of the recommendation and their subsequent behaviour. This issue relates to the harms of inclusion and exclusion described above: indeed, if the system manages to change users' interests through explanations, they will end up seeing different contents from the ones they were originally aiming for. Nonetheless, this may make them perceive to have been assigned to categories which they think they have willingly chosen to belong to, given that the recommendation is seemingly transparent because of explanations. The risks coming from the manipulation of users' preferences are intrinsic to RS-powered digital nudging, but [17] report finding no paper about whether "users felt manipulated or coerced by the proposed nudge". In this context, understanding the extent to which users are influenced by recommendations, on the one side, and their explanations, on the other, is crucial for the assessment of the impact that the current and upcoming regulations will have as regards transparency and self-determination.

The default integration of information about the content within the recommendation could be beneficial for users' awareness of their own preferences. Following the same example as above, a food recommendation might be designed so that the nutritional values of a product that a user has (exploitative policy) or has not (explorative policy) bought before are displayed to them before they can proceed to the order: in this way, the user could be informed about the characteristics of their dietary choices. Moreover, providing explanations would make users aware of the extent to which their preferences have been taken into account by the policy informing the recommendation. Although their impact on users' decision-making is still underexplored, explanations for RSs can be considered a kind of pro-ethical informational nudging [11], as

they improve user-system interaction in direction of transparency and trustworthiness just through the provision of information. In fact, [17] classify explanations as nudging mechanisms within the Decision Information category based on making information visible.

3 REGULATORY FRAMEWORKS

3.1 From platform to court

The classification of harms presented above covers different cases in which automated recommendations would have a negative impact on users' wellbeing. The wide-ranging implications of harms caused by RSs go beyond the individual, acquiring a societal relevance. A case of absolute harm of inclusion covered by the international press concerns the "blackout challenge" on TikTok, which encourages users to film themselves as they choke themselves to the point of fainting and then regain consciousness on camera: various cases emerged in which minors died while trying the challenge. After the most recent cases, which happened in the USA [10] and UK [28], some American families decided to sue the platform as it let the challenge spread and target children through its recommendation algorithm [18]. While this may at first seem a problem of content moderation, it is, at a deeper level, a consequence of the use of RSs in social media platforms, where their main aim is to increase users' engagement. As RSs are often based on uninterpretable machine learning models, it might be difficult to attribute the liability for the harm to the platform. In fact, the platform could argue that contents are displayed to users according to recommendation policies that take their preferences into account, so, if the user liked or kept consuming a harmful content which is later reproposed to them, the system should not be blamed. Moreover, as access to the platform by individuals under a certain age should be supervised by parents, it is the parents' duty to control the online activity of their children. To challenge this argument, one should prove that it is the recommendation policy itself to be biased towards contents aimed at maximizing engagement regardless of the vulnerability of the user: according to this perspective, the platform would be liable for designing RSs that influence users' behaviour to fulfil the interests of the system (DSA, art. 35).

A related argument about platforms' responsibility for the content suggested by their RSs is embraced by petitioners in the Gonzalez vs Google case, which deals with "whether Section 230 [of the US Communication Decency Act] shields Google from liability for allegedly recommending ISIS content posted to YouTube to other YouTube users" [9]. This lawsuit emerged as a result of the deaths caused by the 2015 terrorist attacks in Paris, France, which were carried out by people recruited by ISIS after being exposed to social media content disseminated by the organization through YouTube RSs. In particular, the question posed to the US Supreme Court concerns whether "section 230(c)(l) immunize[s] interactive computer services when they make targeted recommendations of information provided by another information content provider, or only limit the liability of interactive computer services when they engage in traditional editorial functions (such as deciding whether to display or withdraw) with regard to such information" [24]. Petitioners argue that "Section 230(c)(1), which shields intermediaries from liability for "publishing" third-party content, applies only to claims based on the "display" of content, not the "recommendation" of content" (ibidem). In May 2023, the Supreme Court dismissed the case on the ground that it could not by addressed by antiterrorism law, as the "plaintiffs' complaint seems to fail under [...] our decision in Twitter" vs Taamneh, which concerned the same issue of Gonzalez vs Google [25]. If the Supreme Court's ruling had excluded targeted recommendations from the protection provided by Section 230, implying that "the "recommendation" of content is different from the display of content", platforms would have been forced to change their moderation and recommendation processes and users might have lost their "rights to like and promote content in forums where they act as community moderators and effectively boost some content over other content" [27]. As the old debate between freedom of expression and (online) safety eventually focuses on the impact of the influence of RSs, it is crucial for users to understand how algorithmic recommendations function and to shape their design. In fact, the prerequisite for users' self-determination is the knowledge of the sociotechnical systems with which they interact.

3.2 Digital Services Act (DSA): filling the gap left by the AI Act

The DSA addresses this issue with a specific article, according to which "Providers of online platforms that use recommender systems shall set out in their terms and conditions, in plain and intelligible language, the main parameters used in their recommender systems, as well as any options for the recipients of the service to modify or influence those main parameters" (DSA, art.27 (1)). The aim of this provision is to "explain why certain information is suggested to the recipient of the service": therefore, the parameters need to include, at least, "the criteria which are most significant in determining the information suggested to the recipient of the service" (i.e., content) and the reasons for its "relative importance" (i.e., ranking) (DSA, art. 27 (2)). Additionally, when options to modify or influence the main parameters are stated in the terms and conditions, "providers of online platforms shall also make available a functionality that allows the recipient of the service to select and to modify at any time their preferred option" (DSA, art. 27 (3)). In order to make this requirement work in practice, "That functionality shall be directly and easily accessible from the specific section of the online platform's online interface where the information is being prioritised" (ibidem). Moreover, "providers of very large online platforms [VLOPs] and of very large online search engines [VLOSEs] that use recommender systems shall provide at least one option for each of their recommender systems which is not based on profiling"[2] (DSA, art. 38). It is worth noticing that, while the provisions of Article 27 apply to all online platforms, the application of Article 38 is limited to VLOPs and VLOSEs, which therefore represent the only environments in which users will always have the option to choose between at least two types of recommendations[3].

The provisions of Article 27 aim to address four of the aspects of the definition of RS provided by Article 3(s): method, target, input and output. In particular, as a result of the enforcement of the DSA,

[2]Profiling is defined here according to Article 4 (4) of the GDPR.
[3]It is plausible to state that all the VLOPs and VLOSEs identified by the European Commission (https://digital-strategy.ec.europa.eu/en/policies/dsa-vlops) use profiling for automated recommendations, so the provision of Article 38 applies to all of them.

the traditionally passive role of the target might be reversed, as the recipient could determine the method (through the choice of parameters) and, indirectly, also the input (the type of data to be processed through the parameters) that the RS would use to produce its output. This opportunity to enhance transparency and users' self-determination has not been welcomed by a prominent digital company like Meta, which has stated that "the breadth of some of the auditing obligations under the DSA should be clarified/improved as these could become a barrier for growth in the sector" [2]. However, online platforms that are not VLOPs or VLOSEs using RSs based on profiling will not be obliged to provide options for users to modify or influence the parameters if this possibility is not specified in the terms and conditions, and platforms arguably have no interest in providing this possibility voluntarily. Therefore, Article 27 formally grants users the right to influence the recommendation process but only in some limited cases which may not be likely to happen, as [15] point out. Moreover, the practical impact of these provisions will probably depend on users' ability to understand the type and the policy of recommendations.

The rationale of the norms on RSs transparency, introduced in Recital 70, outlines a wider regulatory scope than the one of Article 27: indeed, the statement that "online platforms should consistently ensure that recipients of their service are appropriately informed about how recommender systems impact the way information is displayed, and can influence how information is presented to them" (DSA, recital 70) does not seem to be reflected in the actual provisions of Article 27, at least to the extent that the adverb "consistently" would entail[4]. Nonetheless, online platforms "should clearly present the main parameters for such recommender systems in an easily comprehensible manner to ensure that the recipients understand how information is prioritised for them" (ibidem). A right to explanation for RSs could be identified in this formulation: in fact, the "easily comprehensible manner" of presenting the parameters of RSs so that "the recipients understand how information is prioritised for them" can come to effect only if RSs are explainable.

Relatedly, the DSA will also require VLOPs that display advertisements to "compile and make publicly available in a specific section of their online interface, through a searchable and reliable tool that allows multicriteria queries and through application programming interfaces, a repository" (DSA, art. 39 (1)) featuring the following information: "(a) the content of the advertisement, including the name of the product, service or brand and the subject matter of the advertisement; (b) the natural or legal person on whose behalf the advertisement is presented; (c) the natural or legal person who paid for the advertisement, if that person is different from the person referred to in point (b); (d) the period during which the advertisement was presented; (e) whether the advertisement was intended to be presented specifically to one or more particular groups of recipients of the service and if so, the main parameters used for that purpose including where applicable the main parameters used to exclude one or more of such particular groups; (f) the commercial communications published on the very large online platforms [...]; (g) the total number of recipients of the service reached and, where applicable, aggregate numbers broken down by Member State for the group or groups of recipients that the advertisement specifically targeted." (DSA, art. 39 (2)). The first four points of the cited paragraph concern the metadata of the advertisement: its content, who paid for it, the duration of its permanence on the platform. According to point (e), the platform is required to indicate whether the advertisement was targeted and, if so, the main parameters used for including or excluding categories of users from the targeted. Point (g) would allow to understand indirectly the correspondence between specific clusters of users and the advertisement by which they have been targeted in each EU country. The enforcement of this article has the potential to address the epistemic fragmentation of users due to online targeted advertising considered by [20]. Indeed, if users can access a public repository with information about the parameters used by platforms to segment them into groups for targeting purposes, they can have an idea of how many other people see a particular advertisement and why they see it. The access to this information can reduce the individualization and fragmentation of online experience, as users could eventually become aware of collective platform dynamics, although probably not at a very granular level.

The provisions outlined above are part of a wider regulatory scope. In particular, the DSA aims to address the systemic risks and harms that may emerge from the implementation of RSs in VLOPs and VLOSEs so to avoid violation of fundamental rights and the endangerment of vulnerable people like minors. According to Article 34, "Providers of very large online platforms and of very large online search engines shall diligently identify, analyse and assess any systemic risks in the Union stemming from the design or functioning of their service and its related systems, including algorithmic systems, or from the use made of their services", including: "(a) the dissemination of illegal content through their services"; "(b) any actual or foreseeable negative effects for the exercise of the fundamental rights [...] to human dignity", "to respect for private and family life", "to the protection of personal data", "to freedom of expression and information", "to non-discrimination", "to respect for the rights of the child" and "to a high level of consumer protection"; (c) "any actual or foreseeable negative effects on civic discourse and electoral processes, and public security"; (d) "any actual or foreseeable negative effects in relation to gender-based violence, the protection of public health and minors and serious negative consequences to the person's physical and mental well-being". The risks assessments operated by very large online platforms should take into account, among other aspect, "the design of their recommender systems and any other relevant algorithmic system" (DSA, art. 34(2), which will need to be adapted following risk mitigation measures (DSA, art. 35(1)).

Following the unprecedented regulatory scope of the DSA, the European Commission has founded the European Centre for Algorithmic Transparency (ECAT), whose mission is to contribute with "scientific and technical expertise to the Commission's exclusive supervisory and enforcement role of the systemic obligations on Very Large Online Platforms (VLOPs) and Very Large Online Search Engines (VLOSEs) provided for under the DSA" [1]. The area of competence of the ECAT features "recommender systems, information retrieval and search engines", which will be the subject of research aimed at uncovering their "ethical, economic, legal and social impact" and at developing risk assessment and mitigation

[4]The right to information outlined here is mirrored by Article 13-15 of the GDPR, which will be considered later.

measures for the protection of fundamental rights (ibidem). Such research effort would provide an evidence base for the implementation of the DSA, whose high-level provisions regarding RSs are not currently backed by standards that can bridge the gap between regulatory principles and market practices. The ECAT will also include an inspections team which "will actively help assessing whether very large online platforms and search engines comply with their obligations under the Digital Services Act" by "analysing the design, functioning and impact of advanced algorithms, like recommender systems, in their production environments" through "formal investigations" including "on-site inspections at platforms' premises" (ibidem).

The provisions of the DSA fill the gaps of the EU Artificial Intelligence Act (AIA) [3] concerning RSs. Before the latest amendments approved by the European Parliament in June 2023, references to automated recommendations could be found in only two paragraphs of the AIA proposal: the first occurrence is the definition of AI system as "software that can, for a given set of human-defined objectives, generate outputs such as content, predictions, recommendations, or decisions influencing the environments they interact with" (AIA, art. 3(1)); the second occurrence is the explanation of "automation bias" as the tendency of "automatically relying or overrelying on the output produced by [...] AI systems used to provide information or recommendations for decisions to be taken by natural persons" (AIA. art. 14(4b)). In both the occurrences, "automated recommendations are considered from the perspective of the outcome and not of the process: therefore, they are merely regarded as outputs of an AI system that can have an impact on human decision-making, whilst a specific focus on the design principles of RSs and the risks posed by their biases is completely lacking" [11]. This choice may appear inconsistent with the widespread impact that algorithmic recommendations have on users, which can also include serious harms, as the case mentioned above underlines.

In the compromise text that includes the amendments voted in June 2023[5] [26], RSs are mentioned in two instances. Firstly, Recital 40b outlines how and to which extent the AIA addresses RSs, by specifying that "recommender systems are subject to this Regulation so as to ensure that" they "comply with the requirements laid down under this Regulation, including the technical requirements on data governance, technical documentation and traceability, transparency, human oversight, accuracy and robustness". Only RSs implemented by VLOPs, and especially social media, are considered by the AIA, which complements the DSA by enabling "such very large online platforms to comply with their broader risk assessment and risk-mitigation obligations in Article 34 and 35" of that regulation. Secondly, and most importantly, the AI component of RSs becomes part of the high-risk AI applications listed in Annex III (1(8(ab))) as "AI systems intended to be used by social media platforms that have been designated as very large online platforms [...] in their recommender systems to recommend to the recipient of the service user-generated content available on the platform".

While the AIA refers to the DSA for the identification of VLOPs and the enforcement of the norms concerning RSs, the fact that the AI technologies enabling automated recommendations are eventually included in this regulation testifies a welcomed change of paradigm from the previous versions. The reasons for which RSs have not been considered a high-risk AI technology in the early drafts of the AIA maybe concern the fact that recommendations impact indirectly rather than directly on individuals. A comparative example might be helpful: automated credit risk assessment, which has been included in Annex III since the beginning, is supposed to output a score that helps human decision-makers determine whether a client is suitable to receive a loan. In this case, the system is devoted to performing a content-specific task that supports human decision making (although human decisions often tend to be determined rather than supported by it). Algorithmic recommendations, instead, are not content- but context-specific: the content of their output can vary widely depending on the user, but they are directed by a defined aim within a particular context, i.e. maximizing user engagement in a social media platform.

For this reason, the recommendation does not raise ethical concerns per se, but as regards its domain of application: this may be the reason for which RSs have been initially excluded from the scope of the AIA, which regulates the risks of AI technologies per se, but included in the DSA, which instead addresses specific algorithmic systems as enablers of the services provided by online platforms. The inclusion of the AI systems enabling RSs implemented by VLOPs in Annex III underlines regulators' awareness of the risks stemming from the influence of automated recommendations. Given that the AIA has not been enforced yet, I would like to switch this analysis to another relevant regulation currently in force, i.e. the GDPR, to evaluate its potential impact on RSs transparency.

3.3 General Data Protection Regulation (GDPR) and the right to explanation

Article 22 of the GDPR [4] addresses "automated individual decision making, including profiling" stating that "the data subject shall have the right not to be subject to a decision based solely on automated processing, including profiling, which produces legal effects concerning him or her or similarly significantly affects him or her" (art. 22(1)). RSs are based on profiling, so they can be considered within the regulatory scope of this article. However, there are three exceptions to the provision reported above, which "shall not apply if the decision: (a) is necessary for entering into, or performance of, a contract between the data subject and a data controller; (b) is authorised by Union or Member State law to which the controller is subject and which also lays down suitable measures to safeguard the data subject's rights and freedoms and legitimate interests; or (c) is based on the data subject's explicit consent" (art. 22(2)). When exceptions (a) and (c) apply, "the data controller shall implement suitable measures to safeguard the data subject's rights and freedoms and legitimate interests, at least the right to obtain human intervention on the part of the controller, to express his or her point of view and to contest the decision" (art. 22(3)). Moreover, according to the fourth paragraph of the article, sensitive data should never be collected for profiling. However, it often happens that sensitive data are inferred from non-sensitive data which act as proxies: for instance, income level could be inferred from household address.

[5]The complete list of amendments can be found at:https://www.europarl.europa.eu/doceo/document/TA-9-2023-0236_EN.html

Exception (a) could be claimed in all the cases in which users are asked to accept the terms of service of a platform, which define the contract between the data subject and the data controller. Exception (c) applies when the user is asked for online consent, for example for what concerns cookies. Therefore, it can be argued that automated recommendations comply with the GDPR requirements, given that, when accepting the terms of service, the user is often giving consent to profiling and inferences. On the one side, Article 27 of the DSA aligns with the rationale of GDPR by requiring that explanations of RSs are presented in the terms and conditions, which are not often read by users and therefore may not impact on their awareness of their rights. On the other side, Article 38 of the DSA complements the GDPR by requiring that very large online platforms keep a repository of targeted advertisements, so that users can view the outcome of legitimate profiling.

[13] point out that the nudging potential of automated decision-making systems may, in some cases, lead humans to conform uncritically to their assessments, thereby making the application of Article 22 of the GDPR controversial. In fact, the safeguards against decisions that do not involve humans in the loop are not clarified in Article 22, which does not state how users can determine whether a decision is completely automated. Instead, a hint in this direction is provided by articles 13 and 14, on the right to information, and 15, on the right to access, according to which the controller must give information about the existence of automated decision-making, including profiling, as referred to in Article 22, and, at least in such cases, meaningful information about the logic used, as well as the significance and the intended consequences of such processing for the data subject [13]. This is complemented by Recital 71, which suggests that profiling "should be subject to suitable safeguards, which should include specific information to the data subject and the right to obtain human intervention, to express his or her point of view, to obtain an explanation of the decision reached after such assessment and to challenge the decision". The right to explanation envisaged here is crucial to substantiate the safeguarding claims of the cited articles, but it is not described in further detail.

This lack of precision has been criticized by [33], who identify "several reasons to doubt both the legal existence and the feasibility of such a right": in fact, "the GDPR only mandates that data subjects receive meaningful, but properly limited, information (Articles 13–15) about the logic involved, as well as the significance and the envisaged consequences of automated decision-making systems". Moreover, "the ambiguity and limited scope of the 'right not to be subject to automated decision-making' contained in Article 22 (from which the alleged 'right to explanation' stems) raises questions over the protection actually afforded to data subjects" (ibidem). The DSA goes in the direction of implementing the right to explanation outlined in the GDPR, but the effectiveness of explanations in enhancing users' autonomy is still debated. Future empirical research should be aimed at establishing whether the presence of explanations would substantially contribute to substantiate the users' rights envisioned by these regulations.

4 CONCLUSION

Automated recommendations determine not only what we see on platforms, but also our potential interest for new or different categories of content. This influencing potential can be interpreted as an instance of the "new emerging grey power" of tech companies, which "is exercised about which questions can be asked, when and where, how and by whom and hence what answers can be received in principle" [12]. A platform like TikTok, which is mainly managed through RSs, is a prominent example of this tendency: as the interface is based on an endless flow of recommended content through which the user scrolls, the contents that the user ends up seeing more frequently are related to the single videos that he watches for a longer time. This exploitative policy has already caused harm [10] because, if a video on which a vulnerable person casually spends a few seconds concerns a dangerous activity, then that individual will see the same content more and more and may eventually be influenced by it. In this sense, platforms control the questions that users pose about their interests and, subsequently, the answers that they get: in this way, digital companies end up informing a substantial part of users' online, and sometimes offline, experience. Explanations may be a countermeasure to this harmful tendency of automated recommendations, as they have the potential to make users aware of some of the questions that platforms shape for them. I argue that, in order for this potential to be realized, explanations should be integrated as a readily available, standard feature of recommendations which people may choose to review when they want to, or that appear as a pop-up on the interface of online platforms. Thanks to such a policy, users could understand why they are targeted by specific content and, subsequently, become aware of the extent to which they are influenced by RSs.

The DSA will require digital companies that use RSs and targeted advertising to build mechanisms to grant transparency, in order to enhance users' self-determination and understanding of the systems they use. However, if users are not interested in receiving explanations, or if exposure to explanations does not influence users' perspective on algorithmic recommendations, the provisions of the DSA may not have the expected results. In fact, as [32] underline, "the explanations affect a user's mental model of the recommender system, and in turn the way they interact with the explanations". The contemporary trends of RSs outline an increasing focus on explorative policies, which are likely to shape the future ways of interacting online. This may seem an evolution towards more ethical platform environments, but this is not necessarily the case. Whilst exploitative policies are considered the negative side of automated recommendations because they may lead to filter bubbles, explorative policies can also give rise to risks that should not be left untouched by ethical concerns and regulatory attention. Indeed, from the perspective of digital companies, exploration is mainly a means to get to know users even better than they currently do, by gathering data on unexplored fields of potential interests and preferences. This can lead to an even deeper nudging, which is realized through incremental exposure to contents that can provide fine-grained information on how to induce users to like what they do not know they like yet: for this reason, explorative recommendations could contribute significantly to the grey power that VLOPs already have.

I argue that an effective right to explanation is a preliminary condition for users' self-determination in the platform environment. Explanations can be considered a means to mitigate the negative consequences of the power imbalance between platforms and users. Users cannot shape automated recommendations according to their interests and needs without firstly knowing how and why they are targeted and influenced by RSs: in fact, if someone doesn't know how a system works, they are unlikely to be able to make that system work better. Digital nudging may lead to undesirable outcomes, such as manipulation, if users' perception of the recommendation process is not informed by the knowledge of how it unfolds. In this regard, my contribution points to a prominent policy problem: as explanations are the building blocks of transparency, in order to support self-determination through transparent recommendations it is firstly necessary to educate users to understand not only "what recommenders recommend" [16], but also why they recommend what they recommend. If it is not properly met by regulators on time, this sociotechnical requirement may constrain the positive ethical and societal impact of the DSA provisions. In conclusion, I think that, in order to reduce the power imbalance between platforms and users and limit the influence that the former exert on the latter, policy-makers should: 1) enforce explanations as a user-friendly tool to foster awareness that users can experience on the interface and not only read in the terms and conditions; 2) grant users the possibility of intervening directly and substantially on the strategies through which RSs target them on the platform's interface.

ACKNOWLEDGMENTS

I would like to thank my supervisor professor Andrea Simoncini for his guidance throughout the development of the research resulting in this publication. I would also like to commend the essential support that my colleague Yuhui Zhu gave me in editing the final version of the manuscript.

ABSTRACT

As neural networks increasingly make critical decisions in high-stakes settings, monitoring and explaining their behavior in an understandable and trustworthy manner is a necessity. One commonly used type of explainer is post hoc feature attribution, a family of methods for giving each feature in an input a score corresponding to its influence on a model's output. A major limitation of this family of explainers in practice is that they can disagree on which features are more important than others. Our contribution in this paper is a method of training models with this *disagreement problem* in mind. We do this by introducing a Post hoc Explainer Agreement Regularization (PEAR) loss term alongside the standard term corresponding to accuracy, an additional term that measures the difference in feature attribution between a pair of explainers. We observe on three datasets that we can train a model with this loss term to improve explanation consensus on unseen data, and see improved consensus between explainers other than those used in the loss term. We examine the trade-off between improved consensus and model performance. And finally, we study the influence our method has on feature attribution explanations.

1 INTRODUCTION

As machine learning becomes inseparable from important societal sectors like healthcare and finance, increased transparency of how complex models arrive at their decisions is becoming critical. In this work, we examine a common task in support of model transparency that arises with the deployment of complex black-box models in production settings: explaining which features in the input are most influential in the model's output. This practice allows data scientists and machine learning practitioners to rank features by importance – the features with high impact on model output are considered more important, and those with little impact on model output are considered less important. These measurements inform how model users debug and quality check their models, as well as how they explain model behavior to stakeholders.

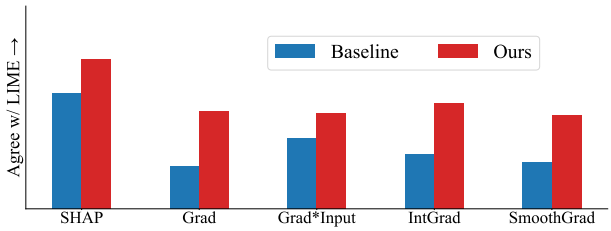

Figure 1: Our loss that encourages explainer consensus boosts the correlation between LIME and other common post hoc explainers. This comes with a cost of less than two percentage points of accuracy compared with our baseline model on the Electricity dataset. Our method improves consensus on six agreement metrics and all pairs of explainers we evaluated. Note that this plot measures the *rank correlation* agreement metric and the specific bar heights depend on this choice of metric.

1.1 Post Hoc Explanation

The methods of model explanation considered in this paper are post hoc local feature attribution scores. The field of explainable artificial intelligence (XAI) is rapidly producing different methods of this type to make sense of model behavior [e.g., 21, 24, 30, 32, 37]. Each of these methods has a slightly different formula and interpretation of its raw output, but in general they all perform the same task of attributing a model's behavior to its input features. When tasked to explain a model's output with a corresponding input (and possible access to the model weights), these methods answer the question, "How influential is each individual feature of the input in the model's computation of the output?"

Data scientists are using post hoc explainers at increasing rates – popular methods like LIME and SHAP have had over 350 thousand

and 6 million downloads of their Python packages in the last 30 days, respectively [23].

1.2 The Disagreement Problem

The explosion of different explanation methods leads Krishna et al. [15] to observe that when neural networks are trained naturally, i.e. for accuracy alone, often post hoc explainers disagree on how much different features influenced a model's outputs. They coin the term *the disagreement problem* and argue that when explainers disagree about which features of the input are important, practitioners have little concrete evidence as to which of the explanations, if any, to trust.

There is an important discussion around local explainers and their true value in reaching the communal goal of model transparency and interpretability [see, e.g., 7, 18, 29]; indeed, there are ongoing discussions about the efficacy of present-day explanation methods in specific domains [for healthcare see, e.g., 8]. Feature importance estimates may fail at making a model more transparent when the model being explained is too complex to allow for easily attributing the output to the contribution of each individual feature.

In this paper, we make no normative judgments with respect to this debate, but rather view "explanations" as signals to be used alongside other debugging, validation, and verification approaches in the machine learning operations (MLOps) pipeline. Specifically, we take the following practical approach: make the amount of explanation disagreement a controllable model parameter instead of a point of frustration that catches stakeholders off-guard.

1.3 Encouraging Explanation Consensus

Consensus between two explainers does not require that the explainers output the same exact scores for each feature. Rather, consensus between explainers means that whatever disagreement they exhibit can be reconciled. Data scientists and machine learning practitioners say in a survey that explanations are in basic agreement if they satisfy agreement metrics that align with human intuition, which provides a quantitative way to evaluate the extent to which consensus is being achieved [15]. When faced with disagreement between explainers, a choice has to be made about what to do next – if such an arbitrary crossroads moment is avoidable via specialized model training, we believe it would be a valuable addition to a data scientist's toolkit.

We propose, as our main contribution, a training routine to help alleviate the challenge posed by post hoc explanation disagreement. Achieving better consensus between explanations does not provide more interpretability to a model inherently. But, it may lend more trust to the explanations if different approaches to attribution agree more often on which features are important. This gives consensus the practical benefit of acting as a sanity check – if consensus is observed, the choice of which explainer a practitioner uses is less consequential with respect to downstream stakeholder impact, making their interpretation less subjective.

2 RELATED WORK

Our work focuses on post hoc explanation tools. Some post hoc explainers, like LIME [24] and SHAP [21], are proxy models trained atop a base machine learning model with the sole intention of "explaining" that base model. These explainers rely only on the model's inputs and outputs to identify salient features. Other explainers, such as Vanilla Gradients (Grad) [32], Gradient Times Input (Grad*Input) [30], Integrated Gradients (IntGrad) [37] and SmoothGrad [34], do not use a proxy model but instead compute the gradients of a model with respect to input features to identify important features.[1] Each of these explainers has its quirks and there are reasons to use, or not use, them all—based on input type, model type, downstream task, and so on. But there is an underlying pattern unifying all these explanation tools. Han et al. [12] provide a framework that characterizes all the post hoc explainers used in this paper as different types of local-function approximation. For more details about the individual post hoc explainers used in this paper, we refer the reader to the individual papers and to other works about when and why to use each one [see, e.g., 5, 13].

We build directly on prior work that defines and explores the disagreement problem [15]. Disagreement here refers to the difference in feature importance scores between two feature attribution methods, but can be quantified several different ways as are described by the metrics Krishna et al. [15] define and use. We describe these metrics in Section 4.

The method we propose in this paper relates to previous work that trains models with constraints on explanations via penalties on the disagreement between feature attribution scores and handcrafted ground-truth scores [26, 27, 41]. Additionally, work has been done to leverage the disagreement between different post-hoc explanations to construct new feature attribution scores that improve metrics like stability and pairwise rank agreement [2, 16, 25].

3 PEAR: POST HOC EXPLAINER AGREEMENT REGULARIZER

Our contribution is the first effort to train models to be both accurate and to be explicitly regularized via consensus between local explainers. When neural networks are trained *naturally* (i.e. with a single task-specific loss term like cross-entropy), disagreement between post hoc explainers often arises. Therefore, we include an additional loss term to measure the amount of explainer disagreement during training to encourage consensus between explanations. Since human-aligned notions of explanation consensus can be captured by more than one agreement metric (listed in A.3), we aim to improve several agreement metrics with one loss function.[2]

Our consensus loss term is a convex combination of the Pearson and Spearman correlation measurements between the vectors of attribution scores (Spearman correlation is just the Pearson correlation on the ranks of a vector).

[1] In many settings, there may be a strong case to consider *interpretable-by-design* models—that is, models that need no proxy model or gradient computation to be explained, and are instead interpretable in their base form. [29] provides an overview of this space, and we specifically call out directions such as falling rule lists [40], generalized additive models [20], and concept/prototype-based models [9, 14]. We acknowledge this direction of research as well as subsequent push-back claiming that performance drops from prioritizing interpretability may be prohibitively high [e.g., when compared to so-called foundation models, see 4]. Given industry uptake of post hoc explanations, our paper focuses on that approach alone.

[2] The PEAR package will be publicly for download on the Package Installer for Python (pip), and it is also available upon request from the authors.

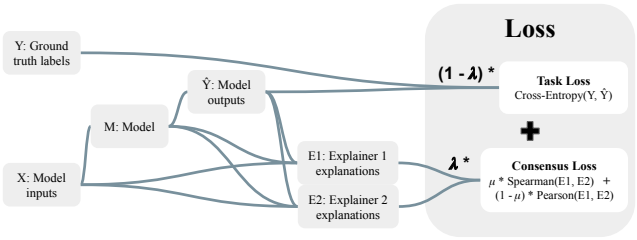

Figure 2: Our loss function measures the task loss between the model outputs and ground truth (task loss), as well as the disagreement between explainers (consensus loss). The weight given to the consensus loss term is controlled by a hyperparameter λ. The consensus loss term term is a convex combination of the Spearman and Pearson correlation measurements between feature importance scores, since increasing both rank correlation (Spearman) and raw-score correlation (Pearson) are useful for improving explainer consensus on our many agreement metrics.

To paint a clearer picture of the need for two terms in the loss, consider the examples shown in Figure 3. In the upper example, the raw feature scores are very similar and the Pearson correlation coefficient is in fact 1 (to machine precision). However, when we rank these scores by magnitude, there is a big difference in their ranks as indicated by the Spearman value. Likewise, in the lower portion of Figure 3 we show that two explanations with identical magnitudes will show a low Pearson correlation coefficient. Since some of the metrics we use to measure disagreement involve ranking and others do not, we conclude that a mixture of these two terms in the loss is appropriate.

While the example in Figure 3 shows two explanation vectors with similar scale, different explanation methods do not always align. Some explainers have the sums of their attribution scores constrained by various rules, whereas other explainers have no such constraints. The correlation measurements we use in our loss provide more latitude when comparing explainers than a direct difference measurement like mean absolute error or mean squared error, allowing our correlation measurement.

More formally, our full loss function is defined as follows. Let f denote a model. Let E_1 and E_2 be any two post-hoc explainers, each of which take a data point x and its predicted label $\hat{y}$ as input and output a vector, which is the same size as x and has corresponding feature attribution scores. We define R to be the ranking function, so it replaces each entry in a vector with the rank of its magnitude among all entries in the vector.[3]

Let the functions $p(a, b)$ and $s(a, b)$ be Pearson and Spearman correlation measurements, respectively. We denote the average value of all entries in a vector with the $\bar{\cdot}$ notation.

$$p(a,b) = \sum_i \frac{(a_i - \bar{a})(b_i - \bar{b})}{\|a\|\|b\|} \tag{1}$$

[3]When more than one of the entries have the same magnitude, they get a common ranking value equal to the average rank if they were ordered arbitrarily.

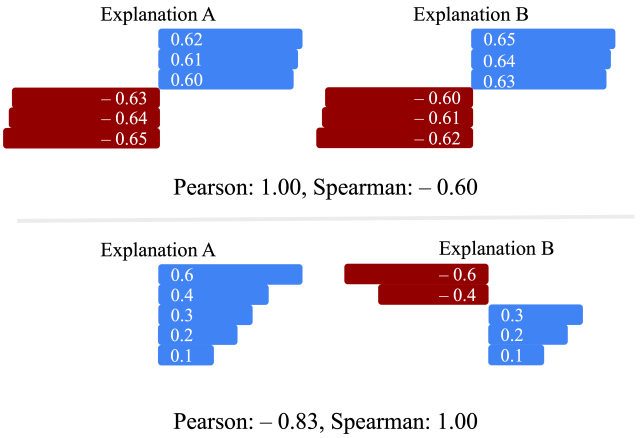

Figure 3: Example feature attribution vectors where Pearson and Spearman show starkly different scores. Recall, both Pearson and Spearman correlation range from -1 to $+1$. Both of these pairs of vectors satisfy some human-aligned notions of consensus. But in each circumstance, one of the correlation metrics gives a low similarity score. Thus, in order to successfully encourage explainer consensus (by all of our metrics), we use both types of correlation in our consensus loss term.

$$s(a,b) = \sum_i \frac{(R(a)_i - \overline{R(a)})(R(b)_i - \overline{R(b)})}{\|R(a)\|\|R(b)\|} \tag{2}$$

We refer to the first term in the loss function as the *task loss*, or ℓ_{task}, and for our classification tasks we use cross-entropy loss. A graphical depiction of the flow from data to loss value is shown in Figure 2. Formally, our complete loss function can be expressed as follows with two hyperparameters $\lambda, \mu \in [0, 1]$. We weight the influence of our consensus term with λ, so lower values give more priority to task loss. We weight the influence between the two explanation correlation terms with μ, so lower values give more weight to Pearson correlation and higher values give more weight to Spearman correlation.

$$\begin{aligned} L(x, y, f, E_1, E_2) = \\ (1-\lambda)\ell_{\text{task}} \\ +\lambda\Big(\mu\, s\big(E_1(x,y), E_2(x,y)\big) \\ +(1-\mu)\, p\big(E_1(x,y), E_2(x,y)\big)\Big) \end{aligned} \tag{3}$$

3.1 Choosing a Pair of Explainers

The consensus loss term is defined for any two explainers in general, but since we train with standard backpropagation we need these explainers to be differentiable. With this constraint in mind, and with some intuition about the objective of improving agreement metrics, we choose to train for consensus between Grad and IntGrad. If Grad and IntGrad align, then the function should become more locally linear in logit space. IntGrad computes the average gradient along a path in input space toward each point being explained. So,

if we train the model to have a local gradient at each point (Grad) closer to the average gradient along a path to the point (IntGrad), then perhaps an easy way for the model to accomplish that training objective would be for the gradient along the whole path to equal the local gradient from Grad. This may push the model to be more similar to a linear model. This is something we investigate with qualitative and quantitative analysis in Section 4.5.

3.2 Differentiability

On the note of differentiability, the ranking function R is not differentiable. We substitute a soft ranking function from the `torchsort` package [3]. This provides a floating point approximation of the ordering of a vector rather than an exact integer computation of the ordering of a vector, which allows for differentiation.

4 THE EFFICACY OF CONSENSUS TRAINING

In this section we present each experiment with the hypothesis it is designed to test. The datasets we use for our experiments are Bank Marketing, California Housing, and Electricity, three binary classification datasets available on the OpenML database [39]. For each dataset, we use a linear model's performance (logistic regression) as a lower bound of realistic performance because linear models are considered inherently explainable.

The models we train to study the impact of our consensus loss term are multilayer perceptrons (MLPs). While the field of tabular deep learning is still growing, and MLPs may be an unlikely choice for most data scientists on tabular data, deep networks provide the flexibility to adapt training loops for multiple objectives [1, 10, 17, 28, 31, 36]. We also verify that our MLPs outperform linear models on each dataset, because if deep models trained to reach consensus are less accurate than a linear model, we would be better off using the linear model.

We include XGBoost [6] as a point of comparison for our approach, as it has become a widely popular method with high performance and strong consensus metrics on many tabular datasets (figures in Appendix A.7). There are cases where we achieve more explainer consensus than XGBoost, but this point is tangential as we are invested in exploring a loss for training neural networks.

For further details on our datasets and model training hyperparameters, see Appendices A.1 and A.2.

4.1 Agreement Metrics

In their work on the disagreement problem, Krishna et al. [15] introduce six metrics to measure the amount of agreement between post hoc feature attributions. Let $[E_1(x)]_i$, $[E_2(x)]_i$ be the attribution scores from explainers for the i-th feature of an input x. A feature's *rank* is its index when features are ordered by the absolute value of their attribution scores. A feature is considered in the *top-k most important* features if its rank is in the top-k. For example, if the importance scores for a point $x = [x_1, x_2, x_3, x_4]$, output by one explainer are $E_1(x) = [0.1, -0.9, 0.3, -0.2]$, then the most important feature is x_2 and its rank is 1 (for this explainer).

Feature Agreement counts the number of features x_i such that $[E_1(x)]_i$ and $[E_2(x)]_i$ are both in the top-k. **Rank Agreement** counts the number of features in the top-k with the same rank in $E_1(x)$ and $E_2(x)$. **Sign Agreement** counts the number of features in the top-k such that $[E_1(x)]_i$ and $[E_2(x)]_i$ have the same sign. **Signed Rank Agreement** counts the number of features in the top-k such that $[E_1(x)]_i$ and $[E_2(x)]_i$ agree on both sign and rank. **Rank Correlation** is the correlation between $E_1(x)$ and $E_2(x)$ (on all features, not just in the top-k), and is often referred to as the Spearman correlation coefficient. Lastly, **Pairwise Rank Agreement** counts the number of pairs of features (x_i, x_j) such that E_1 and E_2 agree on whether x_i or x_j is more important. All of these metrics are formalized as fractions and thus range from 0 to 1, except Rank Correlation, which is a correlation measurement and ranges from -1 to $+1$. Their formal definitions are provided in Appendix A.3.

In the results that follow, we use all of the metrics defined above and reference which one is used where appropriate. When we evaluate a metric to measure the agreement between each pair of explainers, we average the metric over the test data to measure agreement. Both agreement and accuracy measurements are averaged over several trials (see Appendices A.6 and A.5 for error bars).

4.2 Improving Consensus Metrics

The intention of our consensus loss term is to improve agreement metrics. While the objective function explicitly includes only two explainers, we show generalization to unseen explainers as well as to the unseen test data. For example, we train for agreement between Grad and IntGrad and observe an increase in consensus between LIME and SHAP.

To evaluate the improvement in agreement metrics when using our consensus loss term, we compute explanations from each explainer on models trained naturally and on models trained with our consensus loss parameter using $\lambda = 0.5$.

In Figure 4, using a visualization tool developed by Krishna et al. [15], we show how we evaluate the change in an agreement metric (pairwise rank agreement) between all pairs of explainers on the California Housing data.

Hypothesis: *We can increase consensus by deliberately training for post hoc explainer agreement.*

Through our experiments, we observe improved agreement metrics on unseen data and on unseen pairs of explainers. In Figure 4 we show a representative example where Pairwise Rank Agreement between Grad and IntGrad improve from 87% to 96% on unseen data. Moreover, we can look at two other explainers and see that agreement between SmoothGrad and LIME improves from 56% to 79%. This shows both generalization to unseen data and to explainers other than those explicitly used in the loss term. In Appendix A.5, we see more saturated disagreement matrices across all of our datasets and all six agreement metrics.

4.3 Consistency At What Cost?

While training for consensus works to boost agreement, a question remains: How accurate are these models?

To address this question, we first point out that there is a trade-off here, i.e., more consensus comes at the cost of accuracy. With this in mind we posit that there is a Pareto frontier on the accuracy-agreement axes. While we cannot assert that our models are on

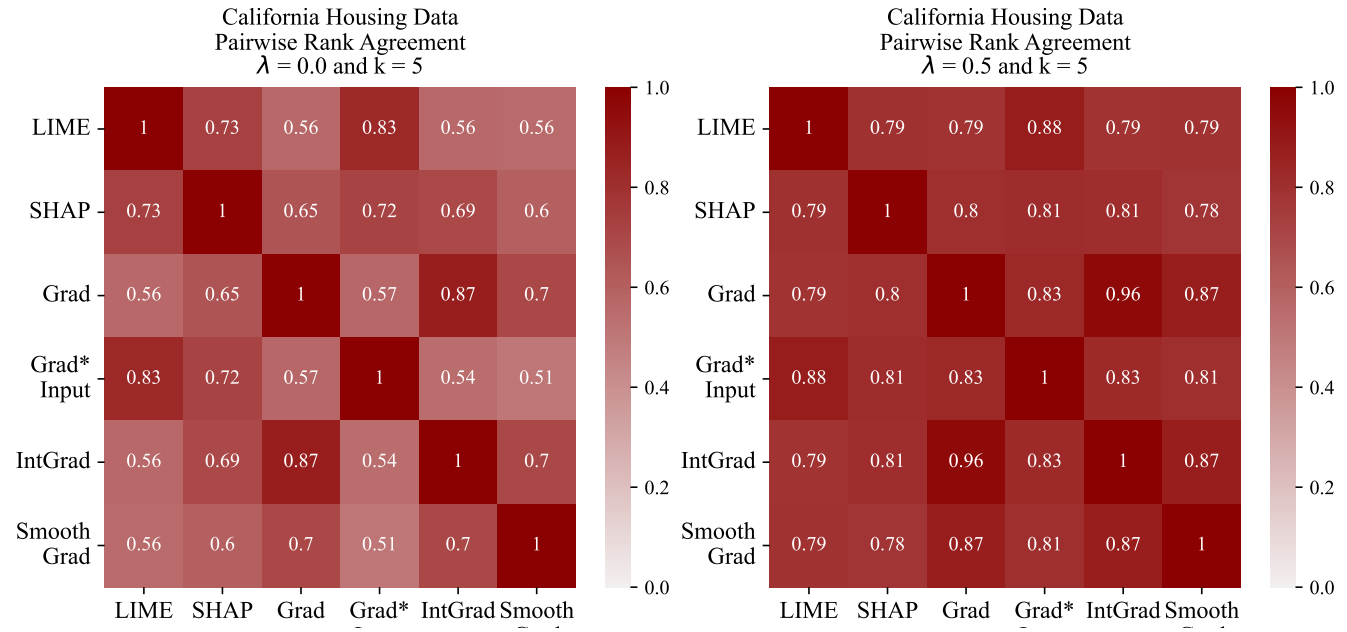

Figure 4: When models are trained naturally, we see disagreement among post hoc explainers (left). However, when trained with our loss function, we see a boost in agreement with only a small cost in accuracy (right). This can be observed visually by the increase in saturation or in more detail by comparing the numbers in corresponding squares.

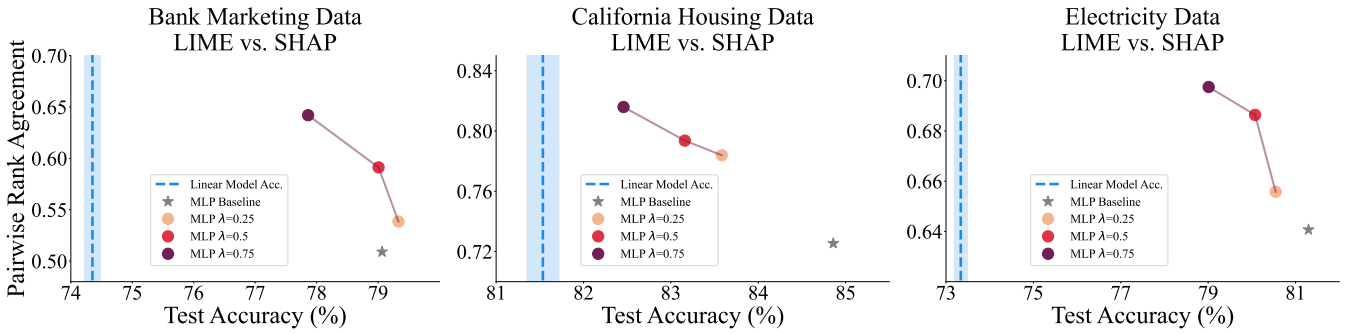

Figure 5: The trade-off curves of consensus and accuracy. Increasing the consensus comes with a drop in accuracy and the trade-off is such that we can achieve more agreement and still outperform linear baselines. Moreover, as we vary the λ value, we move along the trade-off curve. In all three plots we measure agreement with the pairwise rank agreement metric and we show that increased consensus comes with a drop in accuracy, but all of our models are still more accurate than the linear baseline, indicated by the vertical dashed line (the shaded region shows ± one standard error).

the Pareto frontier, we plot trade-off curves which represent the trajectory through accuracy-agreement space that is carved out by changing λ.

Hypothesis: *We can increase consensus with an acceptable drop in accuracy.*

While this hypothesis is phrased as a subjective claim, in reality we define acceptable performance as better than a linear model as explained at the beginning of Section 4. We see across all three datasets that increasing the consensus loss weight λ leads to higher pairwise rank agreement between LIME and SHAP. Moreover, even with high values of λ, the accuracy stays well above linear models indicating that the loss in performance is acceptable. Therefore this experiment supports the hypothesis.

The results plotted in Figure 5 demonstrate that a practitioner concerned with agreement can tune λ to meet their needs of accuracy and agreement. This figure serves in part to illuminate why our hyperparameter choice is sensible—λ gives us control to slide along the trade-off curve, making post hoc explanation disagreement more of a controllable model parameter so that practitioners have more flexibility to make context-specific model design decisions.

4.4 Are the Explanations Still Valuable?

Whether our proposed loss is useful in practice is not completely answered simply by showing accuracy and agreement. A question remains about how our loss might change the explanations in the end. Could we see boosted agreement as a result of some breakdown in how the explainers work? Perhaps models trained with our loss fool explainers into producing uninformative explanations just to appease the agreement term in the loss.

Hypothesis: *We only get consensus trivially, i.e., with feature attributions scores that are uninformative.*

Since we have no ground truth for post hoc feature attribution scores, we cannot easily evaluate their quality [37]. Instead, we reject this hypothesis with an experiment wherein we add random "junky" features to the input data. In this experiment we show that when we introduce junky input features, which by definition have no predictive power, our explainers appropriately attribute near zero importance to them.

Our experimental design is related to other efforts to understand explainers. Slack et al. [33] demonstrate an experimental setup whereby a model is built with ground-truth knowledge that one feature is the only important feature to the model, and the other features are unused. They then adversarially attack the model-explainer pipeline and measure the frequency with which their explainers identify one of the truthfully unimportant features as the most important. Our tactic works similarly, since a naturally trained model will not rely on random features which have no predictive power.

We measure the frequency with which our explainers place one of the junk features in the top-k most important features, using $k = 5$ throughout.

As a representative example, LIME explanations of MLPs trained on this augmented Electricity data put random features in the top five 11.8% of the time on average. If our loss was encouraging models to permit uninformative explanations for the sake of agreement, we might see this number rise. However, when trained with $\lambda = 0.5$, random features are only in the top five LIME features 9.1% of the time – and random chance would have at least one junk feature in the top five over 98% of the time. For results on all three datasets and all six expalainers, see Appendix A.4.

The setting where junk features are most often labelled as one of the top five is when using SmoothGrad to explain models trained on Bank Marketing data with $\lambda = 0$, where for 43.1% of the samples, at least one of the top five is in fact a junk feature. Interestingly, for the same explainer and dataset models trained with $\lambda = 0.5$ lead to explanations that have a junk feature as one of the top five less than 1% of the time, indicating that our loss can even improve this behavior in some settings.

Therefore, we reject this hypothesis and conclude that the explanations are not corrupted by training with our loss.

4.5 Consensus and Linearity

Since linear models are the gold standard in model explainability, one might wonder if our loss is pushing models to be more like linear models. We conduct a quantitative and qualitative test to see whether our method indeed increases linearity.

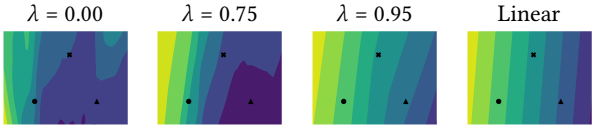

Figure 6: Logit surface contour plots on a plane spanning three real data points from four different models. Left to right: MLPs trained with $\lambda = 0$, $\lambda = 0.75$ and $\lambda = 0.95$ as well as a linear model. Notice that as we increase λ, and move from left to right, we get straighter contours in the logit surface.

Hypothesis: *Encouraging explanation consensus during training encourages linearity.*

Qualitative analysis. In their work on model reproducibility, Somepalli et al. [35] describe a visualization technique wherein a high-dimensional decision surface is plotted in two dimensions. Rather than more complex distance preserving projection tactics, they argue that the subspace of input space defined by a plane spanning three real data points can be a more informative way to visualize how a model's outputs change in high dimensional input space. We take the same approach to study how the logit surface of our model changes with λ. We take three random points from the test set, and interpolate between the three of them to get a planar slice of input space. We then compute the logit surface on this plane (we arbitrarily choose the logit corresponding to the first class). We visualize the contour plots of the logit surface in Figure 6 (more visualizations in Section A.7). As we increase λ, we see that the shape of the contours often tends toward the contour pattern that a linear model takes on that same plane slice of input space.

Quantitative analysis. We can also measure how close to linear a model is quantitatively. The extent to which our models trained with higher λ values are close to linear can be measured as follows. For each of ten random planes in input space (constructed using the three-point method described above), we fit a linear regression model to predict the logit value at each point of the plane, and measure the mean absolute error. The closer this error term is to zero, the more our model's logits on this input subspace resemble a linear model. In Figure 7 we show the error values of the linear fit drop as we increase the weight on the consensus loss for the Electricity dataset. Thus, these analyses support the hypothesis that encouraging consensus encourages linearity.

But if our consensus training pushes models to be closer to linear, does any method that increases the linearity measurement also lead to increased consensus? We consider the possibility that any approach to make models closer to linear improves consensus metrics.

Hypothesis: *Linearity implies more explainer consistency.*

To explore another path toward more linear models, we train a set of MLPs without our consensus loss but with various weight decay coefficients. In Figure 7, we show a drop in linear-best-fit error across the random three-point planes which is similar to the drop observed by increasing λ, showing that increasing weight decay also encourages models to be closer to linear.

But when evaluating these MLPs with increasing weight decay by their consensus metrics, they show near-zero improvement. We

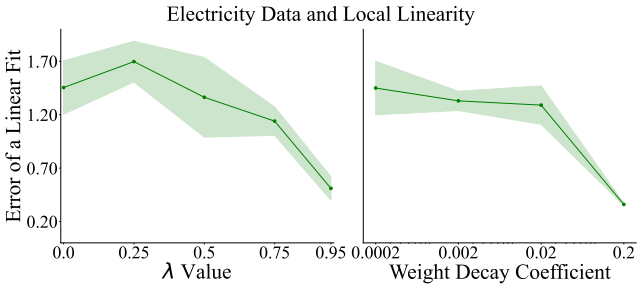

Figure 7: Sampled linear-best-fit error (MAE) measurements as λ increases and as the weight decay coefficient increases. Both approaches lead to lower error of a linear approximation on the Electricity dataset. This indicates that both weight decay and consensus training are correlated with linear fit. The shaded region corresponds to ± one standard error.

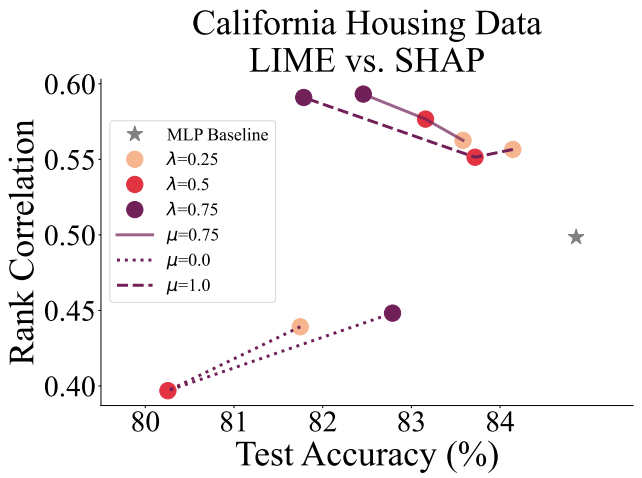

Figure 8: We perform an ablation study of our loss term parameter μ to show why, when training to improve correlation between feature attribution scores, using both Spearman and Pearson correlation can be better than using just one type of correlation.

therefore reject this hypothesis—linearity alone does not seem to be enough to improve consensus on post hoc explanations.

4.6 Two Loss Terms

For the majority of experiments, we set $\mu = 0.75$, which is determined by a coarse grid search. And while it may not be optimal for every dataset on every agreement metric, we seek to show that the extreme values $\mu = 0$ and $\mu = 1$, which each correspond to only one correlation term in the loss, can be suboptimal. This ablation study serves to justify our choice of incorporating two terms in the loss. In Figure 8, we show the agreement-accuracy trade-off for multiple values of μ and of λ. We see that $\mu = 0.75$ shows the more optimal trade-off curve.

In Appendix A.7, where we show more plots like Figure 8 for other datasets and metrics, we see that the best value of μ varies case by case. This demonstrates the importance of having a tunable parameter within our consensus loss term to be tweaked for better performance.

5 DISCUSSION

The empirical results we present demonstrate that our loss term is effective in its goal of boosting consensus among explainers. As with any first attempt at introducing a new objective to neural network training, we see modest results in some settings and evidence that hyperparameters can likely be tuned on a case-by-case basis. It is not our aim to leave practitioners with a how-to guide, but rather to begin exploring how practitioners can control where a model lies along the accuracy-agreement trade-off curve.

We introduce a loss term measuring two types of correlation between explainers, which unfortunately adds more complexity to the machine learning engineer's job of tuning models. But, we show conclusively that there are settings in which using both types of correlation is better than using only one when encouraging explanation consensus.

Another limitation of these experiments as a guide on how to train for consensus is that we only trained with one pair of explainers. Our loss is defined for any pair and perhaps another choice would better suit specific applications.

In light of the contentious debate on whether deep models or decision-tree-based methods are better for tabular data [10, 31, 38], we argue that developing new tools for training deep models can help promote wider adoption for tabular deep learning. Moreover, with the results we present in this work, it is our hope that future work improves these trends, which could possibly lead to neural models that have more agreement (and possibly more accuracy) than their tree-based counterparts (such as XGBoost).

5.1 Future Work

Armed with the knowledge that training for consensus with PEAR is possible, we describe several exciting directions for future work. First, as alluded to above, we explored training with only one pair of explainers, but other pairs may help data scientists who have a specific type of target agreement. Work to better understand how a given pair of explainers in the loss affects the agreement of other explainers at test time could lead to principled decisions about how to use our loss in practice. Indeed, PEAR could fit into larger learning frameworks [22] that aim to select user- and task-specific explanation methods automatically.

It will be crucial to study the quality of explanations produced with PEAR from a human perspective. Ultimately, both the efficacy of a single explanation and the efficacy of agreement between multiple explanations is tied to how the explanations are used and interpreted. Since our work only takes a quantitative approach to demonstrate improvement when regularizing for explanation consensus, it remains to be seen whether actual human practitioners would make better judgments about models trained with PEAR vs models trained naturally.

In terms of model architecture, we chose standard sized MLPs for the experiments on our tabular datasets. Recent work proposes

transformers [36] and even ResNets [10] for tabular data, so completely different architectures could also be examined in future work as well.

Finally, research into developing better explainers could lead to an even more powerful consensus loss term. Recall that IntGrad integrates the gradients over a path in input space. The designers of that algorithm point out that a straight path is the canonical choice due to its simplicity and symmetry [37]. Other paths through input space that include more realistic data points, instead of paths of points constructed via linear interpolation, could lead to even better agreement metrics on actual data.

5.2 Conclusion

In the quest for fair and accessible deep learning, balancing interpretability and performance are key. It is known that common explainers may return conflicting results on the same model and input, to the detriment of an end user. The gains in explainer consensus we achieve with our method, however modest, serve to kick start others to improve on our work in aligning machine learning models with the practical challenge of interpreting complex models for real-life stakeholders.

ACKNOWLEDGMENTS

We thank Teresa Datta and Daniel Nissani at Arthur for their insights throughout the course of the project. We also thank Satyapriya Krishna, one of the authors of the original Disagreement Problem paper, for informative email exchanges that helped shape our experiments.

A APPENDIX

A.1 Datasets

In our experiments we use tabular datasets originally from OpenML and compiled into a set of benchmark datasets from the Inria-Soda team on HuggingFace [11]. We provide some details about each dataset:

Bank Marketing This is a binary classification dataset with six input features and is approximately class balanced. We train on 7,933 training samples and test on the remaining 2,645 samples.

California Housing This is a binary classification dataset with seven input features and is approximately class balanced. We train on 15,475 training samples and test on the remaining 5,159 samples.

Electricity This is a binary classification dataset with seven input features and is approximately class balanced. We train on 28,855 training samples and test on the remaining 9,619 samples.

A.2 Hyperparamters

Many of our hyperparameters are constant across all of our experiments. For example, all MLPs are trained with a batch size of 64, and initial learning rate of 0.0005. Also, all the MLPs we study are 3 hidden layers of 100 neurons each. We always use the AdamW optimizer [19]. The number of epochs varies from case to case. For all three datasets, we train for 30 epochs when $\lambda \in \{0.0, 0.25\}$ and 50 epochs otherwise. When training linear models, we use 10 epochs and an initial learning rate of 0.1.

A.3 Disagreement Metrics

We define each of the six agreement metrics used in our work here.

The first four metrics depend on the top-k most important features in each explanation. Let $top\_features(E, k)$ represent the top-k most important features in an explanation E, let $rank(E, s)$ be the importance rank of the feature s within explanation E, and let $sign(E, s)$ be the sign (positive, negative, or zero) of the importance score of feature s in explanation E.

Feature Agreement

$$\frac{|top\_features(E_1, k) \cap top\_features(E_2, k)|}{k} \tag{4}$$

Rank Agreement

$$\frac{|\bigcup_{s \in S}\{s \in top\_features(E_1, k) \wedge s \in top\_features(E_2, k) \wedge rank(E_1, s) = rank(E_2, s)\}|}{k} \tag{5}$$

Sign Agreement

$$\frac{|\bigcup_{s \in S}\{s \in top\_features(E_1, k) \wedge s \in top\_features(E_2, k) \wedge sign(E_1, s) = signrank(E_2, s)\}|}{k} \tag{6}$$

Signed Rank Agreement

$$\frac{|\bigcup_{s \in S}\{s \in top\_features(E_1, k) \wedge s \in top\_features(E_2, k) \wedge rank(E_1, s) = rank(E_2, s) \wedge sign(E_1, s) = sign(E_2, s)\}|}{k} \tag{7}$$

The next two agreement metrics depend on all features within each explanation, not just the top-k. Let R be a function that computes the ranking of features within an explanation by importance.

Rank Correlation

$$\sum_i \frac{(R(a)_i - \overline{R(a)})(R(b)_i - \overline{R(b)})}{\|R(a)\|\|R(b)\|} \tag{8}$$

Lastly, let $RelR(E, f_i, f_j)$ be a relative ranking function that returns 1 when feature f_i has higher importance than feature f_j in explanation E, and let F be any set of features.

Pairwise Rank Agreement

$$\frac{\sum_{i<j} \mathbb{1}[RelR(E_1, f_i, f_j) = RelR(E_2, f_i, f_j)]}{\binom{|F|}{2}} \tag{9}$$

(Note: Krishna et al. [15] specify in their paper that F is to be a set of features specified by an end user, but in our experiments we use all features with this metric).

A.4 Junk Feature Experiment Results

When we add random features for the experiment in Section 4.4, we double the number of features. We do this to check whether our consensus loss damages explanation quality by placing irrelevant features in the top-K more often than models trained naturally. In Table 1, we report the percentage of the time that each explainer included one of the random features in the top-5 most important features. We observe that across the board, we do not see a systematic increase of these percentages between $\lambda = 0.0$ (a baseline MLP without our consensus loss) and $\lambda = 0.5$ (an MLP trained with our consensus loss).

Table 1: Frequency of junk features getting top-5 ranks, measured in percent.

		LIME	SHAP	GRAD	Input*Grad	IntGrad	SmoothGrad	Random Chance
Bank Marketing	$\lambda = 0.0$	30.4	17.1	1.1	43.2	0.0	43.1	98.9
	$\lambda = 0.5$	25.1	12.0	0.1	34.9	0.0	0.1	
California Housing	$\lambda = 0.0$	22.6	8.7	0.0	24.8	0.0	0.3	98.5
	$\lambda = 0.5$	21.2	20.4	1.4	25.9	1.4	0.9	
Eelectricity	$\lambda = 0.0$	11.8	16.0	4.0	15.8	0.9	6.8	98.5
	$\lambda = 0.5$	9.1	9.5	1.7	8.6	0.8	3.1

ABSTRACT

The operationalization of algorithmic fairness comes with several practical challenges, not the least of which is the availability or reliability of protected attributes in datasets. In real-world contexts, practical and legal impediments may prevent the collection and use of demographic data, making it difficult to ensure algorithmic fairness. While initial fairness algorithms did not consider these limitations, recent proposals aim to achieve algorithmic fairness in classification by incorporating noisiness in protected attributes or not using protected attributes at all.

To the best of our knowledge, this is the first head-to-head study of fair classification algorithms to compare attribute-reliant, noise-tolerant and attribute-unaware algorithms along the dual axes of predictivity and fairness. We evaluated these algorithms via case studies on four real-world datasets and synthetic perturbations. Our study reveals that attribute-unaware and noise-tolerant fair classifiers can potentially achieve similar level of performance as attribute-reliant algorithms, even when protected attributes are noisy. However, implementing them in practice requires careful nuance. Our study provides insights into the practical implications of using fair classification algorithms in scenarios where protected attributes are noisy or partially available.

1 INTRODUCTION

In October 2022, the White House released the Blueprint for an AI Bill of Rights [56]. This document, like other statements of AI principles [21, 30, 47, 49, 57], calls for protections against unfair discrimination (colloquially, *fairness*) to be deeply integrated into all AI systems. Researchers and journalists have led the way in this area, both in terms of identifying unfairness in real world systems [6, 11, 14, 44], and in the development of machine learning (ML) classifiers that jointly optimize for predictive performance and fairness [18, 26, 34, 37] (for a variety of different definitions of fairness [4, 27, 58, 63]).

Despite the widespread acknowledgment that fairness is a key component of trustworthy AI, formidable challenges remain to the adoption of fair classifiers in real world scenarios—chief among them being questions about demographic data itself. Many *classical fair classifiers* assume that protected attributes are available at training time and/or testing time [18] and that this data is accurate. However, demographic data may be noisy for a variety of reasons, including imprecision in human-generated labels [15], reliance on imperfect demographic-inference algorithms to generate protected attributes [23], or the presence of an adversary that is intentionally poisoning demographic data [24]. To attempt to deal with these issues, researchers have proposed *noise-tolerant fair classifiers* that aim to achieve distributional fairness by incorporating the error rate of demographic attributes in the fair classifier optimization process itself [13, 48, 60].

In other instances demographic data may not be available at all, which violates the assumptions of both classical and noise-tolerant fair classifiers. This may occur when demographic data is unobtainable (e.g., laws or social norms impede collection [5, 10]), prohibitively expensive to generate (e.g., when large datasets are scraped from the web [16, 35, 41]), or when laws disallow the use of protected attributes to train classifiers (e.g., direct discrimination [62]). For cases such as these, researchers have proposed *demographic-unaware fair classifiers* that use the latent representations in the feature space of the training data to reduce gaps in classification errors between protected groups, either via assigning higher weights to groups of training examples that are misclassified [28], or by training an auxiliary adversarial model to computationally identify regions of misclassification [39].

Motivated by this explosion of fundamentally different fair classifiers, we present an empirical, head-to-head evaluation of the performance of 14 classifiers in this study, spread across four classes: two *unconstrained classifiers*, seven classical fair classifiers, three noise-tolerant fair classifiers, and two demographic-unaware classifiers. Drawing on the methodological approach used by Friedler et al. [22] in their comparative study of classical fair classifiers, we evaluate the accuracy, stability, and fairness guarantees (defined as the equal odds difference) of these 14 classifiers across four datasets as we vary noise in the protected attribute (sex). To help explain the performance differences that we observe, we calculate and compare the feature importance vectors for our various trained classifiers. This methodological approach

AIES '23, August 08–10, 2023, Montréal, QC, Canada

ACM ISBN 979-8-4007-0231-0/23/08…$15.00
https://doi.org/10.1145/3600211.3604707

enables us to compare the performance of these 14 algorithms under controlled, naturalistic circumstances in an apples-to-apples manner.

Based on our head-to-head evaluation we make the following key observations:

- Two classical fair classifiers, one noise-tolerant fair classifier, and one demographic-unaware fair classifier performed consistently well across all metrics on our experiments.
- The best classifier for each case study showed some variability, confirming that the choice of dataset is an important factor when selecting a model.
- One demographic-unaware fair classifier was able to achieve equal odds for males and females under a variety of ecological conditions, confirming that demographics are not always necessary at training or testing time to achieve fairness.

We release our source code and data[1] so that others can replicate and expand upon our results.

We argue that large-scale, head-to-head evaluations such as the one we conduct in this study are critical for researchers and ML practitioners. Our results act as a checkpoint, informing the community about the relative performance characteristics of classifiers within and between classes. For researchers, this can highlight gaps where novel algorithms are still needed (e.g., noise-tolerant and demographic-unaware classifiers, based on our findings) and provide a framework for rigorously evaluating them. For practitioners, our results highlight the importance of thoroughly evaluating many classifiers from many classes before adopting one in practice, and we provide a roadmap for choosing the best classifiers for a given real-world scenario, depending on the availability and quality of demographic data.

Our study proceeds as follows: in § 2 we present a brief overview of the history of fair models and head-to-head performance evaluation. Next, in § 3, we introduce the 14 classifiers and the metrics we use to evaluate them for predictive performance and fairness. In § 4 we present our experimental approach, including the datasets we use for our four case studies. In § 5 we present the results of our experiments and we discuss our findings in § 6.

2 RELATED WORK

We discuss different classes of fair classifiers, their known shortcomings, and how they have been evaluated in the past.

2.1 Fair Classifiers

Dwork et al. [18] were one of the first to operationalize the idea of fairness in machine learning classifiers, through their key observation that awareness of demographics is crucial for building models that rectify unfair discrimination and historical inequity. Their work takes the idea of awareness literally, by incorporating protected attributes directly into the model and jointly optimizing for accuracy and fairness. Many subsequent works have built on this foundation by developing versions of classical ML classifiers that incorporate fairness constraints (e.g., decision trees, random forests, SVMs, boosting, etc. [46]).

[1]The code and data for replicating this paper can be found at https://github.com/evijit/Awareness_vs_Unawareness

Collectively, we refer to this class of algorithms as classical fair classifiers. They are now widely available to practitioners [9, 42, 52] and have been adopted into real-world systems [19].

While classical fair classifiers are an important advance over their unconstrained predecessors, they rely on a strong assumption that data about protected attributes is accurate. Unfortunately, this may not be true in practice. For example, in contexts like finance and employment candidate screening, demographic data may not be available due to legal constraints or social norms [10, 62], yet the need to fairly classify people remains paramount. To bridge this gap, practitioners may infer peoples' protected attributes using human labelers [8] or algorithms that take names, locations, photos, etc. as input [1]. However, work by Ghosh et al. [23] demonstrates that these inference approaches produce noisy demographic data, and that this noise obviates the fairness guarantees provided by fair models.

With these limitations in mind, researchers have begun developing what we refer to as noise-tolerant fair classifiers that, as the name suggests, jointly optimize for accuracy and fairness in the presence of uncertainty in the protected attribute data. Approaches include robust optimization that adjusts for the presence of noise in the fairness constraint [60], adjusting the "fairness tolerance" value for binary protected groups [40], using noisy attributes to post-process the outputs for fairness instead of the true attributes under certain conditional independence assumptions [7], estimating de-noised constraints that allow for near optimal fairness [13], or a combination of approaches [48].

Noise-tolerant fair classifiers, like classical fair classifiers, still rely on the assumption that protected attributes are available at training time. As we discuss in § 1, however, there are many real-world contexts when this assumption may be violated. The strongest such impediment is legal, i.e., any inclusion of protected attributes in the classifier would be considered illegal direct discrimination.

A different approach for achieving fairness through awareness that is amenable to these strong constraints is embodied by what we refer to as demographic-unaware fair classifiers. These algorithms do not take protected attributes as input, but they attempt to achieve demographic fairness anyway by relying on the latent representations of the training data [28, 39]. Thus, this approach to classification still incorporates a general awareness of unfair discrimination and historical inequity without being directly aware of demographics.

While demographic-unaware fair classifiers are an attractive solution in contexts where protected attributes are unavailable, practical questions about the efficacy of these algorithms remain. First, because these techniques are unsupervised, it is unclear what groups are identified for fairness optimization. Under what circumstances are demographic-unaware fair classifiers able to achieve fairness for social groups that have been historically marginalized or are legally protected? Conversely, are the groups constructed by demographic-unaware fair classifiers arbitrary and thus divorced from salient real-world sociohistorical context? Second, assuming that demographic-unaware fair classifiers do identify and act on meaningful groups of individuals, how does their performance (in terms of predictions and fairness) compare to classical and noise-tolerant fair classifiers? In this study, our goal

is to begin answering these questions about relative performance across all four classes of fair classifiers.

2.2 Head-to-Head Evaluation

It is standard practice for ML researchers to compare the performance of their novel algorithms against competitors. However, these comparisons are rarely comprehensive, i.e., they focus on comparisons with a narrow set of comparable algorithms to demonstrate advances over the state-of-the-art. While these evaluations are crucial for assessing the benefits of new algorithms, they do not paint a complete picture of performance across a variety of different algorithms, spanning both time and fundamental approaches.

Benchmark studies address this gap by focusing on the evaluation of a large set of models under expansive and carefully controlled conditions [22, 29]. These studies provide important context for the ML field, e.g., by identifying models that do not work well in practice, models that have equivalent performance characteristics under a wide range of circumstances, and areas where new models may be needed. To the best of our knowledge, existing benchmark studies focus solely on classical fair classifiers, which motivates us to update their results. Thus, in this study we adopt the methodological approach for evaluation developed by Friedler et al. [22] and build upon their work by evaluating four different classes of classifiers (both fairness constrained and unconstrained).

3 ALGORITHMS AND METRICS

In this section, we introduce the 14 classifiers that we evaluated in this study and the metrics we used to evaluate them.

3.1 Classifiers

We group the classifiers that we evaluated in this study into four classes: (1) unconstrained classifiers that solely optimize for accuracy; (2) classical fair classifiers that require access to protected attributes at training (and sometimes testing) time, and assume that this data are accurate; (3) noise-tolerant fair classifiers that also require access to protected attributes but account for uncertainty in the data; and (4) demographic-unaware fair classifiers that jointly optimize for accuracy and fairness but without access to any protected attribute data. The set of classifiers we have selected is not exhaustive. Instead, we aim to include representative classifiers from the various types of approaches that exist within each class. We discuss the classifiers from each class that we selected for our study below, with further details on related approaches in each subsection.

3.1.1 Unconstrained Classifiers. We chose two classifiers that do not have any fairness constraints, i.e., they only aim to maximize predictive accuracy.

- **Logistic Regression (LR)** is the simplest classifier we evaluate. While LR is demographic-aware because it takes all features (including protected attributes) as model inputs at both train and test time, it is not designed to achieve any fairness criteria.
- **Random Forest (RF)** is an ensemble method for classification built out of decision trees. Like LR, we train RF classifiers on all input features including protected attributes.

3.1.2 Classical Fair Classifiers. We chose seven classifiers from the literature that take protected attributes as input and attempt to achieve demographic fairness. These classifiers vary with respect to how they implement fairness, i.e., by pre-processing data, in-process during model training, or by post-processing the trained model. In particular, there exist many techniques for fairness optimization in this class, such as: reweighting of samples via group sizes [12, 20, 32] or via mutual independence of protected and unprotected features in the latent representations [64, 65], adding fairness constraints during the learning process [2, 3, 34, 63], or by changing the output labels to match some fairness criterion [33, 50]. The seven classifiers we choose below are representative of these different approaches.

- **Sample Reweighting (SREW)** is a pre-processing technique that takes each (group, label) combination in the training data and assigns rebalanced weights to them. The goal of this procedure is to remove imbalances in the training data, with the ultimate aim of ensuring fairness before the classifier is trained [32].
- **Learned Fair Representation (LFR)** is a pre-processing technique that converts the input features into a latent encoding that is designed to represent the training data well while simultaneously hiding protected attribute information from the classifier [64].
- **Adversarial Debiasing (ADDEB)** is an in-process technique that trains a classifier to maximize accuracy while simultaneously reducing an adversarial network's ability to determine the protected attributes from the predictions [65].
- **Exponentiated Gradient Reduction (EGR)** is an in-process technique that reduces fair classification to a set of cost-sensitive classification problems, essentially treating the main classifier itself as a black box and forcing the predictions to be the most accurate under a given fairness constraint [2]. In this case, the constraint is solved as a saddle point problem using the exponentiated gradient algorithm.
- **Grid Search Reduction (GSR)** uses the same set of cost-sensitive classification problems approach as EGR, except in this case the constraints are solved using the grid search algorithm [2, 3].
- **Calibrated Equalized Odds (CALEQ)** is a post-processing technique that optimizes the calibrated classifier score output to find the probabilities that it uses to change the output labels, with an equalized odds objective [50].
- **Reject Option Classifier (ROC)** is a post-processing technique that swaps favorable and unfavorable outcomes for privileged and unprivileged groups around the decision boundaries with the highest uncertainty [33].

Note that the CALEQ and ROC algorithms have access to protected attributes at both train and test time, while the other classifiers only have access to protected attributes at training time.

3.1.3 Noise-tolerant Fair Classifiers. We chose three classifiers from the literature that take protected attributes as input and attempt to achieve demographic fairness even in the presence of

noise. Other than the three classifiers that we chose, we are aware of only one other approach: by Celis et al. [13], who suggests using de-noised constraints to achieve near-optimal fairness.[2]

- **Modified Distributionally Robust Optimization (MDRO)** by Wang et al. [60] is an extension of the Distributionally Robust Optimization (DRO) algorithm [28] that adds a maximum total variation distance in the DRO procedure. By assuming a noise model for the protected attributes, it aims to provide tighter bounds for DRO.
- **Soft Group Assignments (SOFT)**, also by Wang et al. [60], is a theoretically robust approach that first performs "soft" group assignments and then performs classification, with the idea being that if an algorithm is fair in terms of those robust criteria for noisy groups, then they must also be fair for true protected groups [31].
- **Private Learning (PRIV)** is an approach by Mozannar et al. [48] that uses differential privacy techniques to learn a fair classifier while having partial access to protected attributes. The approach requires two steps. The first step is to obtain locally private versions of the protected attributes (like Lamy et al. [40]). Second, following Awasthi et al. [7], PRIV tries to create a fair classifier based on the private attributes. For this study, we select the privacy level hyperparameter to be a medium value (zero).

3.1.4 Demographic-unaware Fair Classifiers. We chose two classifiers from the literature that attempt to achieve fairness without taking protected attributes as input.

- **Adversarially Reweighted Learning (ARL)** harnesses non-protected attributes and labels by utilizing the computational separability of these training instances to divide them into subgroups, and then uses an adversarial reweighting approach on the subgroups to improve classification fairness [39].
- **Distributionally Robust Optimization (DRO)** is an algorithm that attempts to minimize the worst case risk of all groups that are close to the empirical distribution [28]. In the spirit of Rawlsian distributive justice, the algorithm tries to control the risk to minority groups while being oblivious to their identities.

These two classifiers operate under similar principles: they both try to reduce the gap in errors between protected groups by reducing the classification errors between latent groups in the training set. They do however have one difference: while DRO just increases the weights of the training examples that have higher errors, ARL trains an auxillary adversarial network to identify the regions in the latent input space that lead to higher errors and tries to equalize them, a phenomenon Lahoti et al. [39] call *computational identifiability*.

3.2 Evaluation Metrics

To compare the above 14 classifiers head-to-head, we studied their predictive power and their ability to achieve a fairness condition. We also measured the stability of these quantities when noise in the protected attributes was and was not present (described in § 4.2).

To assess predictive performance we computed accuracy, defined as:

$$\text{Accuracy} = \frac{\text{number of correct classifications}}{\text{test dataset size}}. \quad (1)$$

Accuracy is continuous between zero and one with the ideal value being one, which indicates a perfectly predictive classifier.

Many measures of fairness exist in the literature [46]. For the purposes of this study, however, we needed to choose a metric that is supported by all the 14 classifiers so that our comparison is apples-to-apples. The classical and noise-tolerant fair classifiers have support for achieving any user-specified fairness constraint, while the demographic-unaware fair classifiers try to minimize the gap in utility between the protected groups. Based on this limitation, and for the sake of brevity, we choose the Average Odds Difference between two demographic groups as our fairness metric, and subsequently choose Equal Odds Difference (EOD) over both groups as our regularization constraint for the classical and noise-tolerant fair classifiers. EOD is defined as:

$$\text{EOD} = \frac{(\text{FPR}_{\text{unpriv}} - \text{FPR}_{\text{priv}}) + (\text{TPR}_{\text{unpriv}} - \text{TPR}_{\text{priv}})}{2} \quad (2)$$

where TPR is the true positive rate and FPR is the false positive rate. Priv and Unpriv denote the privileged and unprivileged groups, respectively. The ideal value of EOD is zero, which indicates that both groups have equal odds of correct and incorrect classification by the trained classifier.

In this study, when we evaluate fairness, we do so for binary sex attributes. We adopted this approach because the datasets we use in our evaluation all include this attribute (see § 4) and four classifiers in our evaluation (e.g., CALEQ, ROC, EGR, GSR) only support fairness constraints over two groups. Whenever necessary, we consider males to be the privileged group and females to be the unprivileged group. Note that optimizing for fairness between two groups is the simplest scenario that fair classifiers will encounter in practice—if they perform poorly on this task, then they are unlikely to succeed in more complex scenarios with multiple, possibly intersectional, groups.

4 METHODOLOGY

In this section, we describe the approach we used to empirically evaluate the 14 classifiers that we chose for our study.

4.1 Case Studies

To observe how the classifiers perform on real-world data we chose four different datasets. The classification tasks are described below. Each dataset had binary sex as part of the input features.

(1) **Public Coverage [17].** The task is to predict whether an individual (who is low income and not eligible for Medicare) was covered under public health insurance. We used census data from California for the year 2018.
(2) **Employment [17].** The task is to predict whether an individual (between the ages of 16 and 90), is employed. For this task too, we looked at census data from California for the year 2018.
(3) **Law School Admissions [61].** The task is to predict whether a student was admitted to law school.

[2] Celis et al. [13]'s source code only supported Statistical Parity and False Discovery constraints, not EOD, which is why we omitted their classifier from our analysis.

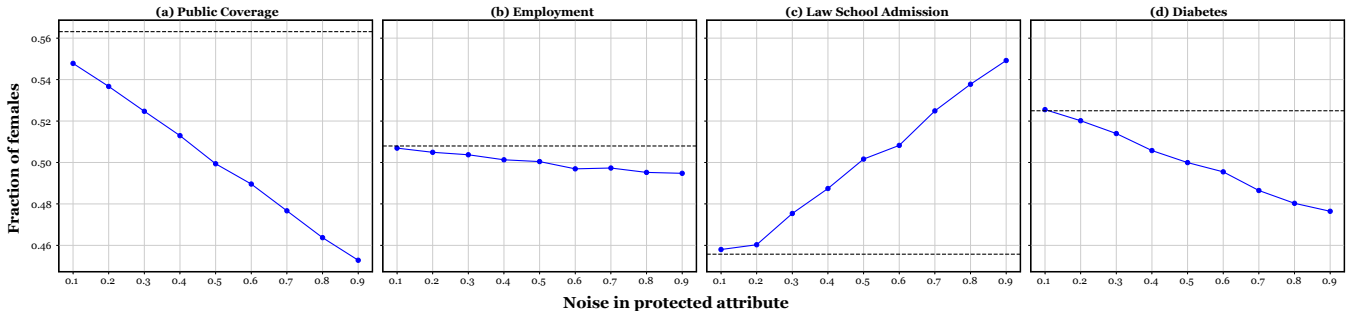

Figure 1: Fraction of females in our datasets after adding synthetic noise. The dashed line indicates the true fraction of females.

(4) **Diabetes [54].** The task is to predict whether a diabetes patient was readmitted to the hospital for treatment after 30 days.

For each of these case studies, we split the dataset into train and test sets in an 80:20 ratio, trained every classifier on the same training set, and then used the trained classifiers to generate predictions on the same testing set. We verified via two-tailed Kolmogorov–Smirnov tests [36, 53] and Mann–Whitney U tests [45] that the test set distribution for every feature was the same as the training set distribution. Finally, we calculated the metrics in § 3.2 on these predictions and compared the results from each classifier head-to-head. We repeated this procedure ten times to assess the stability of accuracy and EOD for each classifier.

4.2 Synthetic Noise

While studying the performance of these classifiers on a variety of real-world datasets is important, in order to get a more thorough understanding of the theoretical fairness and predictivity limits of the classifiers we subjected them to robust synthetic stress tests. As discussed in § 2.1, in the real world, practitioners may not have access to the protected attribute information of people in their dataset. As a result, practitioners may use inference tools to find proxies for protected attributes, which can lead to unexpected, unfair outcomes [23]. To characterize what might happen in such a scenario, we perform the following synthetic experiments:

(1) For each dataset, with a given probability (ranging from 0.1 to 0.9), we randomly flip the protected attribute labels (binary sex in this case) in the dataset. We refer to this probability value as *noise*.
(2) With the synthetically generated dataset from Step 1, we then proceed to split the dataset 80:20, train all 14 algorithms on the same training set, and then calculate predictions on the same test set. The noisy (flipped) labels are passed as inputs to the classifiers at this step.
(3) Next, with the predicted outcomes from Step 2, we calculate accuracy and EOD. Note that we calculate EOD with the *true* protected attributes, i.e., we measure the output bias in terms of the original sex labels from the given dataset.
(4) We repeat Steps 1–3 ten times for each value of noise, to ensure statistical fairness and assess the stability of our metrics per classifier.

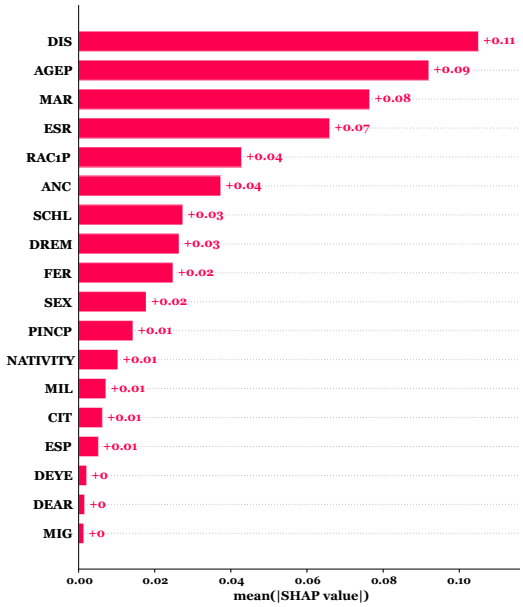

Figure 2: KernelShap feature explanations calculated for the Logistic Regression (LR) classifier when trained on the Public Coverage dataset with no added noise. We used the same approach to calculate feature importances for every classifier-dataset pair at different noise levels.

Figure 1 shows the fraction of females in the noised datasets at each level of noise. The fraction of females goes up or down with noise depending on what the true fraction of females in the different datasets were to begin with.

4.3 Calculating Feature Importance

To help explain the variations in performance that we observed in our results, we calculated feature importance for each of our trained models. Although there are several black-box model explanation tools in the research literature—such as LIME [51], SHAP [43], and Integrated Gradients [55]—we required an explanation method that was model agnostic. The method that we settled on was KernelShap.[3] According to the documentation, KernelShap uses

[3] https://shap-lrjball.readthedocs.io/en/latest/generated/shap.KernelExplainer.html

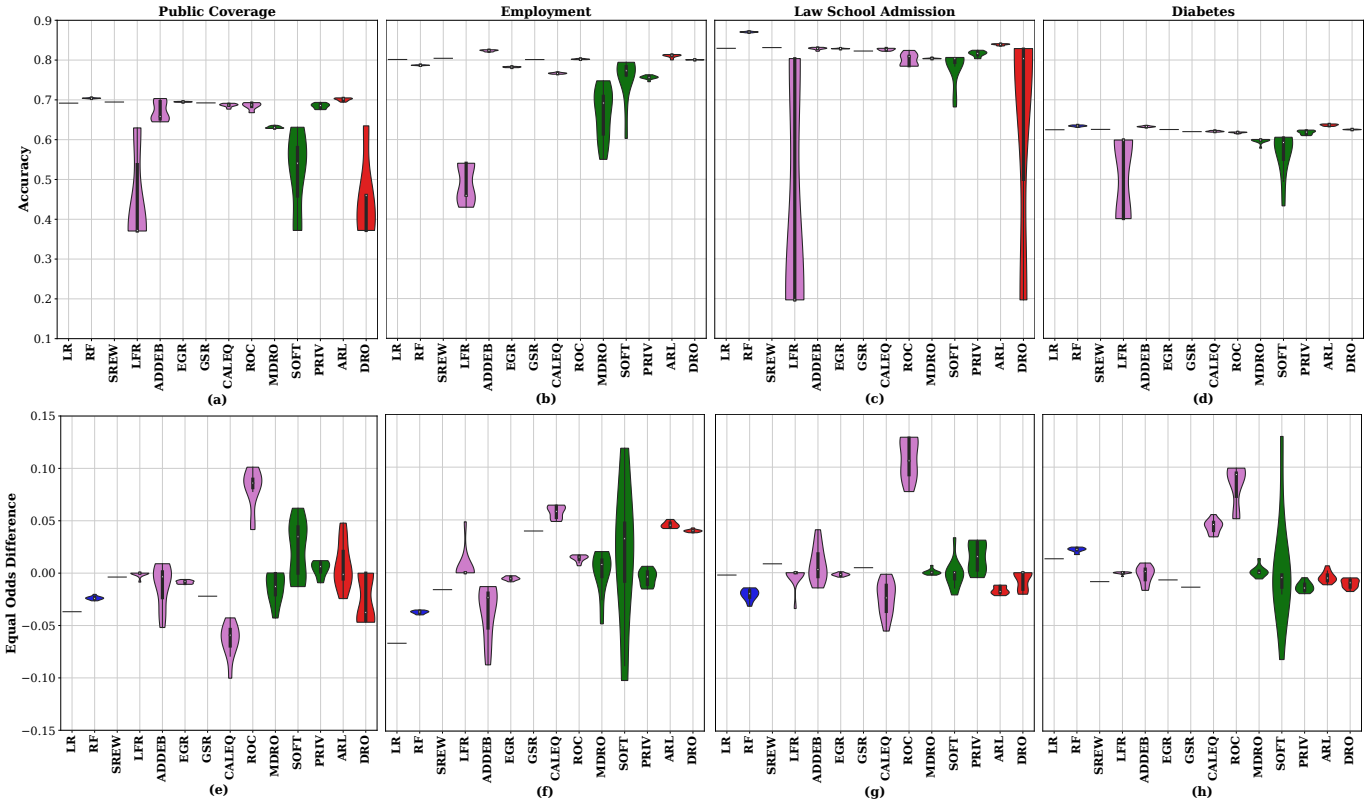

Figure 3: Accuracy and EOD for our 14 classifiers, calculated over four datasets with ten runs each. No noise was added to the protected attribute in these tests. Violins are color coded by class: blue for unconstrained classifiers, purple for classical fair classifiers, green for noise-tolerant fair classifiers, and red for demographic-unaware fair classifiers. LR, SREW, and GSR are deterministic algorithms and therefore appear as fixed points.

a special weighted linear regression model to calculate local coefficients, to estimate the Shapley value (a game theoretic concept that estimates the individual contribution of each player towards the final outcome). As opposed to retraining the model with every combination of features as in vanilla SHAP, KernelShap uses the full model and integrates out different features one by one. It also supports any type of model, not just linear models, and was thus a good candidate for our study.

Figure 2 shows an example distribution of feature importances calculated for the LR algorithm when trained on the Public Coverage dataset at noise level zero (i.e., no noise). In a similar fashion, we used KernelShap to calculate feature importance values for trained classifier outputs at noise levels 0, 0.2, 0.4, 0.6 and 0.8 for all 14 models.

Research by Kumar et al. [38] has shown that different explanation methods often do not agree with each other. We do not claim that the feature importances we calculated using KernelShap are guaranteed to agree with those produced by other tools. Nonetheless, we are specifically interested in the relative importance of the sex feature towards the final outcome as compared to the other input features. Shapley value-based explanations give us a reasonable sense of relative feature importance, as has been empirically shown in previous work [25].

5 RESULTS

In this section, we present the results of our experiments. We begin by examining the baseline performance of the 14 classifiers when there is no noise, followed by their performance in the presence of synthetic noise. Finally, we delve into feature importance explanations to help explain the relative performance characteristics of the classifiers.

5.1 Baseline Characteristics

Figure 3(a–d) shows the accuracy and fairness outcomes for all 14 classifiers when there was no noise in the datasets. We executed each classifier ten times without fixing a random seed and present the resulting distributions of metrics using violin plots. We observe that most of the classifiers achieved comparable accuracy to each other on each dataset, and that most classifiers exhibited stable accuracy over the ten executions of the experiments. Learned Fair Representation (LFR), Soft Group Assignment (SOFT), and Distributed Robust Optimization (DRO) were the exceptions: the former two exhibited unstable accuracy on all four datasets, the latter on two datasets.

As shown in Figure 3(e–h), EOD was considerably more variable over runs than accuracy. The unconstrained classifiers (LR and RF) were relatively stable and, in some cases, achieved roughly

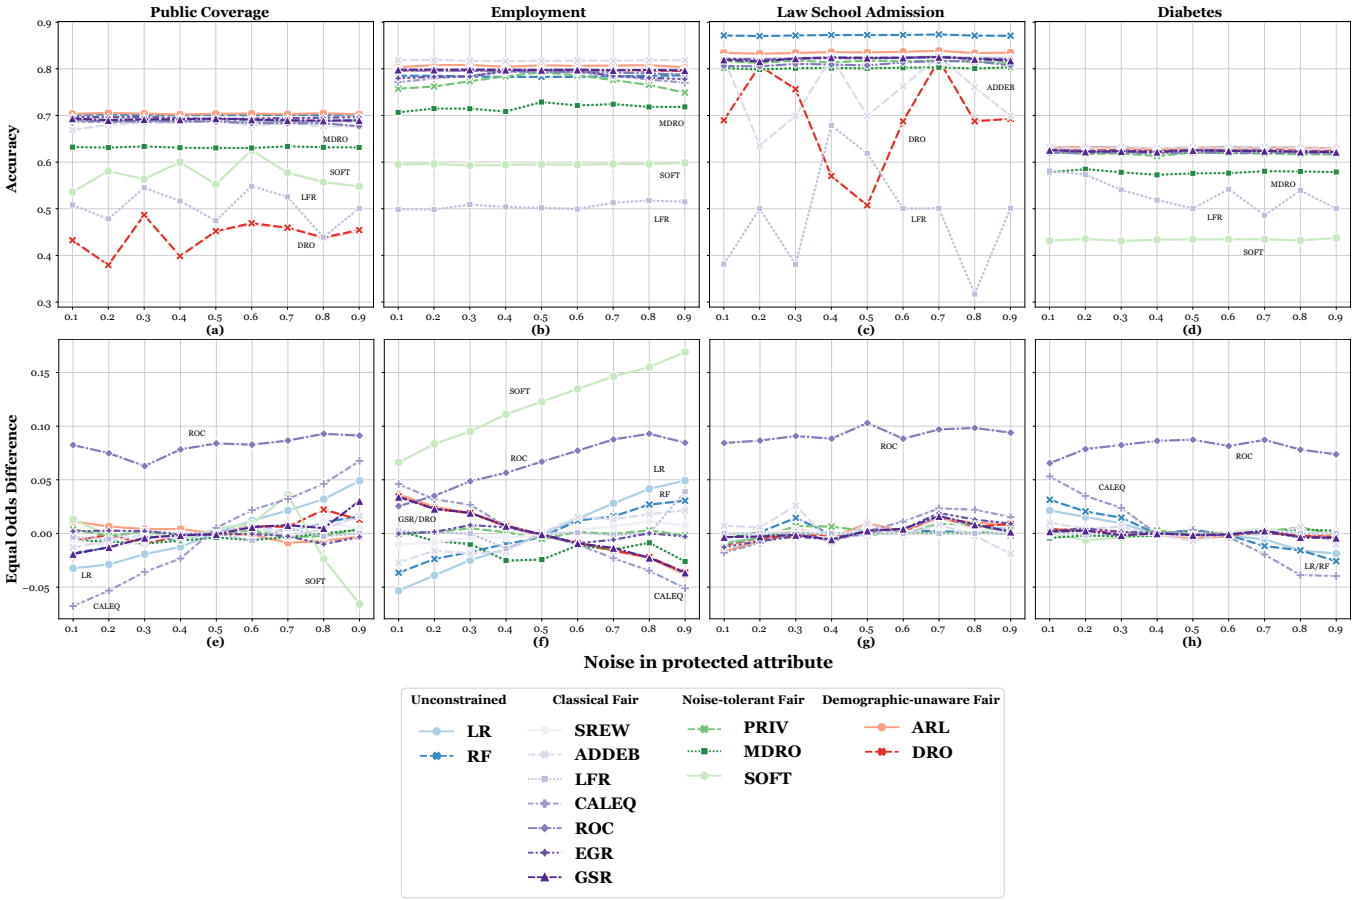

Figure 4: Accuracy and EOD for our 14 classifiers, calculated over four datasets as we increase noise in the protected attribute (sex). Each point is the average of ten runs for a given classifier, dataset, and noise level. Classifiers are color coded according to the legend. We highlight classifiers whose performance significantly diverges from the consensus with annotated labels.

equalized odds (e.g., on the Law School and Diabetes datasets). The classical fair classifier group contained the two least fair classifiers in these experiments (CALEQ and ROC), while the other pre-processing and in-processing algorithms performed relatively better. Adversarial Debiasing (ADDEB) was slightly unstable but the distribution centered around zero. Among the noise-tolerant fair classifiers, Soft Group Assignment (SOFT) was unstable on three out of four datasets, while the other two classifiers (MDRO and PRIV) were relatively more stable and more fair. The two demographic-unaware fair classifiers (ARL and DRO) were unstable on the Public Coverage dataset (Figure 3e) and did not achieve equalized odds on the Employment dataset (Figure 3f). However, ARL and DRO were stable and fair on the remaining two datasets.

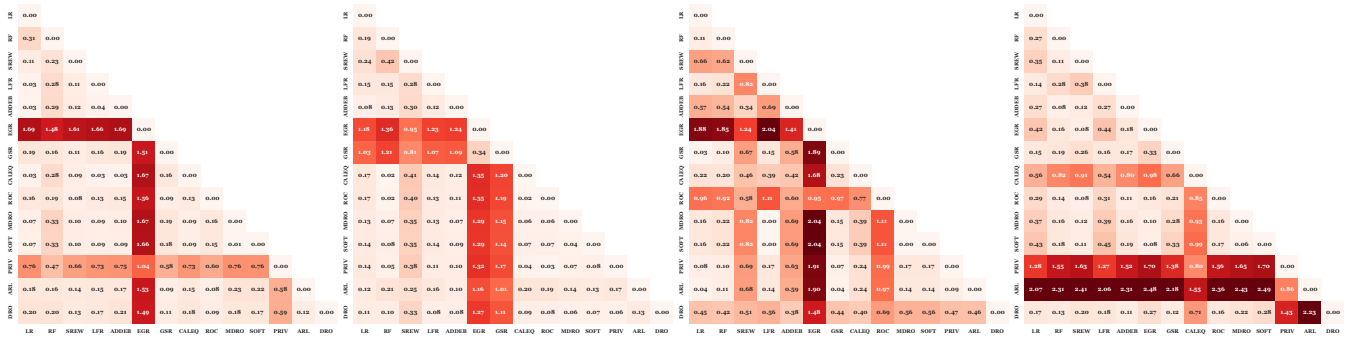
In summary, we observe that the accuracy and fairness performance of these classifiers was dependent on the dataset that they are trained and tested on, i.e., there was no single best classifier. Additionally, we can see that several classifiers are consistently unstable, which explains some of the results that we will present in the next section.

5.2 Characteristics Under Noise

Next, we present the results of experiments where we added noise to the protected attribute of the datasets. We added noise in increments of 0.1 starting from 0.1 and ranging up to 0.9. We added a given amount of noise to each dataset ten times and repeated the experiment, thus we plot the average values of accuracy and EOD for each classifier at each noise level.

Figure 4(a–d) shows the accuracy of the 14 classifiers' outputs as we varied noise. We observe that the MDRO, SOFT, and LFR classifiers had poor accuracy across all datasets and noise levels, while the DRO classifier had poor accuracy in two out of the four datasets. These observations mirror those from Figure 3, i.e., these classifiers exhibited poor average accuracy in the noisy experiments because they were unstable in general. The other classifiers tended to be both accurate and stable, irrespective of noise.

As shown in Figure 4(e–h), the EOD results were much more complex than the accuracy results. ROC generated unfair outputs over all four datasets, at every noise level. Its companion post processing algorithm, CALEQ, exhibited rising EOD with noise for the Public Coverage dataset (Figure 4e) and falling



(a) Public Coverage (b) Employment (c) Law School Admissions (d) Diabetes

Figure 5: Wasserstein distances between the average KernelShap feature importance distributions over different noise levels for the four datasets. Each square compares the average feature importances of two classifiers. Redder squares denote pairs of classifiers with more divergent feature importance distributions.

EOD for the Employment and Diabetes datasets (Figure 4f, h).[4] The unconstrained classifiers (LR and RF) moved in the same direction for every dataset, either rising (Figure 4e, f) or falling (Figure 4h) with noise. The SOFT classifier also exhibited some variable behavior: on the Employment dataset EOD rose with noise (Figure 4f), and on the Public Coverage (Figure 4e) dataset it failed to achieve equal odds at higher noise levels. The remaining classifiers tended to achieve equal odds irrespective of the noise level.

Figure 4 only depicts average values for accuracy and EOD, which is potentially problematic because it may hide instability in the classifiers' performance. To address this we present Figure 7 in the Supplementary Material, which shows the distribution of accuracy and EOD results for each classifier on each dataset at the 0.1, 0.5, and 0.9 noise levels. We observe that, overall, no classifier became consistently less stable as noise increased. Rather, the stability patterns for each classifier mirrored the patterns that we already observed in Figure 3.

In summary, the classifiers that had problematic performance in the baseline experiments (see Figure 3) continued to have issues in the presence of noise. Additionally, the unconstrained classifiers exhibited inconsistent fairness as noise varied. Surprisingly, the noise-tolerant classifiers did not uniformly outperform the other fair classifiers.

5.3 Feature Importance

Finally, we delve into model explanations as a means to further explore the root causes of the classifier performance characteristics that we observed in the previous sections. First, we calculated feature explanations using KernelShap for every classifier at five noise levels—0, 0.2, 0.4, 0.6 and 0.8—using the method we described in § 4.3. Next, we averaged the explanation distributions for each classifier to form a feature importance vector per classifier. Finally, we repeated this process for each dataset. For each dataset, we calculated Wasserstein distances [59] between the feature explanation distributions for each algorithm pair and present the results in Figure 5. Additionally, we plot the rank of the sex feature

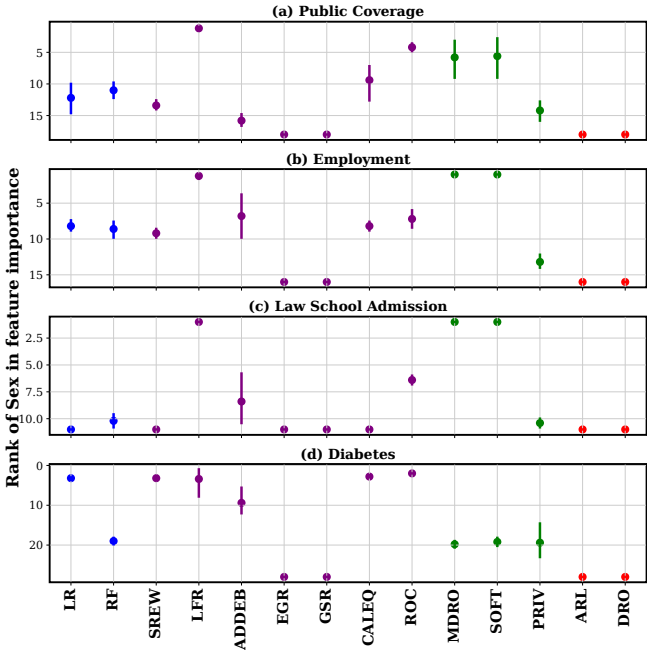


Figure 6: Rank of Sex in the average absolute KernelShap feature importances for the different algorithms in our case studies.

in terms of mean absolute feature importance for each classifier and present the results in Figure 6 (we also show the range of ranks if they vary over noise).

Figure 5 reveals that, with few exceptions (EGR in Public Coverage, EGR and GSR in Employment, EGR and ROC in Law school, and CALEQ, PRIV and ARL in Diabetes), most classifiers had similar feature explanation distributions. We do not observe any clear patterns among the exceptional classifiers, i.e., no classifier consistently diverged from the others across all datasets. Further, we do not observe clear correlations between accuracy, EOD, and feature distribution similarity, suggesting that different classifiers took different paths to reach the same levels of performance.

[4]Note that a higher value of EOD (Equation 3.2) signifies that females received more positive predictions than males.

Figure 6 is more informative than Figure 5. Four of the classifiers that exhibited consistently poor performance—LFR, MDRO, and SOFT (Figure 3a–d), and ROC (Figure 3e–h)—learned to weight the sex feature higher than other features, which may point to the root cause of their accuracy and fairness issues. Similarly, the unconstrained classifiers (LR and RF) exhibited changing EOD with noise levels in three out of four datasets (Figure 4e, f, h), but not for Law School Admissions (Figure 4g), and we observe that they learned a relatively low weight for sex among the available features for the Law School dataset. CALEQ also learned a relatively low weight for sex on the Law School dataset and was subsequently unaffected by noise (Figure 4g), but showed variable trends in EOD for the other three datasets (Figure 4e, f, h) on which it learned a relatively higher weight for sex.

Sex was the lowest ranked feature for the two demographic-unaware fair classifiers (DRO and ARL), which makes sense because they were not given these features as input. EGR and GSR also did not have access to sex while classifying the test dataset, so they also had sex as the lowest ranked feature.

5.4 Fairness-Accuracy Tradeoff

Three algorithms in our list - EGR, GSR, and PRIV, provide a mechanism to control the fairness-accuracy tradeoff via a hyperparameter – namely fairness violation *eps* in the case of EGR and GSR [2], and the privacy level ϵ in the case of PRIV [48]. Based on the experiments the authors of these algorithms did in their papers, we used different *eps* values between 0.01 and 0.20 and ϵ values between -2 and 2 and reran our experiments. We found that tweaking the tradeoff hyperparameter did not contribute meaningfully to the stability and noise resistance capabilities of these algorithms. Consequently we omit these results from the paper.

6 CONCLUSION

In this study, we present benchmark results—in terms of accuracy, fairness, and stability—for 14 ML classifiers divided into four classes. We evaluated these classifiers across four datasets and varying levels of random noise in the protected attribute. Overall, we found that two classical fair classifiers (SREW and EGR), one noise-tolerant fair classifier (PRIV), and one demographic-unaware fair classifier (ARL) performed consistently well across metrics on our experiments. In the future we recommend that ML researchers benchmark their own fair classifiers against these classifiers and that practitioners consider adopting them.

One surprising finding of our study was how well SREW and EGR performed in the face of noise in the protected attribute. Contrast this to noise-tolerant classifiers like MDRO—whose performance did not vary with noise but was inaccurate on some datasets—and SOFT—which was consistently inaccurate and had variable fairness in the face of noise. These results suggest that some classical fair classifiers may actually fare well in the face of noise, and that adopting more complex noise-tolerant fair classifiers may not always be necessary.

Another surprising finding of our study was how well ARL performed. As a demographic-unaware fair classifier it did not have access to the sex feature at training or testing time, yet it achieved fairness performance that was comparable to demographic-aware fair classifiers on three of our datasets, and its fairness performance was noise invariant on three datasets as well. We fit linear regression models on each dataset with sex as the independent variable, but these models did not uncover any obvious proxy features for ARL to use in place of the sex feature. This speaks to the strength of the ARL algorithm's adversarial approach to learning.

On one hand, our results confirm that demographic-unaware fair classifiers can achieve fairness for real-world disadvantaged groups under ecological conditions. This is positive news for practitioners who would like to adopt a fair classifier but lack (high-quality) demographic data. On the other hand, we still urge caution with respect to the adoption of demographic-unaware fair classifiers for practical reasons. First, determining whether a classifier like ARL will achieve acceptable performance in a given context requires thorough evaluation on a dataset that includes demographic data, as we have done here. Second, even if a demographic-unaware fair classifier performs well in testing, its performance may degrade after deployment if the context changes or there is distribution drift [25]. Monitoring the health of a classifier like ARL in the field requires demographic data. In short, adopting a demographic-unaware classifier does not completely obviate the need for at least some high-quality demographic data.

In general, the results of our study point to the need for further development in the areas of noise-tolerant and demographic-unaware fair classifiers. By releasing our source code and data, we hope to provide a solid foundation for evaluating these novel classifiers in the future.

Our study has several limitations. First, we only evaluate classifiers using binary protected attributes. It is unclear how their performance and consistency would change under more complex conditions. That said, we are confident that the classifiers that performed poorly will continue to do so in the presence of more complex fairness objectives. Second, our case studies and synthetic experiments, while thorough, are by no means completely representative of all real world datasets and contexts. We caution that our results should not be generalized indefinitely. Third, we did not evaluate all of the classical fair classifiers from the literature (see Friedler et al. [22] and Mehrabi et al. [46] for more). Our primary focus was on adding to the literature by benchmarking noise-tolerant and demographic-unaware fair classifiers. Finally, in this study we only evaluated one fairness metric—EOD—because it was the common denominator among all of the classifiers we selected. Future work could explore fairness performance further by choosing other fairness metrics along with subsets of amenable classifiers.

ABSTRACT

As algorithms have become ubiquitous in consequential domains, societal concerns about the potential for discriminatory outcomes have prompted urgent calls to address algorithmic bias. In response, a rich literature across computer science, law, and ethics is rapidly proliferating to advance approaches to designing fair algorithms. Yet computer scientists, legal scholars, and ethicists are often not speaking the same language when using the term 'bias.' Debates concerning whether society can or should tackle the problem of algorithmic bias are hampered by conflations of various understandings of bias, ranging from neutral deviations from a standard to morally problematic instances of injustice due to prejudice, discrimination, and disparate treatment. This terminological confusion impedes efforts to address clear cases of discrimination.

In this paper, we examine the promises and challenges of different approaches to disambiguating bias and designing for justice. While both approaches aid in understanding and addressing clear algorithmic harms, we argue that they also risk being leveraged in ways that ultimately deflect accountability from those building and deploying these systems. Applying this analysis to recent examples of generative AI, our argument highlights unseen dangers in current methods of evaluating algorithmic bias and points to ways to redirect approaches to addressing bias in generative AI at its early stages in ways that can more robustly meet the demands of justice.

1 INTRODUCTION

Algorithms exert influence over an increasingly wide range of social domains, including criminal justice, health care, finance, employment, and education [21, 39, 43, 86, 91, 118, 122, 147]. In both the academic literature and at a societal level, there is a growing awareness of the potential for bias or discrimination in the use of algorithms in sociotechnical systems [21, 22, 28, 37, 57, 109, 115, 119, 137]. When claims of discriminatory effects from such systems arise, public calls to address algorithmic fairness follow closely behind [107], leading to considerable attention from regulatory bodies around the world in recent years [14, 15, 17, 66, 85, 132, 143].

While there may be an emerging consensus that algorithms embedded in sociotechnical systems should be designed to be fair, computer scientists, legal scholars, and ethicists are not speaking the same language when using terms such as bias, fairness, and discrimination [108]. In a 2018 survey, Narayanan highlights twenty-one common technical definitions of fairness, a subset that is illustrative, not exhaustive, of mathematical approaches to bias [111], and Suresh and Guttag observe at least seven distinct sources of downstream harm that can arise at different stages of the machine learning lifecycle [136]. Technical definitions of fairness are often incompatible with one another, and the choice of which to employ when designing or evaluating an algorithm for fairness has an enormous influence on outcomes [42, 60, 97]. Further, the relationships between the various technical definitions of fairness and the legal and ethical notions of antidiscrimination, equality, and justice are not well understood.

These considerations are of vital consequence for legislative and enforcement efforts, such as the EU Artificial Intelligence Act [17], the White House's Blueprint for an AI Bill of Rights [143], and the US Federal Trade Commission's call for businesses to test their algorithms regularly to ensure they do not discriminate on the basis of a protected attribute [85, 132]. When assessing algorithmic bias from a legal or policy perspective, one confronts challenges associated with definition, detection, and enforcement [92]. Longstanding antidiscrimination doctrine, for example, protects individuals against discrimination on the basis of certain protected classes tied to social identities of race, sex, and religion and, accordingly, prohibits the consideration of these protected characteristics in decisions that influence economic opportunity [92]. It is well-recognized, however, that, even in cases where algorithms explicitly exclude protected characteristics in their labeling, such features can continue to influence algorithmically-informed decisions [92]. For example, because race is highly correlated with ZIP code, information about an individual's location can serve as a proxy for this protected characteristic even when race is explicitly excluded from consideration [49].

Given the vast quantities of personal data analyzed by platforms, the fact that they do not explicitly use protected characteristics does little to establish confidence that such characteristics do not influence their results [24, 47]. Further, it is unlikely that, if proxies for protected characteristics do influence the results, they will do so in ways that can be proven to be unlawfully discriminatory without access to substantial additional statistical evidence [92].

In this paper, we analyze current approaches to algorithmic bias with respect to their potential as well as continued challenges for addressing harms to individuals, groups, and society. First (§ 2), we analyze differences between technical, legal, and ethical approaches to defining fairness in order to lay the groundwork for a broader understanding of the underlying harms and the values that, as a society, we should seek to protect in designing and enforcing fair algorithms. Then (§ 3), we outline two common approaches to addressing algorithmic bias: disambiguating different notions of bias and designing for justice. We argue that, while promising, both approaches carry risks: disambiguating bias can neutralize the term in ways that undermine public calls for justice and can also be used to avoid accountability for addressing algorithmic harms. Designing for justice and equity seeks to capture the broad range of social harms but also risks collapsing into debates similar to those that plague the algorithmic fairness literature. Lastly (§§ 4 and 5), we apply our analysis to generative AI to demonstrate methods of identifying and disambiguating bias in such systems, and conclude by suggesting forward-looking approaches to ensuring accountability for algorithmically-driven injustices and inequities.

2 WHAT DOES IT MEAN FOR AN ALGORITHM TO BE FAIR?

The literature reflects a broad range of philosophical, legal, and technical approaches to defining fairness that may provide a basis for designing and evaluating fair algorithms. Notably, philosophical and legal notions provide underpinnings for an expansive view of algorithmic harms and algorithmic justice. However, in the technical literature, concerns about harms from sociotechnical systems are often reduced to measuring various forms of bias in algorithmic results.

2.1 Philosophical and Legal Notions of Justice and Antidiscrimination

John Rawls, one of the most influential philosophers on defining justice, contends in his 1971 *A Theory of Justice* that "justice is the first virtue of social institutions" [125]. Justice is the primary normative criterion we should use in evaluating social institutions and, thus, "laws and institutions no matter how efficient and well-arranged must be reformed or abolished if they are unjust" [125]. Rawls argues that principles of justice should apply to the core social institutions that "distribute fundamental rights and duties and determine the division of advantages from social cooperation" [125]. Such political, social, and economic arrangements are the principal focus of justice because they define people's basic rights and duties and "influence their life prospects" [125]. Given the profound influence of algorithms in significant social institutions, including credit, housing, employment, and criminal justice decisions, it is therefore essential to evaluate the justice of algorithmic decisions.

Rawls defends a principle of justice as fairness, not as equivalent terms, but to clarify that principles of justice should specify fair terms of cooperation in society. Determining whether terms are fair is not merely treating similar cases similarly. Instead, Rawls leverages a thought experiment, referred to as the 'original position' [125], to determine which principles could be embraced by people "as free and equal," rather than from a position of domination or subordination [125, 126]. The thought experiment asks people to consider whether they could accept principles of justice no matter where within the social order they fell. Imagine they do not know specifics about their particular situation, but do know general facts about people and society (including facts about racial and gender discrimination, economic inequality, and scarcity). In this scenario, people should choose principles of justice that could be embraced even if they ended up in the least advantaged position in society. If they meet this test and protect the basic dignity of each person, we have some confidence in believing the principles of justice are fair.

Rawls' specific principles of justice have been influential (and controversial) in contemporary theorizing about justice. While applying his theory to algorithms is beyond the scope of this paper, we introduce Rawls because his core methods of thinking about the justice of social institutions illustrate the expansive nature of philosophical approaches that extend beyond applying bias metrics or treating like cases alike. We argue that taking this more expansive view is essential to understanding what is missing when evaluations of fairness are restricted to more limited notions of bias.

Like philosophical notions, antidiscrimination law takes an expansive view of justice in society. Antidiscrimination law developed to address systematic patterns of disadvantage, such as those rooted in the institutions of slavery and Jim Crow segregation in the United States. The Civil Rights Act of 1964 outlawed segregation in public places and prohibited employment discrimination on the basis of race, color, religion, sex, or national origin—with the aim of "dismantling systems of segregation that were endemic to American economic and political systems" [91]. In this way, antidiscrimination law is arguably designed to embody a form of distributive justice, operationalizing principles such as that morally irrelevant characteristics like race and sex should not determine one's opportunities in life [83]. Antidiscrimination law's recognition of harms from discrimination can also be understood through a Rawlsian lens, as rules one might choose in the original position [83]. For instance, the Supreme Court's interpretation of Title VII of the Civil Rights Act of 1964 as prohibiting "not only overt discrimination, but also practices that are fair in form, but discriminatory in operation," including criteria exhibiting a discriminatory preference for or excluding any group and cannot be shown to be related to job performance [6], may reflect what a rational person would choose as a rule for society, not knowing what their own social standing would be [83].

2.2 Technical Measurements of Bias in Algorithms

An expansive and growing number of definitions of algorithmic fairness have been presented and evaluated in the computer science literature [106, 128]. In one survey, Narayanan identifies a broad

collection of fairness definitions, including various notions of statistical bias, group fairness, blindness, individual fairness, process fairness, diversity, and representational harms [111]. Among these, a frequently used fairness definition is statistical bias, i.e., the difference between an estimator's expected value and the true value of the parameter being estimated. Yet, it is widely recognized that statistical bias is inherently limited as a fairness definition because it does not account for biases in the underlying data [111].

For example, the COMPAS risk assessment algorithm employed by many US courts to assess recidivism risk was calibrated to meet fairness defined in terms of statistical bias. It was shown to produce recidivism scores that were only slightly less predictive for black men than white men, seemingly satisfying fairness when understood as statistical bias. However, COMPAS also produced many more false positives among black defendants and false negatives among white defendants due to the data reflecting differences in recidivism prevalence between these groups, which are a product of biases in society [21]. Black men are more likely to live in neighborhoods that have a greater police presence, are subjected to racial profiling by officers, and as a result are re-arrested more often than white men. In this context, the high rate of false positives for black men is particularly concerning, especially when compared to the elevated false negatives for white men, exacerbating the over-incarceration of black men in our criminal justice system [18].

Group fairness definitions measure bias in a model in terms of systematic differences between groups [111]. As one example, the equalized odds definition requires protected and unprotected groups to have equal rates for true positives and false positives [103]. For an algorithm used in support of making loan decisions, for instance, this aims to address potential bias against certain groups that may be learned from the training data, such as that members of historically marginalized groups are denied loans despite being creditworthy. Equalized odds requires ensuring that the fractions of non-defaulters and defaulters approved for loans are equal across groups.

Use of such definitions has limitations, as research has shown that it is impossible to achieve three or more (and, in some cases, even two) group fairness definitions simultaneously [42, 97]. In addition, satisfying even one fairness definition can result in a significant loss in accuracy [45]. For example, in the case of equalized odds, an algorithm must achieve equally high accuracy across all groups, so an algorithm performs only as well as it does on the hardest-to-classify group [75]. Further, where there are disparities in prevalence between groups—resulting, e.g., from measurement bias or historical prejudice—balancing outcomes across different groups requires treating people from different groups differently [23, 103, 111].

The technical literature also introduces tools for mitigating algorithmic bias. Researchers have shown that designing algorithms to be blind to sensitive attributes does not eliminate bias against protected groups, as a sensitive feature such as race may be redundantly encoded in other features such as place of residence [75]. One approach is to explicitly recognize differences in prevalence, such as with Dwork et al.'s *fairness through awareness*, which is based on the principle that "similar individuals should be treated similarly," using a metric that defines how similar two individuals are in the context of a particular decision-making task [55].

2.3 Limitations, Trade-offs, and Gaps Between Definitions

The limitations of technical definitions and the impossibility of satisfying multiple definitions simultaneously requires explicitly addressing the trade-offs between different definitions, as well as between fairness and other considerations such as accuracy [111]. Quantitative definitions also overlook how inequality compounds over time, even through generations, and they cannot resolve conflicts between different values, among other concerns [112]. In practice, the application of such approaches may be limited due to privacy concerns and data minimization policies [93]. Further, there are challenges with respect to measuring bias throughout different stages of the machine learning lifecycle, as measures of bias at one stage may not be reliably correlated with measures in downstream tasks [65].

Some scholars have argued that quantitative approaches are limited in their ability to combat oppression due to being overly formal and limited to isolated decision-making procedures [30, 69, 71, 129]. For example, Green argues that "efforts to formulate mathematical definitions of fairness overlook the contextual and philosophical meanings of fairness" [69] (citing [30, 70, 84, 100, 129]). The various fairness definitions rely on a wide range of understandings of the concept of bias, whether conceptualized as differences between the prediction and the world, different treatment for different groups, human prejudice in the data collection, or other factors [16, 25, 103]. As we will argue below, the wide variety in understandings of bias can impede well-meaning efforts at correcting problematic forms of prejudice, unjust treatment, and discrimination.

Consider, for instance, the relationships between philosophical, legal, and technical definitions of bias in the context of antidiscrimination law. Many scholars have argued that fairness definitions have a role to play in auditing algorithms for evidence of unlawful discrimination (see, e.g., [79, 87]). While antidiscrimination law aims to protect individuals from harmful discrimination stemming from longstanding prejudice, current doctrine is applied more narrowly, in cases where demonstrable harm is shown in a regulated context with a deep history of discrimination, such as employment, housing, education, credit, and public accommodation (see, e.g., [2, 4, 7]). Antidiscrimination law explicitly prohibits discrimination in ads for housing and job opportunities based on protected attributes such as race, sex, age, religion, disability status, and more [1, 3, 5]. This carries through to algorithmic decisions, as recent findings of discrimination have led online platforms to implement changes to address discriminatory targeting and delivery of certain ads [19, 140]. Discrimination may manifest as disparate treatment (see, e.g., [8, 10]), in the case of an algorithm that explicitly considers a protected attribute or where it is intended to classify on the basis of a protected attribute, or as disparate impact (see, e.g., [6, 12]), in the case of an algorithm that has a disproportionate effect on a protected group without a business justification.

Narayanan argues that disparate impact has emerged as the prevailing definition of unintentional algorithmic discrimination in part because it can be readily measured using quantitative tools using existing datasets from a single setting at a single point in time, and that "[i]njustices other than disparate impact seem illegible to regulators" [112]. It is notoriously difficult to establish the intent

behind a human decision, as, for instance, individuals are often not even aware of their own intentions, but it is especially challenging to establish with the rise of algorithmic decision-making. The shift to algorithmic decision-making risks deflecting accountability for addressing harm by companies offsetting their own responsibilities by pointing to the decision-making powers of an algorithmic system—potentially using questions about whether AI systems can have intentions to keep discussions of legal liability stuck in abstract philosophy of mind discussions while avoiding addressing accountability for harms perpetrated through these systems.

Challenges in understanding the relationships between different technical notions of fairness and legal conceptions of fairness, such as those operating within antidiscrimination law [79, 87], do not exhaust the complications in the fairness debate. Crawford argues that most of the technical work on fairness aims to confront instances of allocative harm, leaving unaddressed a category of harms stemming from the use of biased algorithms called representational harms [47].

Allocative harms, according to Crawford, arise when systems allocate or withhold resources or opportunities to people on the basis of their group identity (e.g., when a woman is offered a lower credit limit than her husband despite a shared financial history) [47]. Because allocative harms are discrete, transactional, and easily quantifiable, they lend themselves to technical analysis and intervention through application of the various types of technical definitions of fairness that have been proposed [47]. In contrast, representational harms occur when systems reinforce the subordination of certain groups on the basis of their social identity. Representational harms are difficult to formalize because they are long-term, diffuse, and tied to how people are represented and understood socially [47]. Crawford identifies numerous examples of representational harms such as those involving stereotyping, failures of recognition, harms of denigration, underrepresentation, or ex-nomination (where certain groups are framed as the norm by not giving them names, such as the use of 'athlete' for men vs. 'female athlete' for women) [47].

One way of thinking about allocative harms is through the lens of distributive justice, although this notion extends far beyond the narrow protections in current antidiscrimination law and quantitative definitions of fairness. Likewise, representational harms can be understood through a broader philosophical lens of epistemic injustice, introduced by Fricker [59] to describe ways in which people can be harmed in their capacity as epistemic agents, because these harms of representation reflect and reinforce problematic epistemological frameworks through which we understand and interpret our experiences. Philosophical discussions of justice and fairness aim to capture and analyze both what an ideal theory of justice requires and the ways our existing systems fall short. This broad lens is a useful metric for analyzing instances where algorithmic fairness and antidiscrimination law fall short of their goals.

Applying a philosophical lens for evaluating justice and fairness reveals even broader gaps in the literature. Technical notions of fairness and justice are often "conflated," bearing "the consequence that distributive justice concerns are not addressed explicitly" [98]. Scholars argue that they risk "mirroring some of antidiscrimination discourse's most problematic tendencies" [81] and "often exacerbate oppression and legitimize unjust institutions" [69] (citing [50, 68, 88, 116, 117, 123]). For these reasons, some call for rejecting fairness in favor of alternative frames of justice, equity, or reparation [69]. Bui and Noble argue that "simply striving for fairness in the face of these [unjust] systems of power does little to address" the unjust power structures themselves, and argue for deeply interrogating the underlying power structures and inequalities of such systems [36]. Similarly, D'Ignazio and Klein show how intersectional feminist theories can be applied towards tackling unjust power structures through data science and data ethics [54]. Likewise, Costanza-Chock's principles of design justice call for designers to critically examine how existing practices contribute to the reproduction of systemic oppression and to transform design's values to better meet the aims of social justice [46]. Drawing from intersectional critical theorists, Davis et al. develop a principle of algorithmic reparations, which they argue can name, unmask, and undo both allocative and representational harms in algorithms [50].

We support calls to move beyond discussions of bias to broader notions of justice, but we argue that the challenge is to do so in a way that can actually address unjust power structures. Complex social phenomena and normative goals can be challenging to formalize in ways that can be built into mathematical systems and translated into clear laws and policies [113, 114]. Developing approaches that interface well with both normative and technical understandings will be necessary to ensure protection for individuals, groups, and society, but it must be done with care. It may be appealing for both regulators and technologists to focus on the most readily quantifiable measures of bias, as they can seemingly render abstract problems more concrete. However, there is a risk of narrowing the scope of analysis in ways that can obscure the broader social context that is crucial to understanding algorithmic harm. As Tukey posited with his maxim for data analysis, "[f]ar better an approximate answer to the *right* question, which is often vague, than the *exact* answer to the wrong question, which can always be made precise" [138]. It is critical to focus on developing approaches that address fundamental normative concerns regarding algorithmic harms, even if they might seem vague, rather than focusing on notions of bias just because they lend themselves to quantification and not because they capture what is important.

3 DISAMBIGUATING ALGORITHMIC BIAS: FROM NEUTRALITY TO JUSTICE

Discussions of algorithmic fairness often focus on unpacking specific quantitative definitions of fairness that measure forms of bias arising at certain stages in the development and deployment of algorithmic systems. We refer to the tendency to reduce questions of fairness to discussions of bias metrics as the normative reduction claim. As we outlined in section 2, the reduction of fairness to a bias metric omits broader considerations of justice that the public means to call attention to when critiquing algorithms for the ways they contribute to and perpetuate injustices in society. Although scholars often acknowledge the limitations of normative reduction as tackling a more tractable subset of the problem, the gaps between technical, legal, and ethical approaches to algorithmic bias can undermine even our best efforts to address this problem.

In this section, we discuss current approaches to algorithmic bias and highlight two potential solutions, as well as challenges that arise with each approach. The first approach seeks to disambiguate

different notions of bias. While helpful, this approach lends itself towards neutralizing the term bias in ways that can undermine efforts to address bias and can be used to deflect accountability for addressing algorithmic harms. The second approach seeks to substitute discussions of bias or fairness with discussions of justice, thereby explicitly addressing unjust power structures. This approach is promising insofar as it seeks a broader lens, but, in moving to develop broader discussions of algorithmic justice, theorists must take care not to replicate some of the problems that have beset discussions of algorithmic fairness and bias.

3.1 Current Approaches to Algorithmic Bias

As early as 1996, Friedman and Nissenbaum's normative work on bias identified technical bias, resulting from specific technical constraints, as one of three types of bias that can arise in computer systems [61]. Also important, they argue, are preexisting social biases and emergent biases, which arise out of particular use cases [61]. Since then, increasing attention has been drawn to other significant ways social prejudice can be embedded in data sets, as well as the ways biases can arise when algorithms are trained on data sets that are not representative of the population to which they are applied [56, 115, 119]. Friedman and Nissenbaum call for "freedom from bias" as one of the important criteria by which to judge the acceptability of automated systems [61]. In more recent work, Nissenbaum has disavowed the "seductive diversion" of attempts to "solve bias" in AI systems in ways that can distract from asking whether the systems should be built or used in the first place [123]. Yet within computer science, 'bias' can mean many different things—not all of which can be effectively eliminated given the very nature of algorithmic design. As David Weinberger argues, "bias is machine learning's original sin" because it is embedded into its very essence [142]. By looking for patterns in the data, machine learning systems may find "biased patterns so subtle and complex that they hide from the best-intentioned human attention" [142].

Further, despite the development of a rich body of technical scholarship on algorithmic bias, the term 'bias' is generally not wielded with same degree of precision as other terms used in the computer science literature. Instead, 'bias' is often used as a catch-all to refer to a wide range of behaviors which, in turn, are associated with diverse types of harms, each of which has different types of impacts on different groups of individuals. For instance, in a 2020 analysis of the body of papers on bias in natural language processing, Blodgett et al. found that "the majority of them fail to engage critically with what constitutes 'bias' in the first place," often referring to 'bias' using vague descriptions—or no description at all—and relying instead on unstated assumptions about what makes a system harmful, to whom, and why [33]. Nanayakkara et al. reviewed the broader impact statements for research presented at high-impact AI research conferences and found that, while 'bias' is "frequently mentioned," it is "not always clear whether authors are referring to bias in a societal or technical sense, or whether technical forms of bias are related to social inequalities" [110].

The term 'bias' (or, similarly, 'algorithmic bias') lends more confusion than clarity to the complex array of harms to individuals, groups, and society stemming from the use of algorithms. Algorithmic bias has been used to refer to 'biased' data inputs (including importing social prejudice as well as under- or over-representation of certain groups), 'biased' algorithmic design (including optimization tasks), and 'biases' that result from the algorithms designed in one context being inappropriately used in different contexts [48], tracking the three 'types of bias' Friedman and Nissenbaum highlight [61]. Danks and London go beyond this early work to identify five different meanings of bias: training data bias, algorithmic focus bias, algorithmic processing bias, transfer context bias, and interpretation bias [48]. These biases can also be the result of a deliberate choice, for example, when statistical biases are used to ensure that an algorithm is unbiased relative to a moral standard [48]. Danks and London offer a "taxonomy of different types and sources of algorithmic bias," distinguishing between (i) "neutral or unobjectionable forms of algorithmic bias" and (ii) biases that are "problematic" and therefore demand a response [48]. They argue "there is no coherent notion of 'algorithmic bias"' because the one term refers to statistical, ethical, and legal biases [48]. These different notions of bias can also be separated. It is possible for an algorithm to satisfy technical specifications of fairness (e.g., by offering statistically unbiased predictions) while remaining morally problematic. It is also possible for statistical bias to be morally neutral [58].

Notwithstanding the value in unpacking the many different instances, types, and sources of bias, we argue that the term 'bias' is at best unhelpful and at worst can mask deep injustices. It also can create a false sense that the barriers to addressing bias are insurmountable. This brief survey of meanings of the term illustrates the confusion likely to arise when aiming to mitigate algorithmic bias.

3.2 Two Potential Solutions and Their Challenges

In this section, we highlight two promising approaches to algorithmic bias. One approach, which we call disambiguating algorithmic bias, is to move from broad discussions of bias in favor of identifying the specific notion of bias that is used in a particular instance, as well as the groups affected and where within the lifecycle of the algorithm it occurs. We see examples of this approach when scholars specify the ways bias can arise at different points in the development and deployment of an algorithm [48, 58, 61, 63, 136]. There is great value in specificity in order to track to whom and where the problem occurs, as well as what corrective measures are being used. Efforts to disambiguate and specify the meaning of bias will go a long way towards clarity across disciplines when discussing the wide range of problems and proposed solutions to instances of algorithmic bias. However, this must be done with care, as it also lends itself to using the broad concept of bias in more neutral terms so that it can appropriately capture any instance of deviation from a norm, including technical measures alongside the moral notion.

The second approach to problems arising from the vast array of referents captured by the broad term of algorithmic bias, which we call designing for justice and equity, is to move away from discussions of bias and fairness towards explicit discussions of equity and justice (see, e.g., [36, 46, 50, 67]). We see this approach reflected by scholars who have critiqued the limitations of quantitative measures of bias or fairness in algorithms (see, e.g., [36, 46, 50, 54, 67, 69, 98]).

While we think that there is much to be gained by turning towards more "substantive" understandings of justice and fairness [69], efforts to move in this direction continue to import some of the same challenges that beset efforts to disambiguate questions of bias.

3.2.1 Disambiguating bias—and recognizing the dangers of neutrality. The first approach to disambiguating the range of biases that can arise in algorithms treats bias as a neutral umbrella term capturing any deviation from a norm. Take, for example, Danks and London's argument that sometimes we can use 'neutral' technical forms of bias to help address and correct for the morally problematic forms of bias [48]. Furthermore, they acknowledge the frequent negative connotation of the term 'bias' in English, but they explicitly use the term in "an older and more neutral way" in which "'bias' simply refers to deviation from a standard" [48]. This broader notion in which bias is used to mark deviations from the standard is meant to encapsulate statistical bias (in which estimates deviate from a standard), cases they label "moral bias in which a judgment deviates from a moral norm," and legal, social and psychological biases, all defined in terms of deviation from a norm [48].

However, it is not simply that bias means one (or several) things in the technical literature that are innocently different from the normative uses of the term 'bias' at play when the public expresses concerns of bias. The use of the term 'bias' for all of these different senses can actually hamper our best efforts to try to address problematic forms of injustice, prejudice, and discrimination that underlie public concerns. Most scholars who seek to clarify the many different meanings of algorithmic bias share the normative goal of ensuring that algorithms can live up to our moral standards. However, the broader and more seemingly 'neutral' use of the term bias in all of these instances leads to significant moral confusion. Danks and London suggest that we should avoid calling for an end to algorithmic bias because not all bias is bad and, in fact, some biases are neutral and others can be beneficial to achieving our normative goals, such as in the case where a biased algorithm could be used to "reduce a moral *societal* bias" [48]. Chander, for example, makes the case for designing algorithms to be conscious of protected characteristics, employing algorithmic affirmative action to remedy harms engendered by a "world permeated with the legacy of discriminations past and the reality of discriminations present" [41].

While we agree that additional clarity on how and where deviations from a certain standard arise in the process of designing, training, and deploying algorithms, we do not believe the right move is to neutralize the term bias. Doing so will likely undercut efforts to address real social injustices that can arise. This neutralization of the term bias does help explain why it arises in so many different contexts with so many different implications—but, in so doing, it undercuts the normative force of calls to eliminate bias. After all, if 'bias' is a mere deviation from a standard, bias will never be eliminated and those who resist social change can point to the public naiveté of technical matters and easily dismiss calls for 'unbiased' algorithms as if people were calling for round squares.

Whether or not the public is naive about different statistical measures or how algorithms are optimized to produce the desired result has little bearing on the very real injustices that arise in connection with the pervasive influence of algorithms on various aspects of our modern lives. When the public calls for an end to algorithmic bias, typically this is meant as a call for social justice and to end prejudice, and is tied to long and well-documented histories of racism, sexism, ageism, classism, and other longstanding social prejudices.

Although scholars examining questions of bias or fairness recognize the limitations of technical work and avoid claiming that technical specifications of bias or fairness capture the full complexity of these real-world social problems (see, e.g., [30, 58, 69–71, 81, 84, 100, 129]), standard strategies focus on quantitative measures to identify, quantify, and correct for biases in algorithms in ways that are nevertheless largely divorced from normative understandings of harm [31, 33, 110]. Furthermore, the method of disambiguating bias can also be exploited in ways that can undermine the aims of justice, as we explore through several case studies in the next section.

3.2.2 Designing for justice and equity. The second approach of avoiding the term 'bias' and shifting towards language of equity and justice explicitly seeks to take a broader evaluation of the harms wrought by algorithms in society. However, here too we may collapse into an ever expanding set of debates about how best to specify justice or ways to mathematically formalize and measure philosophical theories of justice. In other words, we risk falling into the same problems that plague the literature on algorithmic bias. For example, when people call for equality, it can quickly lead to debates about what we are trying to make equal and why. We can anticipate that this will repeat the same issues that arise in fairness debates with respect to specifying metrics according to which people should be treated equally. Likewise, for questions of justice: some might worry about how to specify justice mathematically and in a way that is not itself subject to overwhelming disagreement. For both of these claims, the philosophical literature on justice and egalitarianism can provide useful insights—but it will also be easy to conclude there is a lot of continued disagreement and debate about what, e.g., justice requires and how equality should best be measured and protected in society. Such debates may be cited as an excuse to avoid accountability for clear instances of harm.

However, specification of what justice and equality require is worthwhile as a way to get to the heart of the problem in the spirit of Tukey's maxim for data analysis (§2.3). Despite continued debates about which theory of justice is best, there is in fact substantial agreement with respect to some clear instances of harm. As Rawls suggests in his later work seeking to grapple with the continued disagreements in society, in any society that protects freedom of thought and expression, continued disagreement about key normative questions should be expected [126]. Despite continued disagreement, many views are reasonable, and there are a number of rationales by which morally decent people who are reasoning responsibly may come to hold different views. However, this disagreement need not undermine attempts to develop principles of justice that can apply to society broadly. As a society, we can and do find fair terms of social cooperation without requiring everyone to agree to the same moral view.

Rawls argues that there are certain core areas of agreement that any view of justice that could be considered reasonable should be able to capture [125, 126]. Our considered convictions of justice

include ideas like "religious intolerance and racial discrimination are unjust" and, if a theory of justice cannot show why, e.g., racial and gender discrimination are wrong, it should be revised because it fails to capture our considered convictions about justice [125, 126]. Extending this intuition in his later work tackling the broad set of moral and religious disagreements in society [126], Rawls argues that there is substantial agreement that principles of justice should treat people as free, equal moral persons and social institutions should be arranged so that they are substantively (not merely formally) fair. We can leverage these points of agreement to secure legitimate social structures by appealing to these shared areas of agreement (which he calls public reasons) when justifying coercive power. While we cannot expect everyone to agree on every law or policy, their legitimacy depends on whether they are justified in terms of public reasons that can be recognized as reasons of the right kind—i.e., grounded in appeals to freedom, equality, justice, and fairness [126]. We believe a similar lesson can be applied to make progress in addressing clear injustices in algorithmic systems and for adjudicating continued areas of disagreement. Examining algorithmic harms in terms of power imbalances, inequalities, and oppression frame these issues in ways that demand revising unjust structures to better meet the demands of justice.

4 BIAS AND ACCOUNTABILITY IN GENERATIVE AI

Most of the existing literature on algorithmic bias focuses on applications to predictive algorithms, wherein mathematical formulations of bias can be developed, implemented, and tuned for specific tasks and deployments. With the shift towards a new paradigm of generative AI, models are trained on broad data and applied to an extremely wide range of tasks, magnifying the potential for harm. Although the harm to an individual from a single generative AI output might be small, these harms are multiplied dramatically across a large number of users, especially if they are all using the same small set of foundation models [34, 35, 96]. The general public has frequent direct interactions with generative AI models across a broad range of social contexts and the potential for harm is difficult to anticipate. Additionally, generative AI models are used for wide-ranging tasks they are not explicitly trained for, and their characteristics are not well understood. Consequently, their large-scale use presents complex and pressing challenges for addressing algorithmic harms.

Recent scholarship and media coverage of generative AI has uncovered a wide range of examples of harmful representations and associations that are described as evidence of algorithmic bias. In this section, we outline several prominent cases illustrating different types of bias arising in generative AI, including both large language models and vision-language models, to explore what lessons existing approaches to bias developed for the predictive setting have for generative AI. We outline challenges created by the lack of clarity in discussions of algorithmic bias. Disambiguating the kinds of bias involved can be helpful in better identifying and addressing these challenges, but will not go far enough and can too easily be used to deflect accountability for addressing injustices in generative AI. We also show the need to develop tools for evaluating the justice and fairness of algorithms in ways that can capture clear cases of harm, while leaving open productive methods of continued contestation with respect to what justice requires without risking deflection of accountability for algorithmic harms.

4.1 Identifying Bias in Generative AI Models

We highlight a collection of examples from the small but growing body of work exploring harms with respect to large language models and AI image generators, in order to show that, while helpful, disambiguating notions of bias in neutral terminology will not be sufficient guidance to help address normative concerns. We focus on generative AI models because the biases in these models both replicate problems identified by existing research on biased algorithms but also introduce new challenges.

4.1.1 Bias in large language models. Large language models that power popular generative AI services like ChatGPT and Bard have the potential to replicate and amplify existing harmful instances of biased use of language in ways that sustain oppression [26, 27, 51, 53, 72, 94, 141]. The idea that language can be used to perpetuate harm, particularly against marginalized identities, is well established in the philosophical literature on speech and harms (see, e.g., [102]) and has been recognized by law (see, e.g., laws prohibiting hate speech in many countries [9, 13], and the International Criminal Court linking the use of slurs to instances of genocide [11]). A finding from early research on algorithmic bias is that biases in the training set have an enormous influence on the resulting model (see, e.g. [25]). By pulling their training data from the open internet, companies are training the AI systems in ways that amplify racist, misogynistic, and otherwise toxic content that is prevalent on the internet.

Because language models are designed to mirror patterns in natural language, they will predictably encode, reinforce, and perpetuate harmful stereotypes and biases present in the training data, whether due to historical injustice or underrepresentation in a data set [141]. These harms extend beyond allocative harms to, predominantly, more expansive, harder to identify representational harms and instances of epistemic injustice [33]. For example, in focus groups, people with disabilities characterized outputs from large language models as mirroring and reinforcing "perceptions of disability that participants encountered in their lives and dominant media," by emphasizing themes such as visible disability, passivity, lack of autonomy, sadness, and a desire to be "fixed" [62]. Weidinger et al. taxonomize social harms that can arise from large language models producing discriminatory, exclusionary, or toxic language, or performing worse for certain languages and groups [141]. Further, language models have been shown to encode "stereotypical associations," "negative sentiment towards specific groups," and intersectionality effects (i.e., "more bias against identities marginalized along more than one dimension than would be expected based on just the combination of the bias along each of the axes") [27].

4.1.2 Bias in vision-language models. Research has likewise uncovered extensive evidence of bias in vision-language AI models trained on internet-scale data [29, 145, 146]. Data sets used to train vision-language models have been found to contain "troublesome and explicit images and text pairs of rape, pornography, malign

stereotypes, racist and ethnic slurs, and other extremely problematic content" [32]. Vision-language models reflect and magnify this problematic content in various ways that amplify representational harms and epistemic injustices to marginalized populations. Katzman et al. identify and categorize six types of representational harms in image captioning systems: denying people the opportunity to self-identify, reifying social groups, stereotyping, erasing, demeaning, and alienating [90]. As one example, image captioning systems reflect harms of *ex-nomination* [47] by way of a tendency to associate white men, aged 20-59, with being the norm and labeling other groups according to their deviation from this perceived norm [145]. Image captioning systems also demonstrate significant disparities in performance, sentiment, and word choice in captioning of lighter versus darker-skinned individuals [148].

Katzman et al. illustrate how different types of representational harms are in tension with different interventions for bias mitigation in image captioning. For example, they argue that removing potentially sensitive terms such as 'hijab' could result in a system mistagging people wearing hijabs in ways that disrespect or demean them, or in not tagging them at all, "thereby erasing their identities" [90]. Existing research on bias seems to suggest that disambiguating specific instances and types of biases may not go far enough in helping us to mitigate harms caused by these systems. As Zhao et al. highlight, modern systems actually perform less well than older systems, reflecting greater disparities between groups [148]. Despite increased attention to algorithmic bias in recent years, this is not translating into net improvements for marginalized populations.

AI image generation systems appear to amplify these concerns through the ways that vision-language models problematically import and amplify common stereotypes of people. These stereotypes range from who is assumed to hold particular jobs to the reduction of women and girls to sexualized objects. For example, comparing images generated by Stable Diffusion in response to prompts for different professions described by an adjective reveals stereotypes in the model, such as an "assertive firefighter" represented as a white male and a "committed janitor" represented as a person of color [80]. Vision-language models also amplify the sexual objectification of women in society, which Wolfe et al. label *sexual objectification bias*, by "associating images of professional women with sexualized descriptions," "disassociating emotion from images of objectified women," and "generating sexualized images of underage girls" [146]. Harmful associations such as these can influence beliefs and behaviors in real-world contexts, as research has demonstrated that repeated exposure to stereotypical images can be correlated with "discrimination, hostility, and justification of violence against stereotyped peoples" [29] (citing [20, 38, 64, 131]).

4.1.3 Illustration: Bias in the generation of "magic avatars". In 2022, Prisma Labs introduced a "magic avatar" feature for its popular digital retouching app Lensa AI. Employing the open-source Stable Diffusion deep learning model that was trained on a database of over five billion image-text pairs of images and captions scraped from the web, Lensa uses a user's self portraits to retrain the model and generate a collection of digital portraits in different art styles [44].

Reports of social biases, including sexism, misogyny, sexual objectification, racism, and the compounding intersectional nature of oppression, surfaced immediately. One reporter observed that, while her male colleagues' photos were used to generate avatars such as "astronauts" and "fierce warriors," hers, as an Asian woman, generated avatars that were "topless" or with "extremely skimpy clothes and overtly sexualized poses" [77]. Women have long been subject to sexual objectification in society, and this is reflected in online images of women that are sexually objectifying and demeaning. Searching for the term "Asian" on the image databases used to train models such as the one used by Lensa generates results that are "almost exclusively porn" [76, 77]. In similar datasets, the language "an 18 year old girl" is associated with images that "often depict only sexual body parts, with the face omitted, commensurate with findings that objectified female bodies are represented and recognized by their sexual parts" [145, 146]. It is therefore unsurprising that many women have reported similar experiences with Lensa producing highly sexualized avatars based on their photos [104, 133, 134].

Other users have raised concerns over Lensa's tendency to lighten the skin tones and anglicize the features of people of color [133, 134], and to make people's bodies appear thinner [134]. Such representations can contribute to well-documented harms to body image and mental health in connection with social media use, especially for teenage girls. The perception that AI-generated avatars present a "more objective" representation "as if some external, all-knowing being has generated this image of what you [should] look like" has the potential to heighten their impact on a user's body image [95]. Journalists have reported on anecdotal accounts from plastic surgeons and psychologists about patients seeking cosmetic surgery to alter their appearance to more closely resemble their digital avatars, or experiencing distress when confronted with the fact that their actual appearance differs from the AI-tuned photos they have posted on social media [74]. The social biases embedded in such tools can also make it possible for bad actors to easily generate photorealistic nude or otherwise problematic images of a victim using photos often accessible from their social media profile [89]. Drawing from the classifications of harms in [27, 90, 141], these examples engender demeaning representations, stereotypical associations, exclusionary norms, reifying of social groups, intersectionality effects, and worse performance for some groups than others. They also illustrate how harms resulting from biased datasets are magnified and made deeply personal and intimately violating when a generative AI model retrained on an individual's personal data produces harmful images in their likeness.

4.2 Disambiguating Bias and Seeking Accountability in AI

Despite progress on disambiguating various notions of algorithmic bias at different stages of the machine learning lifecycle, a wide range of social biases are persistently magnified and reinforced by generative AI systems. Prior research on fairness in predictive settings provides lessons on the promises and pitfalls of approaches to disambiguating bias and seeking justice that may be instructive towards addressing harms in generative AI systems.

4.2.1 Refusing queries with potentially harmful outputs. In response to public concerns of bias, companies developing generative AI systems have implemented various changes, including, for example, removing offensive content from pre-training datasets and refusing

certain queries that are deemed likely to produce outputs that are explicitly biased or prejudicial [121].

The refusal tactic has been implemented for large language models such as OpenAI's GPT-4 and for vision-language models such as Midjourney's AI image generator. For example, OpenAI seeks to mitigate bias by training for refusals [120], and Midjourney reportedly blocks the use of certain words, such as references to female anatomy, in user prompts, to help prevent the generation of potentially offensive content [78]. Researchers have demonstrated that Midjourney's model learned to associate certain parts of the human anatomy—particularly those related to the female anatomy—with sexual or violent content [78]. Nevertheless, these associations are deeply embedded in the model, and simple workarounds, such as the use of British English spelling, can easily evade the safeguards and produce outputs reflecting such associations [78].

This approach, though useful, is incomplete and backwards-looking—patching instances of problematic outputs as they are discovered. It can also contribute to injustice and inequity, if the model learns from the training for refusal to associate certain marginalized communities with prohibited content [120]. As we will suggest below, we should also adopt a forward-looking approach to designing algorithms that reflect a more just picture of the world we would like rather than piecemeal corrections for the world as it is.

It is critical to identify and address the harm where it operates. Depending on where the bias arises, different interventions may be suitable, such as collecting additional data to balance the training dataset or employing various approaches to measure representational bias in and debias language models [82]. Suresh and Guttag identify seven sources of harm in machine learning, including historical, representation, measurement, aggregation, learning, evaluation, and deployment bias [136]. In the case of AI image generation systems, each harm that is identified could operate at one or more stages. For example, the demeaning representations of Asian women in the Lensa case could reflect *historical bias* due to misogynist and racist beliefs embedded in society and reflected in online content, *representation bias* due to predominantly pornographic representations of Asian women in the training data, *learning bias* if the algorithm amplifies performance disparities between different groups such as Asian women vs. white men, or *evaluation bias* if the bias stems, in part, from the performance of the model being judged with respect to images of white men but underperformance for other groups was not discovered or addressed. This becomes more challenging in generative AI systems actively deployed, whose learning will be subject to malicious actors and prejudices reflected in online content and in the real world. Situating the biases identified in AI systems in the broader social context will help to ensure we are attentive to the broad range of harms and can identify root causes of the harms.

4.2.2 Disambiguating bias but deflecting accountability. Disambiguating bias can help to clarify the types of harms perpetrated, who is impacted, and which aspects of an AI system contribute to this harm. However, it comes with a thus far unrecognized danger—that it can be used to deflect accountability for harm.

One danger is that by pointing to the ways algorithmic bias embeds preexisting social biases into algorithmic systems, the moral problems are deflected away from the technology and instead point back to intractable social problems that have long plagued society. While it is important to acknowledge the persistence of various forms of discrimination and prejudice in the world, the overemphasis on these preexisting biases as the root cause of the problem can reinforce an idea that the AI systems themselves are neutral and are not contributing to the problem.

As Langdon Winner argued in 1980, it is necessary to examine not only the social and economic systems from which a technology arose, but the political qualities of technologies themselves [144]. Often, "the very process of technical development is so thoroughly biased in a particular direction that it regularly produces results counted as wonderful breakthroughs by some social interests and crushing setbacks by others" [144]. In this case, identifying underlying social systems as the cause of bias in AI image generation is only part of the analysis; it is also critical to examine the technology itself, what harms it perpetrates, who is harmed, and how. It is readily foreseeable that a model trained on data scraped indiscriminately from the web will regularly lead to misogynistic and racist imagery. It is likewise foreseeable that white men aged 20-59, who are represented as the norm in vision-language models, would disproportionately receive benefits from this technology, while women and other marginalized groups that are the subjects of denigrating imagery online, would be disproportionately harmed by it.

In response to complaints about pornographic and objectifying images of women, Prisma Labs updated its system to make it more difficult to generate adult-oriented content (i.e., the refusal tactic) and revised its web site to acknowledge the potential for harm to women. It now features a frequently-asked question of "Why do female users tend to get results featuring an over sexualised look?" [99]. They note that "occasional sexualization is observed across all gender categories, although in different ways," and provide an explanation that "[t]he stable Diffusion model was trained on unfiltered Internet content. So it reflects the biases humans incorporate into the images they produce. Creators acknowledge the possibility of societal biases. So do we." [99]. In their acknowledgement of the harm, they point to the social biases embedded in the training data—thereby deflecting the problem from their proprietary algorithm toward the well-known misogyny in the world. Yet the decision to train the algorithm on unfiltered internet content was a deliberate choice on the part of human agents and one that could predictably result in disproportionate harms for marginalized groups given the extensive and well-documented prevalence of racist and misogynistic pornographic content on the web (see, e.g., [115]).

Prisma Lab's framing suggests that its model can only reflect the world as it is. However, technology does not merely shine a neutral mirror on our world. It actively shapes our future by creating new possibilities that extend our imagination about what is possible. This active role is often celebrated by technology innovators—until it attracts negative press. Then, the claim is that the technology is not the cause; it simply reflects broader societal problems.

4.2.3 Technology's role in shaping our future. This brings us to the third core danger we want to highlight. Many discussions of algorithmic bias are set against a false binary that we either have (albeit imperfect) algorithms or the status quo [69]. When presented

with this choice, algorithms can seem preferable. As Miller explains, while algorithms are clearly biased, "the humans they are replacing are significantly more biased" [105]. At least with algorithms, biases can be documented, measured, and adjusted to work toward improving the status quo. There is also evidence that, in some contexts, algorithms can perform better than human decisionmakers at reducing racial disparities and gender inequities [105].

The choice between biased algorithms and the biases of the status quo sets up a false binary grounded in a static picture of the world. However, this relationship is far more dynamic. We can distinguish between two different epistemic contexts from which to assess biases built into algorithms. At times, we can seek to understand the world as it is. For example, when Lensa's or Midjourney's image generation produces predominantly pornographic images of women, this underscores the prevalence of misogynistic images on the web. It can give a new reason to call attention to the deep roots of misogyny and the persistence of this problem in contemporary society.

There is another important epistemic lens that can be adopted by those who create, deploy, and evaluate algorithms—a forward-looking lens that seeks to build a more just future. For interventions to secure algorithmic accountability to effectively address harms in a rapidly evolving landscape of generative AI and other advances, it will be necessary to design sociotechnical systems and regulations with a forward-looking lens rather than to react to instances of harm as they arise. Developers should be aware of social injustice so they can make specific choices for correcting injustice, towards building algorithms that do not reflect the world as it is but instead start to reflect and build the ideals of a more just future.

4.3 Designing Interventions for Accountability

Designing notions of justice that can be embedded in sociotechnical systems and regulations will be critical to ensuring robust interventions for algorithmic accountability. Better training for human labelers, for example, is not enough to ensure robustly just systems, as research has shown that harmful associations along the lines of race, gender, and the intersection of race and gender can be automatically learned by unsupervised vision-language models [135].

Sociotechnical systems require proactive and continual monitoring for algorithmic injustices, and research to develop bias metrics to measure and reduce representational harms such as stereotyping in algorithmic systems is crucial towards developing proactive interventions (see, e.g., [40, 53, 65, 73, 101, 127, 148]). For instance, Dev et al. introduce a framework of representational harms as well as a set of heuristics that can be used to align bias measures in natural language processing with specific harms [52]. Returning to Rawls [126], we can ground conceptions of algorithmic harm in terms of power imbalances, inequalities, and oppression, and demand that sociotechnical systems and the regulatory frameworks that govern their use be designed based on principles of justice—to treat people as free, equal moral persons, and to require social institutions to be arranged so that they are substantively fair.

Although the adoption of sociotechnnical interventions presents numerous practical challenges [128], various approaches that could incorporate a forward-looking lens are emerging, including participatory design, algorithmic auditing, and regulatory oversight.

4.3.1 Participatory design. Because marginalized communities are disproportionately harmed by representational biases, a critical component of interventions for ensuring justice and equity in generative AI is participatory design. Blodgett et al. call for researchers and practitioners to make explicit their normative reasoning and to take into account the "lived experiences of members of communities affected by NLP systems" [33]. In the case of Lensa, conversations with marginalized groups could have promptly alerted the developers to the predictable misogyny and racism that runs rampant on the open internet and is reflected in the generated images. As an illustration of the value of user participation, Gadiraju et al. demonstrated how focus groups with people with disabilities readily surfaced a wide range of ways in which outputs from a large language model, while not producing blatantly offensive outputs, mirrored subtle stereotypes that people with disabilities encounter in their daily lives and in popular media [62]. A better understanding of how communities experience oppression could point to different choices for data curation and model training to reflect ideals of gender and racial equality rather than marginalization and gender-based violence. With deliberate design choices informed by the lived experiences of marginalized groups, generative AI applications could work as well for Asian women as they do for their white male colleagues, and as well for persons with disabilities as for persons without disabilities.

Awareness of the importance of community involvement in the design of public-facing algorithmic systems is growing. In OpenAI's February 2023 response to user concerns about "outputs that they consider politically biased, offensive, or otherwise objectionable," the company announced plans to solicit public input from "as many perspectives as possible" and invest in research and engineering to address bias with improvements based on feedback from the user community [121]. Inviting public input is a step in the right direction, but it is often employed in ways that are more backwards looking to correct errors in deployment rather than forward-looking to anticipate and design more robustly just products.

4.3.2 Algorithmic auditing. Regular auditing and continuous monitoring is another component that is critical to ensuring they meet the demands of justice. One approach is to invite feedback from people who are using these algorithms in a variety of cultural setting. As Shen et al. highlight, regular auditing by everyday users who engage with algorithmic systems in real-world social and cultural contexts is crucial because these users are well-situated to detect algorithmic harms that may go unnoticed by design teams [130]. There are two ways to view algorithmic auditing: this auditing can be used to ensure compliance with clear standards as a method of enforcement, but it can also be used as a forward-looking mode of oversight. Researchers have called for internal audits of algorithms for adherence to ethical standards prior to deployment and for continually monitoring the model throughout its lifecycle [124]. Frameworks for ensuring justice and equity in sociotechnical systems, informed by legal requirements and philosophical theory, could be incorporated in the standards used in such processes.

4.3.3 Regulatory oversight. Another promising model for a forward-looking approach to oversight could put the burden on companies to prove the safety, efficacy, and adherence to justice to a regulatory body before it is deployed or released. This model is inspired

by the U.S. Food and Drug Administration (see, e.g., [139]), which requires pharmaceutical companies to prove that a drug meets strict standards for safety and efficacy before it is approved for use. Adopting a similar model for algorithms and generative AI systems could require organizations developing and deploying the system to demonstrate their safety, efficacy, and adherence to requirements for justice and equity prior to releasing these tools to the public. Stricter standards could be adopted for algorithms designed for use in highly-consequential domains or otherwise expected to have a significant impact on a large number of people.

5 CONCLUSION

Conversations around how to design, implement, and evaluate fair algorithms are impeded by a lack of common understanding of the term 'bias.' One step researchers and practitioners could take is to disambiguate the term bias and adopt instead a wider range of terminology, such as prejudice, discrimination, and statistical weighting, that more accurately expresses when and which types of injustices occur. Yet, even when researchers are precise in locating the specific harm, there is a real danger this can be used to deflect accountability away from the algorithm and its developers. Injustices persist in both the world and in the algorithms that reflect and amplify societal harms. But this need not mean we can hope for no better. We call attention to the interplay between modeling the world as it is and promoting a more just and equitable social order, and argue that the design and use of algorithms has a role to play in both aspects.

ABSTRACT

Acknowledging that society is made up of different sectors with their own rules and structures, this paper studies the relevance of a sector-specific perspective to AI ethics. Incidents with AI are studied in relation to five sectors (police, healthcare, education and academia, politics, automotive) using the AIAAIC repository. A total of 125 incidents are sampled and analyzed by conducting a qualitative content analysis on media reports. The results show that certain ethical principles are found breached across sectors: accuracy/reliability, bias/discrimination, transparency, surveillance/privacy, security. However, results also show that 1) some ethical issues (misinformation, safety, premise/intent) are sector specific, 2) the consequences and meaning of the same ethical issue is able to vary across sectors and 3) pre-existing sector-specific issues are reproduced with these ethical breaches. The paper concludes that general ethical principles are relevant to discuss across sectors, yet, a sector-based approach to AI ethics gives in-depth information on sector-specific structural issues.

1 INTRODUCTION

Artificial Intelligence (AI) has developed as a tool to improve efficiency, reduce costs, and enable new activities in various contexts with pilots and applications in, for example, fraud detection [6], hiring [17], and law enforcement [56]. At the same time, it is widely recognized that the deployment of AI is not without risks. In the past years, AI-related controversies arose across a variety of cases revealing issues ranging from surveillance, to biases and discrimination, and causing harm due to problems with the reliability and security of such systems [14, 30]. The need to account for these ethical issues has been widely acknowledged. With a "turn to ethics" [59:2], actors from industry (e.g., [35, 51]), the public sector (e.g., [5, 40, 54]), and non-governmental organizations (e.g., [2, 18]) have outlined principles to ensure the ethical, responsible and trustworthy development and deployment of artificial intelligence in AI ethics guidelines.

As important as such initiatives are for raising awareness for ethical issues of AI, they have been criticized as being too abstract [39, 57] and offering little to no practical applicability [66, 73, 75]. Furthermore, evaluations of AI ethics guidelines showed them to be too generic [63], vague [60], and hosting a multitude of possible interpretations [62], leading to a lack of clarity regarding how AI

principles should be implemented, interpreted, or prioritized [12]. Based on such critique, some scholars question AI ethics guidelines in principle [52]. However, one possibility to close the "wide and thorny gap between the articulation of these high-level concepts and their actual achievement in the real world" [31:66] is to make AI ethics guidelines less abstract and ambiguous. To make abstract concepts such as ethical principles and values sufficiently concrete, they need to be viewed within a specific context.

This paper explores one approach to make ethics guidelines more tailored towards social context: focusing on sectors and their specific characteristics. A sector-based perspective to AI ethics enables understanding how AI systems are embedded in specific sectoral cultures with e.g. their norms, structures, activities, and routines, which is a perspective that is thus far overlooked in the AI ethics community. To elaborate, sectors are not explicitly used as a conceptual tool, but rather implicitly treated as relevant in relation to AI and robo-ethics in case studies such as elder care [15] or education [64]. To address this gap in the literature, this present paper aims to understand the feasibility of a sector-based approach to AI ethics. Are certain ethical issues found in specific sectors, or are ethical principles breached across sectors? In other words, it will be studied whether it has merit being sensitive to contextual, sector-specific information when understanding AI ethics, or whether overarching and rather general values are sufficient in doing so. Bearing this in mind, the guiding research question reads: How is sectoral context related to breaches of ethical principles?

In order to answer this research question, breaches of ethical principles are operationalized in terms of incidents with AI after deployment, as is listed in media reports in the AI, Algorithmic and Automation Incidents and Controversies (hereafter AIAAIC) repository [1]. Five sectors are selected for an empirical analysis on incidents with AI: healthcare, education and academia, police, politics, automotive. By comparing these sectors and their AI-related incidents, it could be seen whether such incidents occur in isolation (i.e. only within their respective sector), or across sectors. What follows next is an overview of related work in AI ethics with a focus on its principles and guidelines.

2 RELATED WORK

In order to situate this current study in literature, related work that addresses theoretical questions concerning principles and guidelines for ethical AI is discussed, followed by studies that also focus on the sectoral context of AI ethics.

2.1 Principles and guidelines for ethical AI
